Halting problem undecidability and infinitely nested simulation (V2)

The halting theorem counter-examples present infinitely nested simulation (non-halting) behavior to every simulating halt decider. This paper has been rewritten to be more compelling and more concise.

The pathological self-reference of the conventional halting problem proof counter-examples is overcome. The halt status of these examples is correctly determined. A simulating halt decider remains in pure simulation mode until after it determines that its input will never reach its final state. This eliminates the conventional feedback loop where the behavior of the halt decider effects the behavior of its input.

The x86utm operating system was created so that the halting problem could be examined concretely in the high level language of C. H is a function written in C that analyzes the x86 machine language execution trace of other functions written in C. H recognizes simple cases of infinite recursion and infinite loops. The conventional halting problem proof counterexample template is shown to simply be an input that does not halt.

H simulates its input with an x86 emulator until it determines that its input would never halt. As soon as H recognizes that its input would never halt it stops simulating this input and returns 0. For inputs that do halt H acts exactly as if it was an x86 emulator and simply runs its input to completion and then returns 1.

In theoretical computer science the random-access stored-program (RASP) machine model is an abstract machine used for the purposes of algorithm development and algorithm complexity theory. ...The RASP is closest of all the abstract models to the common notion of computer. https://en.wikipedia.org/wiki/Random-access-stored-program-machine

The C/x86 model of computation is known to be Turing equivalent on the basis that it maps to the RASP model for all computations having all of the memory that they need. As long as an C/x86 function is a pure function of its inputs the C/x86 model of computation can be relied upon as a much higher level of abstraction of the behavior of actual Turing machines.

This criteria merely relies on the fact that the UTM simulation of a machine description of a machine is computationally equivalent to the direct execution of this same machine:

halt decider (Olcott 2021)

A halt decider accepts or rejects inputs on the basis of the actual behavior specified by these inputs. Whenever the direct execution or pure simulation of an input would never reach its final state this input is correctly decided as not halting.

In computability theory, the halting problem is the problem of determining, from a description of an arbitrary computer program and an input, whether the program will finish running, or continue to run forever. https://en.wikipedia.org/wiki/Halting_problem

---1--- 2021-11-20 01:27 PM

Because H only acts as a pure simulator of its input until after its halt status decision has been made it has no behavior that can possibly effect the behavior of its input.

Pathological Input to a halt decider is stipulated to mean any input that was defined to do the opposite of whatever its corresponding halt decider decides as Sipser describes:

Now we construct a new Turing machine D with H as a subroutine. This new TM calls H to determine what M does when the input to M is its own description $\langle M \rangle$. Once D has determined this information, it does the opposite. (Sipser:1997:165)

When D is invoked with input **(D)** we have pathological self-reference when D calls H with **(D)** and does the opposite of whatever H returns.

Does D halt on its own machine description (D)?

This question can only be correctly answered after the pathology has been removed. When a halt decider only acts as a pure simulator of its input until after its halt status decision is made there is no feedback loop of back channel communication between the halt decider and its input that can prevent a correct halt status decision. In this case the halt decider is only examining the behavior of the input and has no behavior that can effect the behavior of this input thus can ignore it own behavior.

The standard pseudo-code halting problem template "proved" that the halting problem could never be solved on the basis that neither value of true (halting) nor false (not halting) could be correctly returned form the halt decider to the confounding input.

```
// Simplified Linz(1990) A and Strachey(1965) P
void P(u32 x)
{
  if (H(x, x))
     HERE: goto HERE;
}
```

This problem is overcome on the basis that a simulating halt decider would abort the simulation of its input before ever returning any value to this input. It aborts the simulation of its input on the basis that its input specifies what is essentially infinite recursion (infinitely nested simulation) to any simulating halt decider.

Every input to a simulating halt decider that only stops running when its simulation is aborted unequivocally specifies a computation that never halts. When input to a simulating halt decider cannot possibly reach its final state then we know that this input never halts.

A simulating halt decider H divides all of its input into:

- (1) Those inputs that never halt unless H aborts their simulation (never halting). H aborts its simulation of these inputs an returns 0 for never halting.
- (2) Those inputs that halt while H remains a pure simulator (halting).

 H waits for its simulation of this input to complete and then returns 1 halting.

Simulating partial halt decider H correctly decides that P(P) never halts (V1)

```
#include <stdint.h>
#include <stdio.h>
typedef int (*ptr)();
int H(ptr x, ptr y)
{
    x(y); // direct execution of P(P)
    return 1;
}

// Minimal essence of Linz(1990) Ĥ
// and Strachey(1965) P
int P(ptr x)
{
    H(x, x);
    return 1; // Give P a last instruction at the "c" level
}
int main(void)
{
    H(P, P);
}
```

Computation that halts

a computation is said to halt whenever it enters a final state. (Linz:1990:234)

PSR set: Combinations of H/P having pathological self-reference

For every possible H of H(P,P) invoked from main() where P(P) calls this same H(P,P) and H simulates or executes its input and aborts or does not abort its input P never reaches its last instruction.

PSR subset: Because we know that the input to H(P,P) never halts for the whole **PSR set** and a subset of these H/P combinations aborts the execution or simulation of its input then we know that for this entire subset the input to H(P,P) never halts and H(P,P) halts.

When int main(void) { P(P); } is invoked on H/P elements of the above PSR subset, then we have a cases where the input to H(P,P) never halts and P(P) halts.

The above cases conclusively prove that when the input to H(P,P) never halts and the same P(P) does halt that this does not form any contradiction.

Decidable_PSR subset: The subset of the **PSR subset** where H returns 0 on the basis that H correctly detects that P specifies infinite recursion defines the decidable domain of function H.

H is a function that correctly maps every element of its domain to {0,1} on the basis of whether or not these elements reach their final state and halt. On this basis H is a halt decider.

The above H could detect that its simulated P is calling H(P,P) with the same parameters that it was called with, thus specifying infinite recursion.

Simulating partial halt decider H correctly decides that P(P) never halts (V2)

```
Simplified Linz A (Linz:1990:319)
// Strachey(1965) CPL translated to C
void P(u32 x)
   if(H(x, x))
      HERE: goto HERE;
int main()
   Output("Input_Halts = ", H((u32)P, (u32)P));

The direct execution of P(P) halts (V3)

The execution trace of the x86 emulation of P(P) by simulating halt decider H conclusively proves that P cannot possibly ever reach its final state of 0xc3f. This provides complete proof that that the input to H never halts thus H(P,P)==0 is correct.

P(P) is conditional only on whatever H(P,P) returns. H(P,P) is conditional only on whatever the simulation or execution of its input actually does. These are two entirely different conditions that result in entirely different behavior.

Here are the divergent execution sequences at the C level:

int main(){ H(P,P); }

- (1) main()
- (2) calls H(P,P) that simulates the input to H(P,P)
- (3) that calls H(P,P) which aborts its simulation of P(P) and returns to
- (4) main().

int main(){ P(P); }

- (a) main() calls P(P) that
- (b) calls H(P,P) that simulates the input to H(P,P)
- (c) that calls H(P,P) which aborts its simulation of P(P) and returns to
- (d) P(P) that returns to main()

Peter Linz Ĥ applied to the Turing machine description of itself: (Ĥ)

The following simplifies the syntax for the definition of the Linz Turing machine \hat{H} , it is now a single machine with a single start state. A simulating halt decider is embedded at \hat{H} .qx. It has been annotated so that it only shows \hat{H} applied to $\langle \hat{H} \rangle$, converting the variables to constants.

 \hat{H} .q0 $\langle \hat{H} \rangle \vdash^* \hat{H}$.qx $\langle \hat{H} \rangle \langle \hat{H} \rangle \vdash^* \hat{H}$.qy ∞ If the UTM simulation of the input to \hat{H} .qx $\langle \hat{H} \rangle$ applied to $\langle \hat{H} \rangle$ reaches its own final state.

\hat{H} .q0 $\langle \hat{H} \rangle \vdash^* \hat{H}$.qx $\langle \hat{H} \rangle \langle \hat{H} \rangle \vdash^* \hat{H}$.qn

If the pure simulation of the input to $\hat{H}qx \langle \hat{H} \rangle \langle \hat{H} \rangle$ would never reach its final state (whether or not this simulation is aborted) then it is necessarily true that $\hat{H}qx$ transitions to \hat{H} .qn correctly.

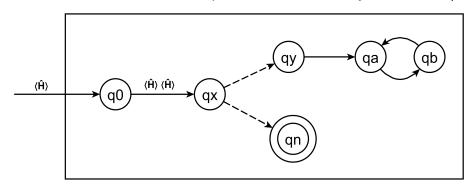

Figure 12.3 Turing Machine Ĥ applied to 〈Ĥ〉

 \hat{H}_{0} copies its input $\langle \hat{H}_{0} \rangle$ to $\langle \hat{H}_{1} \rangle$ then \hat{H}_{0} simulates this input \hat{H}_{0} with its input $\langle \hat{H}_{1} \rangle$ \hat{H}_{0} .q0 copies its input $\langle \hat{H}_{1} \rangle$ to $\langle \hat{H}_{2} \rangle$ then \hat{H}_{0} .qx simulates this input \hat{H}_{1} with its input $\langle \hat{H}_{2} \rangle$ \hat{H}_{1} .q0 copies its input $\langle \hat{H}_{2} \rangle$ to $\langle \hat{H}_{3} \rangle$ then \hat{H}_{1} .qx simulates this input \hat{H}_{2} with its input $\langle \hat{H}_{3} \rangle$ \hat{H}_{2} .q0 copies its input $\langle \hat{H}_{3} \rangle$ to $\langle \hat{H}_{4} \rangle$ then \hat{H}_{2} .qx simulates this input \hat{H}_{3} with its input $\langle \hat{H}_{4} \rangle$...

If the simulating halt decider at \hat{H} .qx never aborts its simulation of its input this input never halts. If \hat{H} .qx aborts its simulation of its input this input never reaches its final state and thus never halts. In all cases for every simulating halt decider at \hat{H} .qx its input never halts.

When the pure simulation of the actual input to \hat{H} .qx $\langle \hat{H} \rangle$ never reaches the final state of this input then \hat{H} .qx transitions to $\vdash^* \hat{H}$.qn is necessarily correct no matter what \hat{H} $\langle \hat{H} \rangle$ does. A halt decider is only accountable for correctly deciding the halt status of its actual input.

When the original Linz H is applied to $\langle \hat{H} \rangle$ ($\hat{H} \rangle$) it sees that its input transitions to \hat{H} .qn. This provides the basis for H to transition to its final state of H.qy.

When \hat{H} .qx is applied to $\langle \hat{H} \rangle$ it sees that none of the recursive simulations of its input ever halt it aborts the simulation of its input and correctly transitions to its final state of \hat{H} .qn.

---8--- 2021-11-20 01:27 PM

The Peter Linz conclusion (Linz:1990:320)

Now \hat{H} is a Turing machine, so that it will have some description in Σ^* , say $\langle \hat{H} \rangle$. This string, in addition to being the description of \hat{H} can also be used as input string. We can therefore legitimately ask what would happen if \hat{H} is applied to $\langle \hat{H} \rangle$.

$$\hat{H}.q0 \langle \hat{H} \rangle \vdash^* \hat{H}.qx \langle \hat{H} \rangle \langle \hat{H} \rangle \vdash^* \hat{H}.qy \infty$$

if Ĥ applied to (Ĥ) halts, and

$$\hat{H}.q0 \langle \hat{H} \rangle \vdash^* \hat{H}.qx \langle \hat{H} \rangle \langle \hat{H} \rangle \vdash^* \hat{H}.qn$$

if \hat{H} applied to $\langle \hat{H} \rangle$ does not halt. This is clearly nonsense. The contradiction tells us that our assumption of the existence of H, and hence the assumption of the decidability of the halting problem, must be false.

My rebuttal to the Peter Linz Conclusion

This explicitly ignores the possibility that the input to \hat{H} .qx $\langle \hat{H} \rangle$ $\langle \hat{H} \rangle$ never halts and \hat{H} transitions to \hat{H} .qn causing \hat{H} $\langle \hat{H} \rangle$ to halt in exactly the same way that the input to H(P,P) never halts and H(P,P) returns 0 causing P(P) to halt.

Glossary of Terms

computation

The sequence of configurations leading to a halt state will be called a computation. (Linz:1990:238)

computation that halts

a computation is said to halt whenever it enters a final state. (Linz:1990:234)

computable function (Olcott 2021)

An algorithm is applied to an input deriving an output.

computer science decider

a decider is a machine that accepts or rejects inputs. https://cs.stackexchange.com/questions/84433/what-is-decider

halt decider (Olcott 2021) A halt decider accepts or rejects inputs on the basis of the actual behavior of the direct execution or simulation of these inputs.

A correct halt decider must base its halt status decision on:

- (a) the actual sequence of instruction steps
- (b) that are actually specified by
- (c) an actual direct execution or
- (d) actual correct simulation of
- (e) the actual input.

If you get rid of any of the "actuals" the halt decider cannot be relied on as correct.

A halt decider must base its halt status decision on the sequence instruction steps (sequence of configurations) specified by the direct execution or correct simulation of its actual input. **

Intuitively, a decider should be a Turing machine that given an input, halts and either accepts or rejects, relaying its answer in one of many equivalent ways, such as halting at an ACCEPT or REJECT state, or leaving its answer on the output tape. https://cs.stackexchange.com/guestions/84433/what-is-decider

Eventually, the whole process may terminate, which we achieve in a Turing machine by putting it into a halt state. A Turing machine is said to halt whenever it reaches a configuration for which δ is not defined; ... so the Turing machine will halt whenever it enters a final state. (Linz:1990:234)

Halting problem undecidability and infinitely nested simulation (V2) November 2021 PL Olcott
