

## Halting Problem Proof from Finite Strings to Final States

When we understand that every potential halt decider must derive a formal mathematical proof from its inputs to its final states previously undiscovered semantic details emerge.

When-so-ever the potential halt decider cannot derive a formal proof from its input strings to its final states of Halts or Loops, undecidability has been decided.

The formal proof involves tracing the sequence of state transitions of the input TMD as syntactic logical consequence inference steps in the formal language of Turing Machine Descriptions.

The proof would essentially be a hypothetical execution trace\*\* of the state transition sequences of the input TMD. It cannot be an actual execution trace or the halt decider could have non-halting behavior. \*\*Like step-by-step mode in a debugger.

If the first element of the input finite string pair is a correct TMD then this proof must necessarily proceed from the specified TMD start state through all of the state transitions of this TMD to the halting or looping behavior of this TMD.

The following has been adapted from material from the this book:  
An Introduction to Formal Languages and Automata by Peter Linz 1990 pages 318-320

We begin our analysis by constructing a hypothetical halt decider: H.

**Figure 12.1 Turing Machine H**

The dashed lines proceeding from state (q0) are represented in the text definition as the asterisk  $\vdash^*$  wildcard character. These conventions are used to encode unspecified state transition sequences.

### **Definition of Turing Machine H (state transition sequence)**

$H.q0 Wm W \vdash^* H.qy$  //  $Wm$  is a TMD that would halt on its input  $W$

$H.q0 Wm W \vdash^* H.qn$  // else

The diagram and the state transition sequence indicate that H begins at its own start state H.q0 and is applied to finite string pair (Wm, W).

Then it proceeds through an unspecified set of state transitions to one of its final states.

H.qy is the final state of H indicating that Wm is a TMD would halt on input W.

H.qn is the final state of H indicating that Wm is Not a TMD that would halt on input W.

In an attempt to provide a valid counter-example proving by contradiction that a Halt Decider cannot possibly exist for every possible TM / Input pair we create Turing Machine  $\hat{H}$  by making the following changes to H:

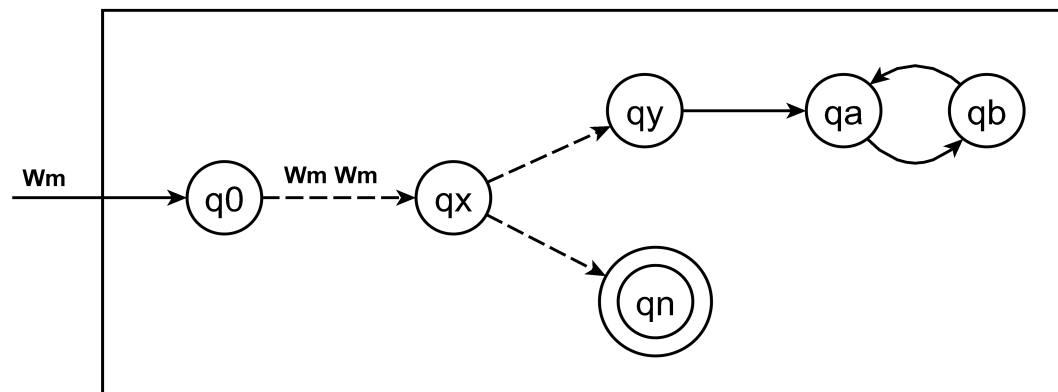

(1)  $\hat{H}$  copies its input Wm a its  $\hat{H}.q_0$  state and transitions to its  $\hat{H}.q_x$  state.

(2)  $\hat{H}$  would begin to evaluate Wm Wm at its  $\hat{H}.q_x$  state in exactly the same way that H would begin to evaluate its Wm W input at its H.q0 state.

(3) States (qa) and (qb) are appended to existing final state ((qy)) such that any transition to state (qy) will cause  $\hat{H}$  to loop.

Since Turing Machine  $\hat{H}$  is created by adapting H, it would have exactly the same behavior at its  $\hat{H}.q_x$  state as H would have at its H.q0 state.

**Figure 12.3 Turing Machine  $\hat{H}$**

**Definition of Turing Machine  $\hat{H}$  (state transition sequence)**

$\hat{H}.q_0 \text{ Wm} \vdash^* \hat{H}.q_x \text{ Wm Wm} \vdash^* \hat{H}.q_y \infty$

$\hat{H}.q_0 \text{ Wm} \vdash^* \hat{H}.q_x \text{ Wm Wm} \vdash^* \hat{H}.q_n$

If Turing Machine H is applied to Turing Machine descriptions [ $\hat{H}$ ] [ $\hat{H}$ ] would H transition to H.y or H.n ?

H [ $\hat{H}$ ] [ $\hat{H}2$ ] // We append a “2” to the second  $\hat{H}$  for clarity

To answer this question we perform an execution trace on H

(1) H begins at its start state H.q0.

(2) H begins to evaluate what [ $\hat{H}$ ] would do on its input [ $\hat{H}2$ ].

Because  $H$  is performing a mathematical proof on finite strings  $[H]$   $[H2]$  the required syntactic logical inference chain is simply the state transitions that  $[H]$  would make on its input  $[H2]$ . In simplest terms  $H$  is performing a step-by-step debug trace of  $[H]$ .

### **Step-by-step debug trace of what $[H]$ would do on its input $[H2]$**

- (3)  $[H]$  would begin at its start state  $[H].q_0$
  - (4)  $[H]$  would make a copy of its input  $[H2]$ , we will call this  $[H3]$ .
  - (5)  $[H]$  would transition to its state  $[H].q_x$ .
  - (6)  $[H]$  would begin to evaluate what  $[H2]$  would do on its input  $[H3]$ .
- Can you see the infinite recursion?

$H$   $[H]$   $[H]$  specifies an infinitely recursive evaluation sequence. Every HP proof by contradiction depends this same infinite recursion. What no one ever noticed before is that the debug trace by the halt decider must abort its evaluation long before it ever reaches the appended infinite loop. Because the formal proof is aborted before ever reaching the final states of  $H$ ,  $H$  is not a decider for  $H$   $[H]$   $[H]$ .

Because of this every TMD in the infinitely recursive sequence is defined in terms of  $H$  each would reject the whole sequence as semantically incorrect before even beginning any halting evaluation, and transition to  $H.q_n$ .

As further evidence that infinitely recursive evaluation sequence has been overlooked we only need to know that every TMD always requires its own TM/Input pair. For any finite sequence of input  $H$  could always decide halting.

If  $H$  did not copy its input and instead simply took two inputs then the Halting Decision would be easy.  $H$  would transition to its  $H.q_y$  state because  $H2$  would transition to its  $H2.q_n$  state on null input. This would cause  $H$  to transition to its  $H.q_n$  state deciding halting for  $[H]$   $[H2]$ .

## Glossary of Terms

A halt determiner H determines halting by deriving a formal mathematical proof from its input strings (b,c) to its own final states. It does this in the language of Turing Machine Descriptions (shown below).

A halt decider is free to decide halting by always saying yes.

A halt determiner H that determines halting for a single pair of input strings (b,c) is a halt determiner for these input strings.

A halt decider that decides halting for a single pair of inputs does not have a conventional term of the art.

A halt determiner H that cannot derive a formal proof from its input strings (b,c) to its own final states because these input strings derive the pathological self-reference error is called undecidable by H for this input pair (b,c).

A halt decider that cannot decide halting for a single pair of inputs because these inputs derive the pathological self-reference error has no conventional term of the art.

A hypothetical halt determiner H that can decide halting for an infinite set of input strings (b,c) is called a universal halt determiner.

A hypothetical halt decider that can decide halting for an infinite set of input strings is called a halt decider.

A TM H that determines Halting / Looping or the error of pathological self-reference for inputs (b,c) is called a halting determinability determiner.

A TM H that decides Halting / Looping or the error of pathological self-reference for inputs (b,c) is called a halting decidability decider.

Pathological self-reference(Olcott 2004) when-so-ever any expression of language refers to itself or a logical equivalent of itself and this reference prevents this expression of language from being resolved to a mutually exclusive semantic dichotomy such as True or False, this expression of language has the semantic error of PSR(Olcott 2004).

Minimal Type Theory coalesces all of the logic levels or predicate logic into a single very simple language based on slight augmentations to the syntax of FOPL. When MTT expressions are translated into directed graphs infinite cycles in this graph indicate the PSR error.

# Turing Machine Description Language

(Generalized from: TM, The Turing Machine Interpreter by David S. Woodruff)

The following is space delimited 'quintuples', each one of which is a five-symbol Turing Machine instruction. It is written in AWK regular expression syntax.

- 1) Current State
- 2) Current Tape Symbol
- 3) Next State
- 4) Write Tape Symbol
- 5) Move Tape Head Left or Right

```
--1--    --2--    --3--    --4--    --5--  
[0-9]+ [\x20-\x7e] [0-9]+ [\x20-\x7e] [LR]
```

If we make a fixed number of (hexadecimal) states then The UTM could simply hold a sorted list of `std::strings`. We no longer need space delimiting because each line is now fixed length. A sorted list would allow state transitions to occur by binary search. This would allow a very simple DFA based syntax checker.

The tape could be constructed using a `std::vector`. Binary Zero end markers would be in the tape alphabet and not the input alphabet. These trigger memory reallocation to enlarge the tape.

David S. Woodruff's definition of his TM Interpreter:

The turing machine starts in state '0' reading the left-most symbol on the tape. The turing machine halts if it is in a state for which there is no quintuple telling it what to do for the symbol being read.

He says that a turing machine indicates a final accept state by transitioning to a state that has not been defined to exist. We could augment this by writing "T" or "F" to the tape indicating True or False.
