Storm risk predictions on Atlantic Ocean  
(PCR6 fusion of five real physical criteria).

Confidence of predictions of Soft Electre Tri  
method based on PCR6 fusion.

*About the cover:* The left image shows the result of the storm risk predictions on Atlantic Ocean based on Soft Electre Tri (SET) method used with five criteria (the 3-h accumulated precipitation, the lifted index, the convective available potential energy, the low-level wind divergence and the divergence of the wind above the top of the convective clouds) with real data, and used with the PCR6 fusion rule of combination of belief functions. The right image shows the quality (confidence level) of the result for each pixel of the left image. For more details, see paper #34 of Part 2 (pages 447-454) of this volume, entitled: *Multi-Criteria Information Fusion for Storm Prediction Based on Belief Functions*, by J. Dezert, A. Bouchard and M. Buguet.

## In memoriam

This book is dedicated to the memory of our good friends and colleagues  
Dr. Ludmil Bojilov (1944-2023) and Prof. Arnaud Martin (1974-2023)  
who have always been active and enthusiastic in tracking,  
and in the development of belief functions.  
We will never forget them.

Ludmil Bojilov.

Albena Tchamova, Ludmil Bojilov,  
Jean Dezert, Florentin Smarandache in Varna.

Arnaud Martin.

Arnaud Martin, Florentin Smarandache in Brest.

Arnaud Martin, Jean Dezert, Grégoire Mercier in Xi'an.

# Table of Contents

F. Smarandache, J. Dezert, A. Tchamova (Editors) Foreword	13
--	----

## PART 1 - THEORETICAL ADVANCES ON DS<sub>m</sub>T

F. Smarandache, J. Dezert Modified PCR Rules of Combination with Degrees of Intersections	17
Y. Dong, X. Li, J. Dezert A Hierarchical Flexible Coarsening Method to Combine BBAs in Probabilities	27
N.R. Mahato, L. Jaulin, S. Chakraverty, J. Dezert Validated Enclosure of Uncertain Nonlinear Equations using SIVIA Monte-Carlo	35
Y. Dong, X. Li, J. Dezert Rough Set Classifier Based on DS <sub>m</sub> T	43
J. Dezert, F. Smarandache Canonical Decomposition of Dichotomous Basic Belief Assignment	51
J. Dezert, F. Smarandache Canonical Decomposition of Basic Belief Assignment for Decision-Making Support	61
J. Dezert, F. Smarandache, A. Tchamova, D. Han Fast Fusion of Basic Belief Assignments Defined on a Dichotomous Frame of Discernment	69
J. Dezert, S. Fidanova, A. Tchamova Fast BF-ICrA Method for the Evaluation of MO-ACO Algorithm for WSN Layout	77
T. Dezert, J. Dezert, F. Smarandache Improvement of Proportional Conflict Redistribution Rules of Combination of Basic Belief Assignments	85
J. Dezert, F. Smarandache Explicit Formulas of PCR5 and PCR6 Fusion Rules for Three Bayesian Basic Belief Assignments	109

## PART 2 - APPLICATIONS OF DS<sub>m</sub>T

# Foreword

This fifth volume on Advances and Applications of DSMT for Information Fusion collects theoretical and applied contributions of researchers working in different fields of applications and in mathematics, and is available in open-access. The collected contributions of this volume have either been published or presented after disseminating the fourth volume in 2015 (available at [fs.unm.edu/DSMT-book4.pdf](http://fs.unm.edu/DSMT-book4.pdf) or [www.onera.fr/sites/default/files/297/2015-DSMT-Book4.pdf](http://www.onera.fr/sites/default/files/297/2015-DSMT-Book4.pdf)) in international conferences, seminars, workshops and journals, or they are new. The contributions of each part of this volume are chronologically ordered.

First Part of this book presents some theoretical advances on DSMT, dealing mainly with modified Proportional Conflict Redistribution Rules (PCR) of combination with degree of intersection, coarsening techniques, interval calculus for PCR thanks to set inversion via interval analysis (SIVIA), rough set classifiers, canonical decomposition of dichotomous belief functions, fast PCR fusion, fast inter-criteria analysis with PCR, and improved PCR5 and PCR6 rules preserving the (quasi-)neutrality of (quasi-)vacuous belief assignment in the fusion of sources of evidence with their Matlab codes.

Because more applications of DSMT have emerged in the past years since the apparition of the fourth book of DSMT in 2015, the second part of this volume is about selected applications of DSMT mainly in building change detection, object recognition, quality of data association in tracking, perception in robotics, risk assessment for torrent protection and multi-criteria decision-making, multi-modal image fusion, coarsening techniques, recommender system, levee characterization and assessment, human heading perception, trust assessment, robotics, biometrics, failure detection, GPS systems, inter-criteria analysis, group decision, human activity recognition, storm prediction, data association for autonomous vehicles, identification of maritime vessels, fusion of support vector machines (SVM), Silx-Furtif RUST code library for information fusion including PCR rules, and network for ship classification.

Finally, the third part presents interesting contributions related to belief functions in general published or presented along the years since 2015. These contributions are related with decision-making under uncertainty, belief approximations, probability transformations, new distances between belief functions, non-classical multi-criteria decision-making problems with belief functions, generalization of Bayes theorem, image processing, data association, entropy and cross-entropy measures, fuzzy evidence numbers, negator of belief mass, human activity recognition, information fusion for breast cancer therapy, imbalanced data classification, and hybrid techniques mixing deep learning with belief functions as well.

We want to thank all the contributors of this fifth volume for their research works and their interests in the development of DSMT, and the belief functions. We are grateful as well to other colleagues for encouraging us to edit this fifth volume, and for sharing with us several ideas and for their questions and comments on DSMT through the years. We thank the International Society of Information Fusion ([www.isif.org](http://www.isif.org)) for diffusing main research works related to information fusion (including DSMT) in the international fusion conferences series over the years.

Florentin Smarandache is grateful to The University of New Mexico, U.S.A., that many times partially sponsored him to attend international conferences, workshops and seminars on Information Fusion.

Jean Dezert is grateful to the Department of Information Processing and Systems (DTIS) of the French Aerospace Lab (Office National d'Études et de Recherches Aéropatiales), Palaiseau, France, for encouraging him to carry on this research and for its financial support.

Albena Tchamova is first of all grateful to Dr. Jean Dezert for the opportunity to be involved during more than 20 years to follow and share his smart and beautiful visions and ideas in the development of the powerful Dezert-Smarandache Theory for data fusion. She is also grateful to the Institute of Information and Communication Technologies, Bulgarian Academy of Sciences, for sponsoring her to attend international conferences on Information Fusion.

Originally published as: F. Smarandache, J. Dezert, *Modified PCR Rules of Combination with Degrees of Intersections*, in Proc. of the 18th Int. Conf. on Information Fusion (Fusion 2015), Washington D.C, USA, July 6–9, 2015, and reprinted with permission.

**Abstract**—In this paper, we propose a modification of PCR5 and PCR6 fusion rules with degrees of intersections for taking into account the cardinality of focal elements of each source of evidence to combine. We show in very simple examples the interest of these new fusion rules w.r.t. classical Dempster-Shafer, PCR6, Zhang’s and Jaccard’s Center rules of combination.

**Keywords:** Information fusion, belief functions, DSMT, PCR6, degrees of intersection.

## I. INTRODUCTION

In this paper, we propose modifications of the Proportional Conflict Redistribution rule no. 6 (PCR6) [1] (Vol. 3) for the combination of basic belief assignments (BBA’s) which integrate the degrees of intersections of focal elements of each source of evidence to combine. Because we consider two possible definitions of degrees of intersections (i.e. Zhang’s and Jaccard’s degrees) and also two normalization methods (simplest and sophisticate), we propose four modified versions of PCR6 rules<sup>1</sup>. After a brief presentation of classical rules of combination and a detailed presentation of our modified PCR6 rules, we evaluate and compare their behaviors in different emblematic examples to guide the choice of the most interesting one.

## II. BELIEF FUNCTIONS AND CLASSICAL FUSION RULES

Belief functions have been introduced by Shafer in 1976 from Dempster’s works [2] in Dempster-Shafer’s theory (DST) of evidence. DST is mainly characterized by a frame of discernment (FoD), sources of evidence represented by basic belief assignment (BBA), belief (Bel) and plausibility (Pl) functions, and Dempster’s rule of combination, denoted as DS rule in the sequel<sup>2</sup> of combination. DST has been modified and extended into Dezert-Smarandache theory [1] (DSMT) to work with quantitative or qualitative BBA and to combine the sources of evidence in a more efficient way thanks to new proportional conflict redistribution (PCR) fusion rules – see [3]–[6] for discussion and examples.

<sup>1</sup>The methodology proposed in this paper is general and can also be applied to modify similarly other PCR rules. Since we consider PCR6 rule the most efficient one [6], we focus our presentation on PCR6 only

<sup>2</sup>DS acronym standing for *Dempster-Shafer* since Dempster’s rule has been widely promoted by Shafer in the development of his mathematical theory of evidence.

More precisely, let’s consider a finite discrete FoD  $\Theta = \{\theta_1, \theta_2, \dots, \theta_n\}$ , with  $n > 1$ , of the fusion problem under consideration and its fusion space  $G^\Theta$  which can be chosen either as the power-set  $2^\Theta$ , the hyper-power set<sup>3</sup>  $D^\Theta$ , or the super-power set  $S^\Theta$  depending on the model that fits with the problem [1]. A BBA associated with a given source of evidence is defined as the mapping  $m(\cdot) : G^\Theta \rightarrow [0, 1]$  satisfying  $m(\emptyset) = 0$  and  $\sum_{A \in G^\Theta} m(A) = 1$ . The quantity  $m(A)$  is called mass of belief of  $A$  committed by the source of evidence. Belief and plausibility functions are defined by

$$\text{Bel}(A) = \sum_{\substack{B \subseteq A \\ B \in G^\Theta}} m(B), \quad \text{and} \quad \text{Pl}(A) = \sum_{\substack{B \cap A \neq \emptyset \\ B \in G^\Theta}} m(B). \quad (1)$$

If for some  $A \in G^\Theta$ ,  $m(A) > 0$  then  $A$  is called a focal element of the BBA  $m(\cdot)$ . When all focal elements are singletons and  $G^\Theta = 2^\Theta$  then the BBA  $m(\cdot)$  is called a Bayesian BBA [2] and its corresponding belief function  $\text{Bel}(\cdot)$  is homogeneous to a (possibly subjective) probability measure, and one has  $\text{Bel}(A) = P(A) = \text{Pl}(A)$ , otherwise in general one has  $\text{Bel}(A) \leq P(A) \leq \text{Pl}(A)$ ,  $\forall A \in G^\Theta$ . The vacuous BBA, or VBBA for short, representing a totally ignorant source is defined as  $m_v(I_t) = 1$ , where the total ignorance defined as  $I_t \triangleq \theta_1 \cup \theta_2 \cup \dots \cup \theta_n$  if the FoD is  $\Theta = \{\theta_1, \theta_2, \dots, \theta_n\}$ . Since in Shafer’s book [2], the total ignorance  $I_t$  is also denoted  $\Theta$ , we will adopt this notation in the sequel.

Many rules have been proposed in the literature over the decades (see [1], Vol. 2 for a detailed list of fusion rules) to combine several distinct sources of evidence represented by the BBA’s  $m_1(\cdot), m_2(\cdot), \dots, m_s(\cdot)$  ( $s \geq 2$ ) defined on same fusion space  $G^\Theta$ . In DST, the combination of  $s \geq 2$  BBA’s is traditionally accomplished with Dempster-Shafer (DS) rule [2] defined by  $m_{1, \dots, s}^{DS}(\emptyset) = 0$  and for all  $X \neq \emptyset$  in  $2^\Theta$

$$m_{1, \dots, s}^{DS}(X) \triangleq \frac{1}{1 - m_{1, \dots, s}(\emptyset)} \sum_{\substack{X_1, \dots, X_s \in 2^\Theta \\ X_1 \cap \dots \cap X_s = X}} \prod_{i=1}^s m_i(X_i), \quad (2)$$

where the numerator of (2) is the mass of belief on the conjunctive consensus on  $X$ . The denominator  $1 - m_{1, \dots, s}(\emptyset)$  is a

<sup>3</sup>which corresponds to a Dedekind’s lattice, see [1] Vol. 1.

normalization constant. The total degree of conflict  $m_{1,\dots,s}(\emptyset)$  between the  $s$  sources of evidences is defined by

$$m_{1,\dots,s}(\emptyset) \triangleq \sum_{\substack{X_1,\dots,X_s \in 2^\Theta \\ X_1 \cap \dots \cap X_s = \emptyset}} \prod_{i=1}^s m_i(X_i). \quad (3)$$

DS rule is associative and commutative and preserves the neutrality of the VBBA.  $s$  sources of evidence are said in total conflict if  $m_{1,\dots,s}(\emptyset) = 1$ . In this case the combination of the sources by DS rule cannot be done because of the mathematical 0/0 indeterminacy in (2). In DS rule,  $m_{1,\dots,s}(\emptyset)$  is redistributed to all focal elements of the conjunctive operator only proportionally to their mass (i.e. without taking care of their cardinalities). So with DS rule and with combination of 2 BBA's, the product  $m_1(X_1)m_2(X_2)$  is transferred to  $X_1 \cap X_2 = X$  only, no matter how the ratio between the cardinality of  $X$  and  $X_1 \cup X_2$  varies. This DS principle of redistribution has been questioned by Zhang in [7] and Fixsen and Malher in [8] because it does not discriminate the case where  $X_1 \cup X_2$  is large but  $X_1 \cap X_2$  is small with respect to the case where  $X_1 \cup X_2$  is small but  $X_1 \cap X_2$  is large. To palliate this problem, Zhang proposed in 1994 a modified version of DS rule [7] including a measure of degree of intersection of focal elements. The general formula of this modified DS rule is defined by  $m_{1,\dots,s}^D(\emptyset) = 0$  and for all  $X \neq \emptyset$  in  $2^\Theta$

$$m_{1,\dots,s}^D(X) \triangleq \frac{1}{K_{1,\dots,s}^D} \cdot \sum_{\substack{X_1,\dots,X_s \in 2^\Theta \\ X_1 \cap \dots \cap X_s = X}} D(X_1, \dots, X_s) \prod_{i=1}^s m_i(X_i), \quad (4)$$

where  $D(X_1, \dots, X_s)$  denotes a measure of the degree of intersection between the focal elements  $X_1, X_2, \dots, X_s$ , and where  $K_{1,\dots,s}^D$  is a normalization constant allowing to get  $\sum_{X \in 2^\Theta} m_{1,\dots,s}^D(X) = 1$ . Because the measure of degree of intersection  $D(X_1, \dots, X_s)$  can be defined in different ways, this yields to different versions of the modified DS rule above. In [7], Zhang suggested to define  $D(X_1, \dots, X_s)$  as

$$D^Z(X_1, \dots, X_s) \triangleq \frac{|X_1 \cap X_2 \cap \dots \cap X_s|}{|X_1| \cdot |X_2| \cdot \dots \cdot |X_s|}, \quad (5)$$

where  $|X_1 \cap X_2 \cap \dots \cap X_s|$  is the cardinality of the intersection of the focal elements  $X_1, X_2, \dots, X_s$ , and  $|X_1|, |X_2|, \dots, |X_s|$  their cardinalities. Replacing  $D(X_1, \dots, X_s)$  by  $D^Z(X_1, \dots, X_s)$  in the formula (4) defines Zhang's Center Rule (ZCR) of combination [7], denoted  $m_{1,\dots,s}^{ZCR}(\cdot)$  in the sequel. The normalization constant of ZCR is denoted  $K_{1,\dots,s}^{ZCR}$ .

If we use Jaccard's index as measure of the degree of intersection [9] which is defined by

$$D^J(X_1, \dots, X_s) \triangleq \frac{|X_1 \cap X_2 \cap \dots \cap X_s|}{|X_1 \cup X_2 \cup \dots \cup X_s|}, \quad (6)$$

then we obtain Jaccard's center rule (JCR) of combination, and we denote it  $m_{1,\dots,s}^{JCR}(\cdot)$ , in replacing  $D(X_1, \dots, X_s)$  by  $D^J(X_1, \dots, X_s)$  in the formula (4). The normalization constant of JCR is denoted  $K_{1,\dots,s}^{JCR}$ . ZCR and JCR rules are particular instances of Modified DS rule (MDS) proposed by Fixsen and Mahler in [8]. ZCR and JCR are commutative but not

idempotent. It can be proved that Zhang's degree is associative that is  $D^Z(X_1, X_2, \dots, X_s) = D^Z(X_1, D^Z(X_2, \dots, X_s))$ , whereas Jaccard's degree is not associative. If one combines three (or more) BBA's and there is no conflicting mass, then ZCR is associative, whereas JCR is not associative. If there is conflicting masses, then ZCR is still associative, but JCR is not associative. Zhang's and Jaccard's degrees pose a problem because ZCR and JCR become strictly equivalent with DS rule when the cardinality is 1 for all relevant sets, or when  $|X_1 \cap X_2 \cap \dots \cap X_s| = |X_1| \cdot |X_2| \cdot \dots \cdot |X_s|$  in the circumstance of conflicting evidence. Therefore, it inherits the same limitations as DS rule – see example 2 in Section V.

The doubts of the validity of DS rule has been discussed by Zadeh in 1979 [10]–[12] based on a very simple example with two highly conflicting sources of evidences. Since 1980's, many criticisms have been done about the behavior and the justification of such DS rule. More recently, Dezert et al. in [3], [4], [18] have put in light other counter-intuitive behaviors of DS rule even in low conflicting cases and showed serious flaws in logical foundations of DST [5]. To overcome the limitations and problems of DS rule of combination, a new family of PCR rules have been developed in DSMT framework [1]. In PCR rules, we transfer the conflicting mass only to the elements involved in the conflict and proportionally to their individual masses, so that the specificity of the information is entirely preserved. The general principle of PCR consists: 1) to apply the conjunctive rule, 2) to calculate the total or partial conflicting masses; 3) then redistribute the (total or partial) conflicting mass proportionally on non-empty sets according to the integrity constraints one has for the frame  $\Theta$ . Because the proportional transfer can be done in different ways, there exist several versions of PCR rules of combination. PCR6 fusion rule has been proposed by Martin and Osswald in [1] Vol. 2, Chap. 2, as a serious alternative to PCR5 fusion rule proposed originally by Smarandache and Dezert in [1] Vol. 2, Chap. 1. When only two BBA's are combined, PCR6 and PCR5 fusion rules coincide, but they differ in general as soon as more than two sources have to be combined altogether. Recently, it has been proved in [6] that only PCR6 rule is consistent with the averaging fusion rule which allows to estimate the empirical (frequentist) probabilities involved in a discrete random experiment, and that is why we recommend to use it in applications when possible. For Shafer's model of FoD<sup>4</sup>, the PCR6<sup>5</sup> combination of two BBA's  $m_1(\cdot)$  and  $m_2(\cdot)$  is defined by  $m_{1,2}^{PCR5/6}(\emptyset) = 0$  and for all  $X \neq \emptyset$  in  $2^\Theta$

$$m_{1,2}^{PCR5/6}(X) = \sum_{\substack{X_1, X_2 \in 2^\Theta \\ X_1 \cap X_2 = X}} m_1(X_1)m_2(X_2) + \sum_{\substack{Y \in 2^\Theta \setminus \{X\} \\ X \cap Y = \emptyset}} \left[ \frac{m_1(X)^2 m_2(Y)}{m_1(X) + m_2(Y)} + \frac{m_2(X)^2 m_1(Y)}{m_2(X) + m_1(Y)} \right], \quad (7)$$

<sup>4</sup>that is when  $G^\Theta = 2^\Theta$ , and assuming all elements exhaustive and exclusive.

<sup>5</sup>which turns to be equal to PCR5 formula in case of fusion of two BBA's only.

where all denominators in (7) are different from zero. If a denominator is zero, that fraction is discarded. All propositions/sets are in a canonical form [1]. Basic MatLab codes of PCR rules can be found in [1], [13] or from the toolboxes repository on the web [14]. The general and concise formula of PCR6 rule for combining  $s > 2$  sources of evidences is

$$m_{1,2,\dots,s}^{PCR6}(X) = m_{1,2,\dots,s}(X) + CR^{PCR6}(X) \quad (8)$$

where  $m_{1,2,\dots,s}(X)$  corresponds to the conjunctive consensus on  $X$  between  $s$  sources of evidence, which is defined by

$$m_{1,2,\dots,s}(X) \triangleq \sum_{\substack{X_1, \dots, X_s \in 2^\Theta \\ X_1 \cap \dots \cap X_s = X}} \prod_{i=1}^s m_i(X_i), \quad (9)$$

and where  $CR^{PCR6}(X)$  is the part of the conflicting masses redistributed back to the focal element  $X$  according to PCR6 redistribution principle, that is

$$CR^{PCR6}(X) \triangleq \sum_{k=1}^{s-1} \sum_{\substack{X_{i_1}, X_{i_2}, \dots, X_{i_k} \in G^\Theta \setminus X \\ (\bigcap_{j=1}^k X_{i_j}) \cap X = \emptyset}} \sum_{(i_1, i_2, \dots, i_k) \in \mathcal{P}^s(\{1, \dots, s\})} [m_{i_1}(X) + m_{i_2}(X) + \dots + m_{i_k}(X)] \cdot \frac{m_{i_1}(X) \dots m_{i_k}(X) m_{i_{k+1}}(X_{i_{k+1}}) \dots m_{i_s}(X_{i_s})}{m_{i_1}(X) + \dots + m_{i_k}(X) + m_{i_{k+1}}(X_{i_{k+1}}) + \dots + m_{i_s}(X_{i_s})}. \quad (10)$$

In Eq.(10),  $\mathcal{P}^s(\{1, \dots, s\})$  is the set of all permutations of the elements  $\{1, 2, \dots, s\}$ . It should be observed that  $X_{i_1}, X_{i_2}, \dots, X_{i_s}$  may be different from each other, or some of them equal and others different, etc. As discussed and justified in [6], we focus here and in the sequel on PCR6 rule of combination rather than PCR5, but the general formula of PCR5 rule can be found in [1], [6] with examples, and a concise PCR5 general formula similar to (11) is possible. Like the averaging fusion rule, the PCR5 and PCR6 fusion rules are commutative but not associative.

### III. PCR6 RULE WITH DEGREES OF INTERSECTION

As presented in the previous section, the original versions of PCR5 or PCR6 rules of combination (as well as original DS rule) use only part of the whole information available (i.e. the values of the masses of belief only), because they do not exploit the cardinalities of focal elements entering in the fusion process. Because the cardinalities of focal elements are fully taken into account in the computation of the measure of degree of intersection between sets, we propose to improve PCR rules using this measure. The basic idea is to replace any conjunctive product by its discounted version thanks to the measure of degree of intersection  $D$  when the intersection of focal elements is not empty. The product of partial (or total) conflicting masses are not discounted by the measure of degree of intersection because the degree of intersection between two (or more) conflicting focal elements always equals zero, that is if  $X \cap Y = \emptyset$ , then  $D(X, Y) = 0$ . Because there are different ways to define degrees of intersection between set (here we consider only Zhang's and Jaccard' degrees), and

there are different ways to make the normalization because of the weighted conjunctive product involved in formulas, we come up with several versions of modified PCR6 rule of combination. We consider in fact two main modified versions of PCR6. The first modified version uses a classical normalization step based on the division by a normalization factor. The second modified version uses a sophisticate normalization step as shown through the general modified PCR6 formulas.

#### A. Simplest modified PCR6 rule

The simplest modified PCR6 rule including the measure of degree of intersection between sets is defined for  $s \geq 2$  BBA by  $m_{1,2,\dots,s}^{DPCR6}(\emptyset) = 0$  and for any non empty  $X \in 2^\Theta$ , by

$$m_{1,2,\dots,s}^{DPCR6}(X) \triangleq \frac{1}{K_{1,2,\dots,s}^{DPCR6}} \cdot [m_{1,2,\dots,s}^D(X) + CR^{PCR6}(X)], \quad (11)$$

where  $K_{1,2,\dots,s}^{DPCR6}$  is a normalization constant allowing to get  $\sum_{X \in 2^\Theta} m_{1,2,\dots,s}^{DPCR6}(X) = 1$ ;  $CR^{PCR6}(X)$  is the part of the conflicting masses redistributed back to the focal element  $X$  according to PCR6 redistribution principle and defined by (10); and  $m_{1,2,\dots,s}^D(X)$  is the discounted conjunctive consensus by the measure of the degree of intersection, defined by

$$m_{1,2,\dots,s}^D(X) \triangleq \sum_{\substack{X_1, \dots, X_s \in 2^\Theta \\ X_1 \cap \dots \cap X_s = X}} D(X_1, \dots, X_s) \prod_{i=1}^s m_i(X_i). \quad (12)$$

A similar general formula holds for the modified PCR5 rule with degrees of intersection between focal elements. For the fusion of two BBA's  $m_1(\cdot)$  and  $m_2(\cdot)$ , the modified PCR6 and PCR5 formulas coincide and reduce to the formula below

$$m_{1,2}^{DPCR5/6}(X) = \frac{1}{K_{1,2}^{DPCR5/6}} \cdot \left[ \sum_{\substack{X_1, X_2 \in 2^\Theta \\ X_1 \cap X_2 = X}} D(X_1, X_2) m_1(X_1) m_2(X_2) + \sum_{\substack{Y \in 2^\Theta \setminus \{X\} \\ X \cap Y = \emptyset}} \left[ \frac{m_1(X)^2 m_2(Y)}{m_1(X) + m_2(Y)} + \frac{m_2(X)^2 m_1(Y)}{m_2(X) + m_1(Y)} \right] \right]. \quad (13)$$

Depending on the degree of intersection we take (either  $D^Z$  or  $D^J$ ), we get two versions of this modified PCR6 rule. The result of the fusion for each version will be denoted  $m_{1,2,\dots,s}^{ZPCR6}(\cdot)$  and  $m_{1,2,\dots,s}^{JPCR6}(\cdot)$  in the sequel. ZPCR6 and JPCR6 rules<sup>6</sup> are commutative but not associative.

#### B. Sophisticate modified PCR6 rule

We propose here a more sophisticate modified PCR6 rule which does not use the normalization by the division with a normalization constant but which makes a proportional redistribution of the non conflicting mass missing from the discounted conjunctive rule (after including a degree of intersection). Before providing the general formula of this sophisticate modified PCR6 rule, let's explain how the redistribution that we propose is done in the two BBA's case at first for simplicity.

<sup>6</sup>ZPCR6 and JPCR6 denote the PCR6 rules modified with Zhang's and Jaccard's degrees of intersection respectively.

Let's suppose to have only two BBA's  $m_1(\cdot)$  and  $m_2(\cdot)$  defined on the same FoD  $\Theta$  (assuming Shafer's model for simplicity). When  $X_1 \cap X_2 = X$ , then  $(1 - D(X_1, X_2))m_1(X_1)m_2(X_2)$  will be transferred back to  $X_1$  and  $X_2$  proportionally with respect to their masses (following PCR5/6 principle), that is:

$$\frac{\alpha}{m_1(X_1)} = \frac{\beta}{m_2(X_2)} = \frac{(1 - D(X_1, X_2))m_1(X_1)m_2(X_2)}{m_1(X_1) + m_2(X_2)},$$

whence,

$$\alpha = (1 - D(X_1, X_2)) \cdot \frac{m_1^2(X_1)m_2(X_2)}{m_1(X_1) + m_2(X_2)},$$

$$\beta = (1 - D(X_1, X_2)) \cdot \frac{m_1(X_1)m_2^2(X_2)}{m_1(X_1) + m_2(X_2)}.$$

The formula of this sophisticate modified combination rule, denoted<sup>7</sup> SDPCR5/6, is given by  $m_{1,2}^{SDPCR5/6}(\emptyset) = 0$  and by

$$m_{1,2}^{SDPCR5/6}(X) \triangleq \sum_{\substack{X_1, X_2 \in 2^\Theta \\ X_1 \cap X_2 = X}} D(X_1, X_2)m_1(X_1)m_2(X_2)$$

$$+ \sum_{\substack{Y \in 2^\Theta \setminus \{X\} \\ X \cap Y = \emptyset}} \left[ \frac{m_1(X)^2 m_2(Y)}{m_1(X) + m_2(Y)} + \frac{m_2(X)^2 m_1(Y)}{m_2(X) + m_1(Y)} \right]$$

$$+ \sum_{\substack{Y \in 2^\Theta \setminus \{X\} \\ X \cap Y \neq \emptyset}} (1 - D(X, Y)) \left[ \frac{m_1(X)^2 m_2(Y)}{m_1(X) + m_2(Y)} \right.$$

$$\left. + \frac{m_2(X)^2 m_1(Y)}{m_2(X) + m_1(Y)} \right]. \quad (14)$$

The third sum of Eq.(14) represents the non-conflicting mass missing from the conjunctive rule including a degree of intersection. As for ZPCR6 or JPCR6 rules, we can choose Zhang's or Jaccard's degrees (or any other measures of degree of intersection if preferred). The generalization of this principle of redistribution of missing discounting conjunctive masses yields the following general sophisticate modified PCR6 rule of combination.

$$m_{1,2,\dots,s}^{SDPCR6}(X) = m_{1,2,\dots,s}^D(X) + CR^{PCR6}(X) + MR^{PCR6}(X), \quad (15)$$

where  $MR^{PCR6}(X)$  is the part of the missing conjunctive masses due to discounting back to the focal element involved in the conjunction which is redistributed according to PCR6 redistribution principle.  $MR^{PCR6}(X)$  is defined by

$$MR^{PCR6}(X) \triangleq \sum_{k=1}^{s-1} \sum_{\substack{X_{i_1}, X_{i_2}, \dots, X_{i_k} \in 2^\Theta \setminus X \\ (\cap_{j=1}^k X_{i_j}) \cap X \neq \emptyset}} \sum_{(i_1, i_2, \dots, i_k) \in \mathcal{P}^s(\{1, \dots, s\})} (1 - D(X, \dots, X, X_{i_{k+1}}, \dots, X_{i_s})) \cdot \sum_{j=1}^k m_{i_j}(X)$$

$$\cdot \frac{m_{i_1}(X) \dots m_{i_k}(X) m_{i_{k+1}}(X_{i_{k+1}}) \dots m_{i_s}(X_{i_s})}{m_{i_1}(X) + \dots + m_{i_k}(X) + m_{i_{k+1}}(X_{i_{k+1}}) + \dots + m_{i_s}(X_{i_s})}. \quad (16)$$

SZPCR6 and SJPCR6 rules<sup>8</sup> are commutative but not associative.

<sup>7</sup>S letter in this acronym stands for *Sophisticate*.

<sup>8</sup>SZPCR6 and SJPCR6 denote the PCR6 rules modified with Zhang's and Jaccard's degrees of intersection respectively.

#### IV. ANALYSIS OF THE NEUTRALITY OF VBBA

When there is no conflict between BBA's, DS, PCR5 or PCR6 rules reduce to the conjunctive rule which preserves the neutrality of VBA. When there is conflict between BBA's only DS preserves neutrality of VBA because DS is associative. In general, PCR5 and PCR6 do not preserve the neutrality of the VBA if more than two conflicting BBA's (including the VBA) are combined altogether<sup>9</sup>. In general, the VBA  $m_v(\cdot)$  is not a neutral element for the conjunctive rule of combination discounted with Jaccard's degree of intersection when combining two (or more) BBA's as shown in the following counterexample. If we take  $\Theta = \{A, B\}$ , with  $A \cap B = \emptyset$ , and  $m_1(\cdot)$  defined as  $m_1(A) = 0.5$ ,  $m_1(B) = 0.3$  and  $m_v(A \cup B) = 0.2$ . Then the result of the JCR fusion is  $m_{1,v}^{JCR}(A) \approx 0.4167$ ,  $m_{1,v}^{JCR}(B) = 0.25$  and  $m_{1,v}^{JCR}(A \cup B) \approx 0.3333$ , which shows that  $m_{1,v}^{JCR}(\cdot) \neq m_1(\cdot)$ . The VBA  $m_v(\cdot)$  is a neutral element for the ZCR combination of  $m_1(\cdot)$  with the VBA  $m_v(\cdot)$ , because the discounted conjunctive mass for any focal element  $X$  is  $m_{1,v}(X) = \frac{|X \cap \Theta|}{|X| \cdot |\Theta|} m_1(X) m_v(\Theta) = \frac{|X|}{|X| \cdot |\Theta|} m_1(X) \cdot 1 = \frac{1}{n} m_1(X)$ , where  $n = |\Theta|$ . The normalization constant equals  $K_{1,v}^{ZCR} = \sum_X \frac{1}{n} m_1(X) = 1/n$ . Therefore, after dividing by  $K_{1,v}^{ZCR}$ , we always gets  $m_{1,v}^{ZCR}(X) = m_1(X)$  for any focal element  $X$  of  $m_1(\cdot)$ . Same property holds if we combine three (or more) BBA's with the VBA and even if these BAA's are in conflict or not. Because  $D^Z(X_1, \dots, X_n, \Theta) = D^Z(X_1, \dots, X_n)/|\Theta|$  and  $m_v(\Theta) = 1$ , the constant  $|\Theta|$  always simplifies in normalization step of ZCR and because conjunctive rule and Zhang's degree are associative. In the general case, ZPCR6, SZPCR6, JPCR6 and SJPCR6 do not preserve the neutrality of the VBA. This can be verified using the simple example of the footnote no 9. More precisely, the combination  $[m_1 \oplus m_2 \oplus \dots \oplus m_n \oplus m_v](\cdot)$  is not equal to  $[m_1 \oplus m_2 \oplus \dots \oplus m_n](\cdot)$ . In the very specific case when there is no conflict between the BBA's, only ZPCR6 rule preserves the neutrality of VBA because it coincides with ZCR.

#### V. EXAMPLES

Here we analyze the behavior of the different rules (DS, PCR6, ZCR, JCR, ZPCR6, JPCR6, SZPCR6 and SJPCR6) in emblematic examples to determinate which one presents the best interest for the combination of BBA's.

##### Example 1: (No conflicting case)

Let's consider the FoD  $\Theta = \{A_1, A_2, \dots, A_{10}\}$  with Shafer's model, and the following two BBA's to combine  $m_1(A_1) = 0.9$ ,  $m_1(\Theta) = 0.1$ ,  $m_2(X) = 0.9$  and  $m_2(\Theta) = 0.1$  where the focal element  $X$  of  $m_2(\cdot)$  can take the values  $A_1, A_1 \cup A_2, A_1 \cup A_2 \cup A_3, \dots$ , or  $\Theta$ .

In this case, the DS and PCR5/6 rules coincide with the conjunctive rule of combination because there is no

<sup>9</sup>For example, if one considers  $\Theta = \{A, B\}$  with Shafer's model, and the BBA's  $\{m_1(A) = a_1, m_1(B) = b_1, m_1(\Theta) = c_1\}$ ,  $\{m_2(A) = a_2, m_2(B) = b_2, m_2(\Theta) = c_2, m_v(\Theta) = 1\}$ . Then  $[m_1 \oplus m_2](\cdot) \neq [m_1 \oplus m_2 \oplus m_v](\cdot)$  (where  $\oplus$  denotes the PCR5 or PCR6 fusion rule) because in  $m_1 \oplus m_2$  nothing from the redistribution of the conflicting mass goes to ignorance, contrarily to what happens in  $[m_1 \oplus m_2 \oplus m_v](\cdot)$ .

conflicting mass to redistribute because  $m_{1,2}(\emptyset) = 0$ . If  $X = A_1$ , then  $m_{1,2}^{DS}(A_1) = m_{1,2}^{PCR6}(A_1) = m_1(A_1)m_2(A_1) + m_1(A_1)m_2(\Theta) + m_1(\Theta)m_2(A_1) = 0.99$  and  $m_{1,2}^{DS}(\Theta) = m_{1,2}^{PCR6}(\Theta) = m_1(\Theta)m_2(\Theta) = 0.01$ , which is a reasonable result since the belief in  $A_1$  is reinforced because each source does strongly support the same hypothesis  $A_1$ . When  $X \supset A_1$  and  $|X| > 1$ , the behavior of the conjunctive rule becomes questionable because one always gets

$$\begin{aligned} m_{1,2}^{DS}(A_1) &= m_{1,2}^{PCR5/6}(A_1) = m_1(A_1)(m_2(X) + m_2(\Theta)) = 0.9, \\ m_{1,2}^{DS}(X) &= m_{1,2}^{PCR5/6}(X) = m_1(\Theta)m_2(X) = 0.09, \\ m_{1,2}^{DS}(\Theta) &= m_{1,2}^{PCR5/6}(\Theta) = m_1(\Theta)m_2(\Theta) = 0.01. \end{aligned}$$

When  $X \rightarrow \Theta$ ,  $m_2(\cdot)$  tends to become a fully ignorant source of evidence, and the combination of  $m_1(\cdot)$  with  $m_2(\cdot)$  tends towards  $m_1(\cdot)$  because  $m_2(\cdot)$  brings none useful information at all in this limit case. This behavior of conjunctive rule is then conform with what we intuitively expect. However, when  $|X|$  decreases from  $r = 10$  to  $r = 2$ , the behavior of conjunctive rule (and in this case DS and PCR6 rules also) is not very satisfactory, because we obtain same results on the mass of  $A_1$  whatever the cardinality of  $X$  is. In fact, it is rather intuitively expected that after the combination, the mass of  $A_1$  should substantially increase if the cardinality of  $X$  decreases because  $m_2(\cdot)$  becomes more and more specific (and focused towards  $A_1$ ). When  $m_2(\cdot)$  is more in agreement with  $m_1(\cdot)$ , the combination of  $m_1(\cdot)$  with  $m_2(\cdot)$  should reinforce the belief on  $A_1$  when  $|X|$  decreases, which is not what happens with the pure (strict) conjunctive rule.

Let's examine how ZCR, JCR rules work in this example. Let  $|X| = r \geq 1$ , and  $r \leq 10$ . Also  $|\Theta| = |A_1 \cup A_2 \cup \dots \cup A_{10}| = 10$ . If we compute the (unnormalized) discounted conjunctive fusion with Zhang's degree of intersection, we get

$$\begin{aligned} m_{1,2}^Z(A_1) &= \frac{|A_1 \cap X|}{|A_1| \cdot |X|} m_1(A_1)m_2(X) + \frac{|A_1 \cap \Theta|}{|A_1| \cdot |\Theta|} m_1(A_1)m_2(\Theta) \\ &= \frac{1}{r}(0.9)(0.9) + \frac{1}{10}(0.9)(0.1) = \frac{0.81}{r} + 0.009, \\ m_{1,2}^Z(X) &= \frac{|\Theta \cap X|}{|\Theta| \cdot |X|} m_1(\Theta)m_2(X) = \frac{1}{10}(0.1)(0.9) = 0.009, \\ m_{1,2}^Z(\Theta) &= \frac{|\Theta \cap \Theta|}{|\Theta| \cdot |\Theta|} m_1(\Theta)m_2(\Theta) = \frac{1}{10}(0.1)(0.1) = 0.001. \end{aligned}$$

If we compute the (unnormalized) discounted conjunctive fusion with Jaccard's degree of intersection, we get

$$\begin{aligned} m_{1,2}^J(A_1) &= \frac{|A_1 \cap X|}{|A_1 \cup X|} m_1(A_1)m_2(X) + \frac{|A_1 \cap \Theta|}{|A_1 \cup \Theta|} m_1(A_1)m_2(\Theta) \\ &= \frac{1}{r}(0.9)(0.9) + \frac{1}{10}(0.9)(0.1) = \frac{0.81}{r} + 0.009, \\ m_{1,2}^J(X) &= \frac{|\Theta \cap X|}{|\Theta \cup X|} m_1(\Theta)m_2(X) = \frac{r}{10}(0.1)(0.9) = 0.009 \cdot r, \\ m_{1,2}^J(\Theta) &= \frac{|\Theta \cap \Theta|}{|\Theta \cup \Theta|} m_1(\Theta)m_2(\Theta) = \frac{10}{10}(0.1)(0.1) = 0.01. \end{aligned}$$

After normalization of  $m_{1,2}^Z(\cdot)$  by  $K_{1,2}^Z = \frac{0.81}{r} + 0.019$ , and  $m_{1,2}^J(\cdot)$  by  $K_{1,2}^J = \frac{0.81}{r} + 0.009 \cdot r + 0.010$  we get the result

of ZCR and JCR rules, which are

$$\begin{aligned} m_{1,2}^{ZCR}(A_1) &= [\frac{0.81}{r} + 0.009]/K_{1,2}^Z, & m_{1,2}^{JCR}(A_1) &= [\frac{0.81}{r} + 0.009]/K_{1,2}^J, \\ m_{1,2}^{ZCR}(X) &= 0.009/K_{1,2}^Z, & m_{1,2}^{JCR}(X) &= 0.009 \cdot r/K_{1,2}^J, \\ m_{1,2}^{ZCR}(\Theta) &= 0.001/K_{1,2}^Z, & m_{1,2}^{JCR}(\Theta) &= 0.01/K_{1,2}^J. \end{aligned}$$

In the limit case when  $r = 1$  we get

$$\begin{aligned} m_{1,2}^{ZCR}(A_1) &= 0.988, & m_{1,2}^{JCR}(A_1) &= 0.988, \\ m_{1,2}^{ZCR}(\Theta) &= 0.012, & m_{1,2}^{JCR}(\Theta) &= 0.012. \end{aligned}$$

In the limit case when  $r = 10$  we get

$$\begin{aligned} m_{1,2}^{ZCR}(A_1) &= 0.90, & m_{1,2}^{JCR}(A_1) &= 0.4337, \\ m_{1,2}^{ZCR}(\Theta) &= 0.10, & m_{1,2}^{JCR}(\Theta) &= 0.5263. \end{aligned}$$

Clearly, one sees that both ZCR and JCR have now a good expected behavior when  $|X|$  decreases, but only ZCR provides also a good behavior when  $r = 10$  because in this case one gets  $m_{1,2}^{ZCR}(\cdot) = m_1(\cdot)$  which is normal because  $m_2(\cdot)$  is the VBA (fully ignorant source). With JCR, the result we obtain when  $|X| = r = 10$  is not good because  $m_{1,2}^{ZCR}(\cdot) \neq m_1(\cdot)$ . Because there is no conflict, ZPCR6 rule coincides with ZCR rule in this example, and JPCR6 rule coincides with JCR rule. Therefore, JPCR6 rule does not work well (at least for this example) as explained previously. The evaluation of masses of  $A_1$  and of  $\Theta$  after the combination of  $m_1(\cdot)$  with  $m_2(\cdot)$  for the different rules is shown in Fig. 1 and Fig. 2 respectively and for different values of  $r = |X|$ .

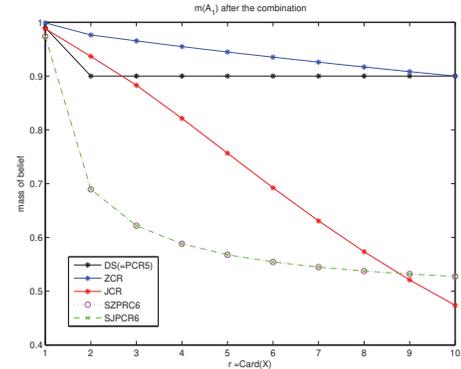

Figure 1.  $m(A_1)$  after combination of  $m_1(\cdot)$  with  $m_2(\cdot)$ .

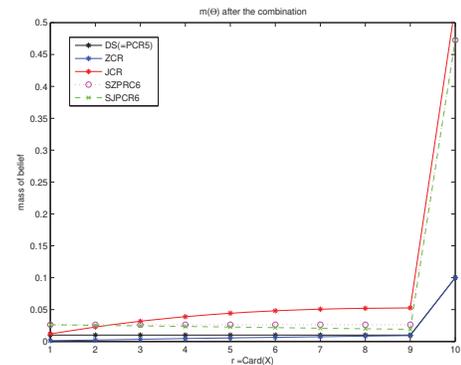

Figure 2.  $m(\Theta)$  after combination of  $m_1(\cdot)$  with  $m_2(\cdot)$ .

If we apply sophisticate normalization procedures we obtain<sup>10</sup> with SZPCR6 and SJPCR6

$$\begin{aligned} m_{1,2}^{SZPCR6}(A_1) &= 0.0819 + 0.81 \cdot \frac{1}{r} + 0.405 \cdot \frac{r-1}{r}, \\ m_{1,2}^{SZPCR6}(X) &= 0.0819 + 0.405 \cdot \frac{r-1}{r}, \\ m_{1,2}^{SZPCR6}(\Theta) &= 0.0262, \end{aligned}$$

$$\begin{aligned} m_{1,2}^{SJPCR6}(A_1) &= 0.0819 + 0.81 \cdot \frac{1}{r} + 0.405 \cdot \frac{r-1}{r}, \\ m_{1,2}^{SJPCR6}(X) &= 0.009 \cdot r + 0.405 \cdot \frac{r-1}{r} + (10-r) \cdot 0.0081, \\ m_{1,2}^{SJPCR6}(\Theta) &= 0.0181 + (10-r) \cdot 0.0081. \end{aligned}$$

In the limit case, when  $r = 1$  we get

$$\begin{aligned} m_{1,2}^{SZPCR6}(A_1) &= 0.9738, & m_{1,2}^{SJPCR6}(A_1) &= 0.9738, \\ m_{1,2}^{SZPCR6}(\Theta) &= 0.0262, & m_{1,2}^{SJPCR6}(\Theta) &= 0.0262. \end{aligned}$$

In the limit case, when  $r = 10$  we get

$$\begin{aligned} m_{1,2}^{SZPCR6}(A_1) &= 0.5274, & m_{1,2}^{SJPCR6}(A_1) &= 0.5274, \\ m_{1,2}^{SZPCR6}(\Theta) &= 0.4726, & m_{1,2}^{SJPCR6}(\Theta) &= 0.4726. \end{aligned}$$

This result shows clearly that SZPCR6 and SJPCR6 rules behave better than conjunctive rule (and so better than DS and PCR6 rules) in the limit case when  $X = A_1$  because after the combination the mass committed to  $A_1$  is reinforced (as it is naturally expected). But the reinforcement of mass of  $A_1$  is lower than with ZPCR6 or JPCR6 rules<sup>11</sup> based on simple normalization because the sophisticate normalization procedure degrades the specificity of the information. In the other limit case when  $r = 10$ , (i.e.  $X = \Theta$ , and  $m_2(\cdot)$  equals the VBA) SZPCR6 and SJPCR6 rules do not work well because clearly one has  $m_{1,2}^{SZPCR6}(\cdot) \neq m_1(\cdot)$  and  $m_{1,2}^{SJPCR6}(\cdot) \neq m_1(\cdot)$  also. So we at least have shown one example where SZPCR6 and SJPCR6 are not very efficient and consequently, we do not recommend to use them. In summary, only ZCR and ZPCR6 (equivalent to ZCR in this example) allow to get an acceptable behavior for combining the two BBA's  $m_1(\cdot)$  and  $m_2(\cdot)$  for any focal element  $X \supseteq A_1$ .

### Example 2 (Zadeh [10], [12]): (Conflicting case)

Let's  $\Theta = \{A, B, C\}$  with Shafer's model, and the two BBA's to combine  $m_1(A) = 0.9$ ,  $m_1(C) = 0.1$ ,  $m_2(B) = 0.9$  and  $m_2(C) = 0.1$ .

In this case, Shafer's conflict is  $m_{1,2}(\emptyset) = m_1(A)(m_2(B) + m_2(C)) + m_1(C)m_2(B) = 0.9 + 0.1 \cdot 0.9 = 0.99$ . If we use DS rule (2), we get  $m_{1,2}^{DS}(C) = 1$ . The discounted conjunctive consensus  $D(C, C)m_1(C)m_2(C)$  (with Zhang's or Jaccard's degree) is always equal to the un-discounted conjunctive consensus  $m_1(C)m_2(C) = 0.01$  because  $D^Z(C, C) = \frac{|C \cap C|}{|C| \cdot |C|} = 1$  and  $D^J(C, C) = \frac{|C \cap C|}{|C \cup C|} = 1$ . Therefore the degree of intersection does not impact the conjunctive combination result

<sup>10</sup>Here there is no conflicting mass to redistribute which makes the derivation more easier.

<sup>11</sup>which coincide here with ZCR and JCR rule because there is no conflicting mass to redistribute.

and ZCR and JCR rules (4) give same counter-intuitive result as DS rule, that is  $m_{1,2}^{ZCR}(C) = m_{1,2}^{JCR}(C) = m_{1,2}^{DS}(C) = 1$ .

Because the degree of intersection does not impact the conjunctive combination part of PCR6 rule in this example, modified PCR6 rules (ZPCR6, JPCR6, SZPCR6 and SJPCR6) give the same result as PCR6 rule which is  $m_{1,2}^{PCR5/6}(A) = 0.486$ ,  $m_{1,2}^{PCR5/6}(B) = 0.486$  and  $m_{1,2}^{PCR5/6}(C) = 0.028$ .

In summary, ZCR and JCR rules do not help to modify the result obtained by DS rule in Zadeh's example and cannot be viewed as real alternatives to DS rule for this example. Conversely, ZPCR6, JPCR6, SZPCR6 and SJPCR6 rule (which coincide with PCR6 rule in this example) remain good alternatives to DS rule.

### Example 3 (Voorbraak [15]): (Conflicting case)

Let's consider the FoD  $\Theta = \{A, B, C\}$  with Shafer's model, and the following two BBA's to combine  $m_1(A) = 0.5$ ,  $m_1(B \cup C) = 0.5$ ,  $m_2(C) = 0.5$ , and  $m_2(A \cup B) = 0.5$ .

One has  $m_{1,2}(\emptyset) = m_1(A)m_2(C) = 0.25$ , and DS rule gives  $m_{1,2}^{DS}(A) = m_{1,2}^{DS}(B) = m_{1,2}^{DS}(C) = 1/3$ . As reported by Voorbraak [15], this result is counterintuitive, since intuitively  $B$  seems to *share* twice a probability mass of 0.5, while both  $A$  and  $C$  only have to share once 0.5 with  $B$  and are once assigned 0.5 individually. This counterintuitive result comes from the fact that DS rule implicitly assumes that all possible pairs of focal elements are equally confirmed by the combined evidence, while intuitively, in this example  $B = (B \cup C) \cap (A \cup B)$  is less confirmed than  $A = A \cap (A \cup B)$  and  $C = (B \cup C) \cap C$ . With ZCR and JCR rules, we get

$$\begin{aligned} m_{1,2}^{ZCR}(A) &= 0.40, & m_{1,2}^{JCR}(A) &= 0.375, \\ m_{1,2}^{ZCR}(B) &= 0.20, & m_{1,2}^{JCR}(B) &= 0.250, \\ m_{1,2}^{ZCR}(C) &= 0.40, & m_{1,2}^{JCR}(C) &= 0.375. \end{aligned}$$

Contrarily to DS rule, with ZCR or JCR rules one sees that the mass committed to  $B$  is less than of  $A$  and of  $C$  which is a more reasonable result. In applying PCR6 rule, we also circumvent this problem because we get from Eq. (13),  $m_{1,2}^{PCR6}(A) = 0.375$ ,  $m_{1,2}^{PCR6}(B) = 0.25$  and  $m_{1,2}^{PCR6}(C) = 0.375$  (same as with JCR results for this particular example).

With ZPCR6 rule, we compute at first the following (un-normalized) discounted conjunctive masses added with proportional conflict redistribution

$$\begin{aligned} m_{1,2}^Z(A) &= \frac{|A \cap (A \cup B)|}{|A| \cdot |A \cup B|} m_1(A)m_2(A \cup B) + \frac{1}{2} m_{1,2}(\emptyset) = 0.25, \\ m_{1,2}^Z(B) &= \frac{|(B \cup C) \cap (A \cup B)|}{|B \cup C| \cdot |A \cup B|} m_1(B \cup C)m_2(A \cup B) = 0.0625, \\ m_{1,2}^Z(C) &= \frac{|(B \cup C) \cap C|}{|B \cup C| \cdot |C|} m_1(B \cup C)m_2(C) + \frac{1}{2} m_{1,2}(\emptyset) = 0.25. \end{aligned}$$

After a simple normalization (dividing by  $K_{1,2}^Z = 0.25 + 0.0625 + 0.25 = 0.5625$ ), we get finally

$$\begin{aligned} m_{1,2}^{ZPCR6}(A) &= 0.25/0.5625 \approx 0.4444, \\ m_{1,2}^{ZPCR6}(B) &= 0.0625/0.5625 \approx 0.1112, \\ m_{1,2}^{ZPCR6}(C) &= 0.25/0.5625 \approx 0.4444. \end{aligned}$$

Similarly, if we apply JPCR6 rule based on Jaccard's index and simple normalization step, we will get the following result

$$\begin{aligned} m_{1,2}^{JPCR6}(A) &= [(0.25/2) + 0.125]/K_{1,2}^J \approx 0.4286, \\ m_{1,2}^{JPCR6}(B) &= (0.25/3)/K_{1,2}^J = 0.1428, \\ m_{1,2}^{JPCR6}(C) &= [(0.25/2) + 0.125]/K_{1,2}^J \approx 0.4286, \end{aligned}$$

where the normalization factor equals  $K_{1,2}^J = (0.25/2) + 0.125 + (0.25/3) + (0.25/2) + 0.125 \approx 0.5833$ .

These results show that ZPCR6 and JPCR6 rules diminish substantially the mass committed to  $B$  (as expected) and reinforce more strongly the masses of  $A$  and  $C$  than with ZCR, JCR or PCR6 rules.

If we apply the sophisticate normalization for SZPCR6, the lost discounted mass  $(1 - \frac{|A \cap (A \cup B)|}{|A| \cdot |A \cup B|})m_1(A)m_2(A \cup B) = 0.125$  is redistributed to  $A$  and to  $A \cup B$  proportionally<sup>12</sup> to  $m_1(A) = 0.5$  and  $m_2(A \cup B) = 0.5$ . Similarly, the second lost discounted mass  $(1 - \frac{|B \cup C \cap (A \cup B)|}{|B \cup C| \cdot |A \cup B|})m_1(B \cup C)m_2(A \cup B) = 0.1875$  is redistributed to  $B \cup C$  and to  $A \cup B$  proportionally to  $m_1(B \cup C) = 0.5$  and  $m_2(A \cup B) = 0.5$ , and the third lost discounted mass  $(1 - \frac{|B \cup C \cap C|}{|B \cup C| \cdot |C|})m_1(B \cup C)m_2(C) = 0.125$  is redistributed to  $B \cup C$  and to  $C$  proportionally to  $m_1(B \cup C) = 0.5$  and  $m_2(C) = 0.5$ . Similar computations are done for SJPCR6 in replacing Zhang's degree by Jaccard's degree of intersection. Finally we obtain with SZPCR6 and SJPCR6 the following combined masses:

$$\begin{aligned} m_{1,2}^{SZPCR6}(A) &= 0.3125, & m_{1,2}^{SZPCR6}(A \cup B) &= 0.15625, \\ m_{1,2}^{SZPCR6}(B) &= 0.0625, & m_{1,2}^{SZPCR6}(B \cup C) &= 0.15625, \\ m_{1,2}^{SZPCR6}(C) &= 0.3125, \end{aligned}$$

and

$$\begin{aligned} m_{1,2}^{SJPCR6}(A) &= 0.3125, & m_{1,2}^{SJPCR6}(A \cup B) &\approx 0.14585, \\ m_{1,2}^{SJPCR6}(B) &\approx 0.0833, & m_{1,2}^{SJPCR6}(B \cup C) &\approx 0.14585, \\ m_{1,2}^{SJPCR6}(C) &= 0.3125. \end{aligned}$$

Of course, these results are a bit less specific than with ZPCR6 and JPCR6, which is normal. As shown, SZPCR6 and SJPCR6 rules diminish also the mass committed to  $B$  (as expected) but reinforce less strongly the masses of  $A$  and  $C$  because the specificity of the result is degraded because one gets positive masses committed to new uncertainties  $A \cup B$  and  $B \cup C$ . For this example, ZPCR6 and JPCR6 are the most interesting rules for combining BBA's  $m_1(\cdot)$  and  $m_2(\cdot)$ .

<sup>12</sup>equally in fact in this case.

#### Example 4 (Dezert et al. [3]): (Conflicting case)

This emblematic example is very interesting to analyze because for in this case the DS rule does not respond to level of conflict between the sources. This *anomaly* has been analyzed and discussed in details in [3].

Let's consider the FoD  $\Theta = \{A, B, C\}$  with Shafer's model, and the following two BBA's to combine

$$\begin{aligned} m_1(A) &= 0.9, & m_1(A \cup B) &= 0.1, & m_2(A \cup B) &= 0.1, \\ m_2(C) &= 0.7, & m_2(A \cup B \cup C) &= 0.2. \end{aligned}$$

In this example, the two sources are not vacuous (they are truly informative), they are in conflict because  $m_{1,2}(\emptyset) = 0.7$  but DS rule does not respond to the level of conflict because one gets  $m_{1,2}(\cdot) = m_1(\cdot)$ . In fact, the second source has no impact in the DS fusion as if it is equivalent to the VBA.

If we apply PCR6 rule of combination the first partial conflict  $m_1(A)m_2(C) = 0.72$  is redistributed to  $A$  and  $C$  proportionally to  $m_1(A)$  and  $m_2(C)$ , and the second conflict  $m_1(A \cup B)m_2(C) = 0.08$  is redistributed to  $A \cup B$  and to  $C$  proportionally to  $m_1(A \cup B)$  and  $m_2(C)$ . So with PCR6 rule (7), we obtain  $m_{1,2}^{PCR6}(A) = 0.6244$ ,  $m_{1,2}^{PCR6}(A \cup B) = 0.0388$  and  $m_{1,2}^{PCR6}(C) = 0.3369$ . One sees that the PCR6 fusion result now reacts with the value of second sources because  $m_{1,2}^{PCR6}(\cdot) \neq m_1(\cdot)$  which makes sense if both sources are equireliable, truly informative and in some disagreement.

In discounting with Zhang's degree, one gets the (unnormalized) discounted conjunctive BBA

$$\begin{aligned} m_{1,2}^Z(A) &= \frac{1}{2}(0.9)(0.1) + \frac{1}{3}(0.9)(0.2) = 0.1050, \\ m_{1,2}^Z(A \cup B) &= \frac{2}{2 \cdot 2}(0.1)(0.1) + \frac{2}{2 \cdot 3}(0.1)(0.2) \approx 0.0117. \end{aligned}$$

After the normalization by the factor  $K_{1,2}^Z = 0.1050 + 0.0117 = 0.1167$ , we get finally  $m_{1,2}^{ZCR}(A) = 0.1050/0.1167 \approx 0.9$  and  $m_{1,2}^{ZCR}(A \cup B) \approx 0.0117/0.1167 \approx 0.1$ . Therefore as with DS rule, we get same behavior with ZCR rule that is  $m_{1,2}^{ZCR}(\cdot) = m_1(\cdot)$  as if the second informative source does not count in the fusion process, which is abnormal.

If we use Jaccard's degree, one gets

$$\begin{aligned} m_{1,2}^J(A) &= \frac{1}{2}(0.9)(0.1) + \frac{1}{3}(0.9)(0.2) = 0.1050, \\ m_{1,2}^J(A \cup B) &= \frac{2}{2}(0.1)(0.1) + \frac{2}{3}(0.1)(0.2) \approx 0.0233. \end{aligned}$$

After the normalization by the factor  $K_{1,2}^J = 0.1050 + 0.0233 = 0.12833$ , we get finally  $m_{1,2}^{JCR}(A) \approx 0.8182$  and  $m_{1,2}^{JCR}(A \cup B) \approx 0.1818$ . One sees that JCR fusion result is not equal to the BBA  $m_1(\cdot)$ , which means that  $m_2(\cdot)$  has had some impact in the fusion process with JCR (as expected). However, it is not clear why such JCR result will really make sense or not. Because we have already shown in Example 1, that it can happen than JCR does not work well, we have serious

doubt on the interest of using JCR result in such emblematic example.

With ZPCR6 rule of combination, we obtain  $m_{1,2}^{ZPCR6}(A) = \frac{1}{K_{1,2}^{ZPCR6}}[0.1050 + x(A)] = 0.56250$ ,  $m_{1,2}^{ZPCR6}(A \cup B) = \frac{1}{K_{1,2}^{ZPCR6}}[0.0117 + x(A \cup B)] = 0.0250$ , and  $m_{1,2}^{ZPCR6}(C) = \frac{1}{K_{1,2}^{ZPCR6}}[x_1(C) + x_2(C)] = 0.4125$ , where  $K_{1,2}^{ZPCR6}$  is the normalization constant, and where  $x(A) = m_1(A) \frac{m_1(A)m_2(C)}{m_1(A)+m_2(C)} = 0.354375$  is the part of the conflicting mass  $m_1(A)m_2(C) = 0.63$  transferred to  $A$ ;  $x_1(C) = m_1(C) \frac{m_1(A)m_2(C)}{m_1(A)+m_2(C)} = 0.275625$  is the part of the conflicting mass  $m_1(A)m_2(C) = 0.63$  transferred to  $C$ ;  $x(A \cup B) = m_1(A \cup B) \frac{m_1(A \cup B)m_2(C)}{m_1(A \cup B)+m_2(C)} = 0.00875$  is the part of the conflicting mass  $m_1(A \cup B)m_2(C) = 0.07$  transferred to  $A \cup B$ ; and  $x_2(C) = m_1(C) \frac{m_1(A \cup B)m_2(C)}{m_1(A \cup B)+m_2(C)} = 0.06125$  is the part of the conflicting mass  $m_1(A \cup B)m_2(C) = 0.07$  transferred to  $C$ .

With JPCR6 rule of combination, we obtain  $m_{1,2}^{JPCR6}(A) \approx 0.55458$ ,  $m_{1,2}^{JPCR6}(A \cup B) = 0.03873$  and  $m_{1,2}^{JPCR6}(C) = 0.40669$ , which is close to ZPCR6 result. Comparatively to PCR6, we diminish the mass of belief committed to  $A$  and to  $A \cup B$  and we reinforce the mass committed to  $C$  using ZPCR6 and JPCR6 rules. We do not give results with SZPCR6 and SJPCR6 due to space constraint and because we know that these rules do not perform so well as shown in the previous examples.

**Example 5 (Sebbak [16]):** (Conflicting case with 3 sources)

Let's consider the FoD  $\Theta = \{A, B, C\}$  with Shafer's model, and the following three BBA's to combine

$$\begin{aligned} m_1(A) &= 0.8, & m_1(A \cup B \cup C) &= 0.2, \\ m_2(A) &= 0.1, & m_2(C) &= 0.9, \\ m_3(A) &= 0.4, & m_3(A \cup B \cup C) &= 0.6. \end{aligned}$$

The conjunctive rule gives

$$\begin{aligned} m_{1,2,3}(A) &= m_1(A)m_2(A)m_3(A) + m_1(A)m_2(A)m_3(\Theta) \\ &\quad + m_1(\Theta)m_2(A)m_3(\Theta) + m_1(\Theta)m_2(A)m_3(A) = 0.10 \\ m_{1,2,3}(C) &= m_1(\Theta)m_2(C)m_3(\Theta) = 0.108 \end{aligned}$$

with the total conflicting mass

$$\begin{aligned} m_{1,2,3}(\emptyset) &= m_1(A)m_2(C)m_3(A) + m_1(A)m_2(C)m_3(\Theta) \\ &\quad + m_1(\Theta)m_2(C)m_3(A) = 0.792. \end{aligned}$$

With DS rule we get  $m_{12}^{DS}(A) \approx 0.4808$  and  $m_{12}^{DS}(C) \approx 0.5192$ , and With PCR5 and PCR6 rules [17]

$$\begin{aligned} m_{1,2,3}^{PCR5}(A) &= 0.3450, & m_{1,2,3}^{PCR6}(A) &= 0.4340, \\ m_{1,2,3}^{PCR5}(C) &= 0.5327, & m_{1,2,3}^{PCR6}(C) &= 0.4437, \\ m_{1,2,3}^{PCR5}(\Theta) &= 0.1223, & m_{1,2,3}^{PCR6}(\Theta) &= 0.1223. \end{aligned}$$

Note that with PCR5 one gets  $0.4247/0.7920 \approx 53.62\%$  of the total conflicting mass redistributed to  $C$ , but not *almost all conflicting mass*. Using PCR6,  $C$  actually gained from the total conflicting mass only  $0.3357/0.7920 \approx 42.3864\%$ , not even

half of it, not *almost all of the conflicting mass (the majority)* as the authors wrongly claimed in [16].

With ZCR and JCR rules, one gets

$$\begin{aligned} m_{1,2,3}^{ZCR}(A) &= 0.8125, & m_{1,2,3}^{JCR}(A) &= 0.6032, \\ m_{1,2,3}^{ZCR}(\Theta) &= 0.1875, & m_{1,2,3}^{JCR}(\Theta) &= 0.3968. \end{aligned}$$

With ZPCR6, JPCR6, SZPCR6 and SJPCR6 rules<sup>13</sup> one gets

$$\begin{aligned} m_{1,2,3}^{ZPCR6}(A) &= 0.4511, & m_{1,2,3}^{JPCR6}(A) &= 0.4405, \\ m_{1,2,3}^{ZPCR6}(C) &= 0.4061, & m_{1,2,3}^{JPCR6}(C) &= 0.4210, \\ m_{1,2,3}^{ZPCR6}(\Theta) &= 0.1428, & m_{1,2,3}^{JPCR6}(\Theta) &= 0.1385. \\ m_{1,2,3}^{SZPCR6}(A) &= 0.4102955, & m_{1,2,3}^{SJPCR6}(A) &= 0.412699, \\ m_{1,2,3}^{SZPCR6}(C) &= 0.3984240, & m_{1,2,3}^{SJPCR6}(C) &= 0.409718, \\ m_{1,2,3}^{SZPCR6}(\Theta) &= 0.1912805, & m_{1,2,3}^{SJPCR6}(\Theta) &= 0.177616. \end{aligned}$$

One sees that  $C$  gained  $(0.4061 - 0.108)/0.7920 \approx 37.64\%$  using ZPCR6,  $(0.4210 - 0.108)/0.7920 \approx 39.52\%$  using JPCR6,  $(0.398424 - 0.108)/0.7920 \approx 36.67\%$  using SZPCR6, and  $(0.409718 - 0.108)/0.7920 \approx 38.10\%$  using SJPCR6.

## VI. CONCLUSIONS

The modifications of the PCR6 rule of combination presented exploit judiciously Zhang's and Jaccard's degrees of intersections of focal elements. Our analysis shows that ZPCR6 rule is in fact the most interesting modified PCR6 rule because it behaves well in all emblematic examples contrarily to other rules. SZPCR6 and SJPCR6 rules are more complicate to implement and they increase the non-specificity of the result in general which is not good for helping the decision-making. So we do not recommend them for applications. All these rules are not associative and do not preserve the neutrality of VBA when some sources are in conflict.

**Abstract**—In many applications involving epistemic uncertainties usually modeled by belief functions, it is often necessary to approximate general (non-Bayesian) basic belief assignments (BBAs) to subjective probabilities (called Bayesian BBAs). This necessity occurs if one needs to embed the fusion result in a system based on the probabilistic framework and Bayesian inference (e.g. tracking systems), or if one wants to use classical decision theory to make a decision. There exists already several methods (probabilistic transforms) to approximate any general BBA to a Bayesian BBA. From a fusion standpoint, two approaches are usually adopted: 1) one can approximate at first each BBA in subjective probabilities and use Bayes fusion rule to get the final Bayesian BBA, or 2) one can fuse all the BBAs with a fusion rule, typically Dempster-Shafer's, or PCR6 rules (which is very costly in computations), and convert the combined BBA in a subjective probability measure. The former method is the simplest method but it generates a high loss of information included in original BBAs, whereas the latter is intractable for high dimension problems. This paper presents a new method to achieve this task based on hierarchical decomposition (coarsening) of the frame of discernment, which can be seen as an intermediary approach between the two aforementioned methods. After the presentation of this new method, we show through simulations how it performs with respect to other methods.

**Keywords:** Information fusion, belief functions, DST, DSMT, PCR6 rule, coarsening.

## I. INTRODUCTION

The theory of belief functions, known as Dempster-Shafer Theory (DST) has been developed by Shafer [1] in 1976 from Dempster's works [2]. Belief functions allow to model epistemic uncertainty and they have been already used in many applications since the 1990's [3], mainly those related to expert systems, decision-making support and information fusion. To palliate some limitations of DST, Dezert and Smarandache have proposed an extended mathematical framework of belief functions with new efficient quantitative and qualitative rules of combinations, which is called DSMT (Dezert and Smarandache Theory) in the literature [4], [5] with applications listed in [6]. One of the major drawbacks of DST and DSMT is their high computational complexities, as soon as the fusion space (i.e. frame of discernment - FoD) and the number of sources to combine are large<sup>1</sup>.

<sup>1</sup>DSMT is more complex than DST, and the Proportional Conflict Redistribution rule #6 (PCR6 rule) becomes computationally intractable in the worst case as soon as the frame of discernment has at least six elements.

To reduce the computational cost of operations with belief functions when the number of focal elements is very large, several approaches have been proposed by different authors. Basically, the existing approaches rely either on efficient implementations of computations as proposed for instance in [7], [8], or on approximation techniques of original Basic Belief Assignment (BBA) to combine [9]–[12], or both. In many applications involving epistemic uncertainties usually modeled by belief functions, it is often necessary to approximate general (non-Bayesian) basic belief assignments (BBAs) to subjective probabilities (called Bayesian BBAs). This necessity occurs if one needs to embed the fusion result in a system based on the probabilistic framework and Bayesian inference (e.g. tracking systems), or if one wants to use classical decision theory to make a decision. From a fusion standpoint, two approaches are usually adopted: 1) one can approximate at first each BBA in subjective probabilities and use Bayes fusion rule to get the final Bayesian BBA, or 2) one can fuse all the BBAs with a fusion rule, typically Dempster-Shafer's, or PCR6 rules (which is very costly in computations), and convert the combined BBA in a subjective probability measure. The former method is the simplest method but it generates a high loss of information included in original BBAs, whereas the latter direct method is intractable for high dimension problems. This paper presents a new method to achieve this task based on hierarchical decomposition (coarsening) of the frame of discernment, which can be seen as an intermediary approach between the two aforementioned methods.

This paper presents a new approach to fuse BBAs into a Bayesian BBA in order to reduce computational burden and keep the fusion tractable even for large dimension problems. This method is based on a hierarchical decomposition (coarsening) framework which allows to keep as much as possible information of original BBAs in preserving lower complexity. The main contributions of this paper are:

- 1) the presentation of the FoD bintree decomposition on which will be done the BBAs approximations;
- 2) the presentation of the fusion of approximate BBAs from bintree representation.

This hierarchical structure allows to encompass bintree decomposition and BBAs approximations on it to obtain the

final approximate fused Bayesian BBA.

This paper is organized as follows. In section II, we recall some basics of DST and DSMT that are relevant to the new method presented in this paper. More details with examples can easily be found in [1], [5]. We will also briefly recall our preliminary works about hierarchical coarsening of FoD. Section III presents the novel hierarchical flexible (adaptive) coarsening method which can be regarded as the extension of our previous works. Two simple examples are given in section IV to illustrate the detailed calculation steps. Simulation experiments are presented in section V to show the rationality of this new approach. Finally, Sect.VI concludes the paper with future works perspectives.

## II. MATHEMATICAL BACKGROUND

This section provides a brief reminder of basics of DST and DSMT, and of original hierarchical coarsening method which are necessary for the presentation and the understanding of the more general flexible coarsening approximate method of section III.

### A. Basics of DST and DSMT

In DST framework, the frame of discernment<sup>2</sup>  $\Theta \triangleq \{\theta_1, \dots, \theta_n\}$  ( $n \geq 2$ ) is a set of exhaustive and exclusive elements (hypotheses) which represent the possible solutions of the problem under consideration and thus Shafer's model assumes  $\theta_i \cap \theta_j = \emptyset$  for  $i \neq j$  in  $\{1, \dots, n\}$ . A basic belief assignment (BBA)  $m(\cdot)$  is defined by the mapping:  $2^\Theta \mapsto [0, 1]$ , verifying  $m(\emptyset) = 0$  and  $\sum_{A \in 2^\Theta} m(A) = 1$ . In DSMT, one can abandon Shafer's model (if Shafer's model doesn't fit with the problem) and refute the principle of the third excluded middle<sup>3</sup>. Instead of defining the BBAs on the power set  $2^\Theta \triangleq (\Theta, \cup)$  of the FoD, the BBAs are defined on the so-called *hyper-power set* (or Dedekind's lattice) denoted  $D^\Theta \triangleq (\Theta, \cup, \cap)$  whose cardinalities follows Dedekind's numbers sequence, see [5], Vol.1 for details and examples. A (generalized) BBA, called a mass function,  $m(\cdot)$  is defined by the mapping:  $D^\Theta \mapsto [0, 1]$ , verifying  $m(\emptyset) = 0$  and  $\sum_{A \in D^\Theta} m(A) = 1$ . DSMT framework encompasses DST framework because  $2^\Theta \subset D^\Theta$ . In DSMT we can take into account also a set of *integrity constraints* on the FoD (if known), by specifying all the pairs of elements which are really disjoint. Stated otherwise, Shafer's model is a specific DSMT model where all elements are known to be disjoint.  $A \in D^\Theta$  is called a focal element of  $m(\cdot)$  if  $m(A) > 0$ . A BBA is called a Bayesian BBA if all of its focal elements are singletons and Shafer's model is assumed, otherwise it is called non-Bayesian [1]. A full ignorance source is represented by the vacuous BBA  $m_v(\Theta) = 1$ . The belief (or credibility) and plausibility functions are respectively defined by  $Bel(X) \triangleq \sum_{Y \in D^\Theta | Y \subseteq X} m(Y)$  and  $Pl(X) \triangleq \sum_{Y \in D^\Theta | Y \cap X \neq \emptyset} m(Y)$ .  $BI(X) \triangleq [Bel(X), Pl(X)]$  is called the belief interval of

$X$ . Its length  $U(X) \triangleq Pl(X) - Bel(X)$  measures the degree of uncertainty of  $X$ .

In 1976, Shafer did propose Dempster's rule<sup>4</sup> to combine BBAs in DST framework. DS rule is defined by  $m_{DS}(\emptyset) = 0$  and  $\forall A \in 2^\Theta \setminus \{\emptyset\}$ ,

$$m_{DS}(A) = \frac{\sum_{B, C \in 2^\Theta | B \cap C = A} m_1(B)m_2(C)}{1 - \sum_{B, C \in 2^\Theta | B \cap C = \emptyset} m_1(B)m_2(C)}. \quad (1)$$

DS rule formula is commutative and associative and can be easily extended to the fusion of  $S > 2$  BBAs. Unfortunately, DS rule has been highly disputed during the last decades by many authors because of its counter-intuitive behavior in high or even low conflict situations, and that is why many rules of combination have been proposed in the literature to combine BBAs [13]. To palliate DS rule drawbacks, the very interesting PCR6 (Proportional Conflict redistribution rule #6) has been proposed in DSMT and it is usually adopted<sup>5</sup> in recent applications of DSMT. The fusion of two BBAs  $m_1(\cdot)$  and  $m_2(\cdot)$  by the PCR6 rule is obtained by  $m_{PCR6}(\emptyset) = 0$  and  $\forall A \in D^\Theta \setminus \{\emptyset\}$

$$m_{PCR6}(A) = m_{12}(A) + \sum_{B \in D^\Theta \setminus \{A\} | A \cap B = \emptyset} \left[ \frac{m_1(A)^2 m_2(B)}{m_1(A) + m_2(B)} + \frac{m_2(A)^2 m_1(B)}{m_2(A) + m_1(B)} \right], \quad (2)$$

where  $m_{12}(A) = \sum_{B, C \in D^\Theta | B \cap C = A} m_1(B)m_2(C)$  is the conjunctive operator, and each element  $A$  and  $B$  are expressed in their disjunctive normal form. If the denominator involved in the fraction is zero, then this fraction is discarded. The general PCR6 formula for combining more than two BBAs altogether is given in [5], Vol. 3. We adopt the generic notation  $m_{12}^{PCR6}(\cdot) = PCR6(m_1(\cdot), m_2(\cdot))$  to denote the fusion of  $m_1(\cdot)$  and  $m_2(\cdot)$  by PCR6 rule. PCR6 is not associative and PCR6 rule can also be applied in DST framework (with Shafer's model of FoD) by replacing  $D^\Theta$  by  $2^\Theta$  in Eq. (2).

### B. Hierarchical coarsening for fusion of Bayesian BBAs

Here, we briefly recall the principle of hierarchical coarsening of FoD to reduce the computational complexity of PCR6 combination of original Bayesian BBAs. The fusion of original non-Bayesian BBAs will be presented in the next section.

This principle was called *rigid grouping* in our previous works [17]–[19]. The goal of this coarsening is to replace the original (refined) Frame of Discernment (FoD)  $\Theta$  by a set of coarsened ones to make the computation of PCR6 rule tractable. Because we consider here only Bayesian BBA to combine, their focal elements are only singletons of the FoD  $\Theta \triangleq \{\theta_1, \dots, \theta_n\}$ , with  $n \geq 2$ , and we assume Shafer's model of the FoD  $\Theta$ .

A coarsening of the FoD  $\Theta$  means to replace it with another FoD less specific of smaller dimension  $\Omega = \{\omega_1, \dots, \omega_k\}$  with  $k < n$  from the elements of  $\Theta$ . This can be done in many

<sup>2</sup>We use the symbol  $\triangleq$  to mean equals by definition.

<sup>3</sup>The third excluded middle principle assumes the existence of the complement for any elements/propositions belonging to the power set  $2^\Theta$ .

<sup>4</sup>We use DS index to refer to Dempster-Shafer's rule (DS rule) because Shafer did really promote Dempster's rule in his milestone book [1].

<sup>5</sup>PCR6 rule coincides with PCR5 when combining only two BBAs [5].

ways depending the problem under consideration. Generally, the elements of  $\Omega$  are singletons of  $\Theta$ , and disjunctions of elements of  $\Theta$ . For example, if  $\Theta = \{\theta_1, \theta_2, \theta_3, \theta_4\}$ , then the possible coarsened frames built from  $\Theta$  could be, for instance,  $\Omega = \{\omega_1 = \theta_1, \omega_2 = \theta_2, \omega_3 = \theta_3 \cup \theta_4\}$ , or  $\Omega = \{\omega_1 = \theta_1 \cup \theta_2, \omega_2 = \theta_3 \cup \theta_4\}$ , etc. When dealing with Bayesian BBAs, the projection<sup>6</sup>  $m^\Omega(\cdot)$  of the original BBA  $m^\Theta(\cdot)$  is simply obtained by taking

$$m^\Omega(\omega_i) = \sum_{\theta_j \subseteq \omega_i} m^\Theta(\theta_j). \quad (3)$$

The hierarchical coarsening process (or rigid grouping) is a simple dichotomous approach of coarsening obtained as follows:

- If  $n = |\Theta|$  is an even number:

The disjunction of the  $n/2$  first elements  $\theta_1$  to  $\theta_{n/2}$  of  $\Theta$  define the element  $\omega_1$  of  $\Omega$ , and the last  $n/2$  elements  $\theta_{n/2+1}$  to  $\theta_n$  of  $\Theta$  define the element  $\omega_2$  of  $\Omega$ , that is

$$\Omega \triangleq \{\omega_1 = \theta_1 \cup \dots \cup \theta_{n/2}, \omega_2 = \theta_{n/2+1} \cup \dots \cup \theta_n\},$$

and based on (3), one has

$$m^\Omega(\omega_1) = \sum_{j=1, \dots, \frac{n}{2}} m^\Theta(\theta_j), \quad (4)$$

$$m^\Omega(\omega_2) = \sum_{j=\frac{n}{2}+1, \dots, n} m^\Theta(\theta_j). \quad (5)$$

For example, if  $\Theta = \{\theta_1, \theta_2, \theta_3, \theta_4\}$ , and one considers the Bayesian BBA  $m^\Theta(\theta_1) = 0.1$ ,  $m^\Theta(\theta_2) = 0.2$ ,  $m^\Theta(\theta_3) = 0.3$  and  $m^\Theta(\theta_4) = 0.4$ , then  $\Omega = \{\omega_1 = \theta_1 \cup \theta_2, \omega_2 = \theta_3 \cup \theta_4\}$  and  $m^\Omega(\omega_1) = 0.1 + 0.2 = 0.3$  and  $m^\Omega(\omega_2) = 0.3 + 0.4 = 0.7$ .

- If  $n = |\Theta|$  is an odd number:

In this case, the element  $\omega_1$  of the coarsened frame  $\Omega$  is the disjunction of the  $\lceil n/2 + 1 \rceil$ <sup>7</sup> first elements of  $\Theta$ , and the element  $\omega_2$  is the disjunction of other elements of  $\Theta$ . That is

$$\Omega \triangleq \{\omega_1 = \theta_1 \cup \dots \cup \theta_{\lceil n/2 + 1 \rceil}, \omega_2 = \theta_{\lceil n/2 + 1 \rceil + 1} \cup \dots \cup \theta_n\},$$

and based on (3), one has

$$m^\Omega(\omega_1) = \sum_{j=1, \dots, \lceil \frac{n}{2} + 1 \rceil} m^\Theta(\theta_j), \quad (6)$$

$$m^\Omega(\omega_2) = \sum_{j=\lceil \frac{n}{2} + 1 \rceil + 1, \dots, n} m^\Theta(\theta_j). \quad (7)$$

For example, if  $\Theta = \{\theta_1, \theta_2, \theta_3, \theta_4, \theta_5\}$ , and one considers the Bayesian BBA  $m^\Theta(\theta_1) = 0.1$ ,  $m^\Theta(\theta_2) = 0.2$ ,  $m^\Theta(\theta_3) = 0.3$ ,  $m^\Theta(\theta_4) = 0.3$  and  $m^\Theta(\theta_5) = 0.1$ , then  $\Omega = \{\omega_1 = \theta_1 \cup \theta_2 \cup \theta_3, \omega_2 = \theta_4 \cup \theta_5\}$  and  $m^\Omega(\omega_1) = 0.1 + 0.2 + 0.3 = 0.6$  and  $m^\Omega(\omega_2) = 0.3 + 0.1 = 0.4$ .

<sup>6</sup>For clarity and convenience, we put explicitly as upper index the FoD for which the belief mass refers.

<sup>7</sup>The notation  $\lceil x \rceil$  means the integer part of  $x$ .

Of course, the same coarsening applies to all original BBAs  $m_s^\Theta(\cdot)$ ,  $s = 1, \dots, S$  of the  $S > 1$  sources of evidence to work with less specific BBAs  $m_s^\Omega(\cdot)$ ,  $s = 1, \dots, S$ . The less specific BBAs (called coarsened BBAs by abuse of language) can then be combined with PCR6 rule of combination according to formula (2). This dichotomous coarsening method is repeated iteratively  $l$  times as schematically represented by a bintree<sup>8</sup>. The last step of this hierarchical process is to calculate the combined (Bayesian) BBA of all focal elements according to the connection weights of the bintree structure, where the number of iterations (or layers)  $l$  of the tree depends on the cardinality  $|\Theta|$  of the original FoD  $\Theta$ . Specifically, the assignment of each focal element is updated according to the connection weights of link paths from root to terminal nodes. This principle is illustrated in details in the following example.

**Example 1:** Let's consider  $\Theta = \{\theta_1, \theta_2, \theta_3, \theta_4, \theta_5\}$ , and the following three Bayesian BBAs

Focal elem.	$m_1^\Theta(\cdot)$	$m_2^\Theta(\cdot)$	$m_3^\Theta(\cdot)$
$\theta_1$	0.1	0.4	0
$\theta_2$	0.2	0	0.1
$\theta_3$	0.3	0.1	0.5
$\theta_4$	0.3	0.1	0.4
$\theta_5$	0.1	0.4	0

The hierarchical coarsening and fusion of BBAs is obtained from the following steps:

**Step 1:** We define the bintree structure based on iterative half split of FoD as shown in Fig. 1.

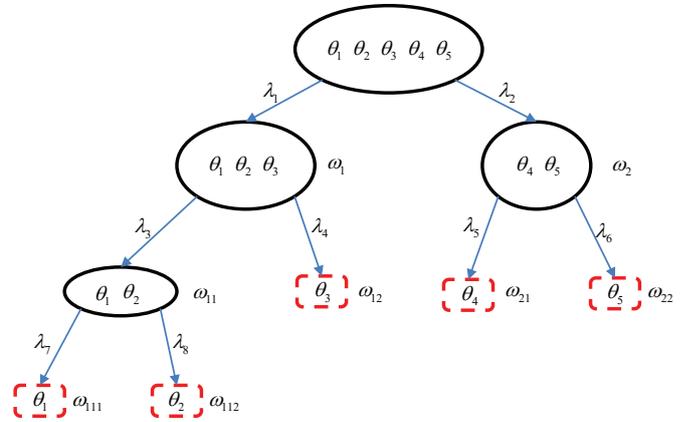

Figure 1: Fusion of Bayesian BBAs using bintree coarsening for Example 1.

The connecting weights are denoted as  $\lambda_1, \dots, \lambda_8$ . The elements of the frames  $\Omega_l$  are defined as follows:

- At layer  $l = 1$ :  $\Omega_1 = \{\omega_1 \triangleq \theta_1 \cup \theta_2 \cup \theta_3, \omega_2 \triangleq \theta_4 \cup \theta_5\}$
- At layer  $l = 2$ :

$$\Omega_2 = \{\omega_{11} \triangleq \theta_1 \cup \theta_2, \omega_{12} \triangleq \theta_3, \omega_{21} \triangleq \theta_4, \omega_{22} \triangleq \theta_5\}$$

<sup>8</sup>Here we consider bintree only for simplicity, which means that the coarsened frame  $\Omega$  consists of two elements only. Of course a similar method can be used with tri-tree, quad-tree, etc.

- At layer  $l = 3$ :  $\Omega_3 = \{\omega_{111} \triangleq \theta_1, \omega_{112} \triangleq \theta_2\}$

**Step 2:** The BBAs of elements of the (sub-)frames  $\Omega_l$  are obtained as follows:

- At layer  $l = 1$ , we use (6)-(7) because  $|\Theta| = 5$  is an odd number. Therefore, we get

Focal elem.	$m_1^{\Omega_1}(\cdot)$	$m_2^{\Omega_1}(\cdot)$	$m_3^{\Omega_1}(\cdot)$
$\omega_1 \triangleq \theta_1 \cup \theta_2 \cup \theta_3$	0.6	0.5	0.6
$\omega_2 \triangleq \theta_4 \cup \theta_5$	0.4	0.5	0.4

- At layer  $l = 2$ : We work with the two subframes  $\Omega_{21} \triangleq \{\omega_{11}, \omega_{12}\}$  and  $\Omega_{22} \triangleq \{\omega_{21}, \omega_{22}\}$  of  $\Omega_2$  with the BBAs:

Focal elem.	$m_1^{\Omega_{21}}(\cdot)$	$m_2^{\Omega_{21}}(\cdot)$	$m_3^{\Omega_{21}}(\cdot)$
$\omega_{11} \triangleq \theta_1 \cup \theta_2$	$\frac{1}{2}$	$\frac{4}{5}$	$\frac{1}{6}$
$\omega_{12} \triangleq \theta_3$	$\frac{1}{2}$	$\frac{1}{5}$	$\frac{5}{6}$

Focal elem.	$m_1^{\Omega_{22}}(\cdot)$	$m_2^{\Omega_{22}}(\cdot)$	$m_3^{\Omega_{22}}(\cdot)$
$\omega_{21} \triangleq \theta_4$	$\frac{3}{4}$	$\frac{1}{5}$	1
$\omega_{22} \triangleq \theta_5$	$\frac{1}{4}$	$\frac{4}{5}$	0

These mass values are obtained by the proportional redistribution of the mass of each focal element with respect to the mass of its parent focal element in the bin tree. For example, the value  $m_2^{\Omega_{21}}(\omega_{11}) = 4/5$  is derived by taking

$$m_2^{\Omega_{21}}(\omega_{11}) = \frac{m_2^\Theta(\theta_1) + m_2^\Theta(\theta_2)}{m_2^\Theta(\theta_1) + m_2^\Theta(\theta_2) + m_2^\Theta(\theta_3)} = \frac{0.4}{0.5} = \frac{4}{5}.$$

Other mass values are computed similarly using this proportional redistribution method.

- At layer  $l = 3$ : We use again the proportional redistribution method which gives us

Focal elem.	$m_1^{\Omega_3}(\cdot)$	$m_2^{\Omega_3}(\cdot)$	$m_3^{\Omega_3}(\cdot)$
$\omega_{111} \triangleq \theta_1$	$\frac{1}{3}$	1	0
$\omega_{112} \triangleq \theta_2$	$\frac{2}{3}$	0	1

**Step 3:** The connection weights  $\lambda_i$  are computed from the assignments of coarsening elements. In each layer  $l$ , we fuse sequentially<sup>9</sup> the three BBAs using PCR6 formula (2). More precisely, we compute at first  $m_{(12)3}^{PCR6, \Omega_1}(\cdot) = PCR6(m_1^{\Omega_1}(\cdot), m_2^{\Omega_1}(\cdot))$  and then  $m_{(12)3}^{PCR6, \Omega_2}(\cdot) = PCR6(m_{(12)3}^{PCR6, \Omega_1}(\cdot), m_3^{\Omega_2}(\cdot))$ . Hence, we obtain the following connecting weights in the bintree:

- At layer  $l = 1$ :

$$\lambda_1 = m_{(12)3}^{PCR6, \Omega_1}(\omega_1) = 0.6297,$$

$$\lambda_2 = m_{(12)3}^{PCR6, \Omega_1}(\omega_2) = 0.3703.$$

- At layer  $l = 2$ :

$$\lambda_3 = m_{(12)3}^{PCR6, \Omega_{21}}(\omega_{11}) = 0.4137,$$

$$\lambda_4 = m_{(12)3}^{PCR6, \Omega_{21}}(\omega_{12}) = 0.5863,$$

$$\lambda_5 = m_{(12)3}^{PCR6, \Omega_{22}}(\omega_{21}) = 0.8121,$$

$$\lambda_6 = m_{(12)3}^{PCR6, \Omega_{22}}(\omega_{22}) = 0.1879.$$

<sup>9</sup>Because PCR6 fusion is not associative, we should apply the general PCR6 formula to get best results. Here we use sequential fusion to reduce the computational complexity even if the fusion result is approximate.

- At layer  $l = 3$ :

$$\lambda_7 = m_{(12)3}^{PCR6, \Omega_3}(\omega_{111}) = 0.3103,$$

$$\lambda_8 = m_{(12)3}^{PCR6, \Omega_3}(\omega_{112}) = 0.6897.$$

**Step 4:** The final assignment of belief mass to the elements of original FoD  $\Theta$  are calculated using the product of the connection weights of link paths from root (top) node to terminal nodes (leaves). We finally get the following *resulting combined and normalized Bayesian BBA*

$$m^\Theta(\theta_1) = \lambda_1 \cdot \lambda_3 \cdot \lambda_7 = 0.6297 \cdot 0.4137 \cdot 0.3103 = 0.0808,$$

$$m^\Theta(\theta_2) = \lambda_1 \cdot \lambda_3 \cdot \lambda_8 = 0.6297 \cdot 0.4137 \cdot 0.6897 = 0.1797,$$

$$m^\Theta(\theta_3) = \lambda_1 \cdot \lambda_4 = 0.6297 \cdot 0.5863 = 0.3692,$$

$$m^\Theta(\theta_4) = \lambda_2 \cdot \lambda_5 = 0.3703 \cdot 0.8121 = 0.3007,$$

$$m^\Theta(\theta_5) = \lambda_2 \cdot \lambda_6 = 0.3703 \cdot 0.1879 = 0.0696.$$

### III. NEW HIERARCHICAL FLEXIBLE COARSENING METHOD

Contrary to the (rigid) hierarchical coarsening method presented in section II, in our new flexible coarsening approach the elements  $\theta_i$ ,  $i = 1, \dots, n$  in FoD  $\Theta$  will not be half split to build coarsening focal elements  $\omega_j$ ,  $j = 1, \dots, k$  of the FoD  $\Omega_l$ . In the hierarchical flexible (adaptive) coarsening method, the elements  $\theta_i$  chosen to belong to the same group are determined using the consensus information drawn from the BBAs provided by the sources. Specifically, the degrees of disagreement between the provided sources on decisions  $(\theta_1, \theta_2, \dots, \theta_n)$  are first calculated using the belief-interval based distance  $d_{BI}$  [16], [20] to obtain *disagreement vector*. Then, the k-means algorithm is applied for clustering elements  $\theta_i$ ,  $i = 1, \dots, n$  based on the corresponding value in consensus vector. It is worth noting that values of disagreement reflect the preferences of independent sources of evidence for the same focal element. If they are small, it means that all sources have a consistent opinion and these elements should be clustered in the same group. Conversely, if disagreement values are large, it means that the sources have strong disagreement on these focal elements, and these focal elements need to be clustered in another group.

#### A. Calculating the disagreement vector

Let us consider several BBAs  $m_s^\Theta(\cdot)$ , ( $s = 1, \dots, S$ ) defined on same FoD  $\Theta$  of cardinality  $|\Theta| = n$ . The specific BBAs  $m_{\theta_i}(\cdot)$ ,  $i = 1, \dots, n$  entirely focused on  $\theta_i$  are defined by  $m_{\theta_i}(\theta_i) = 1$ , and for  $X \neq \theta_i$   $m_{\theta_i}(X) = 0$ . The disagreement of opinions of two sources about  $\theta_i$  is defined as the  $L_1$ -distance between the  $d_{BI}$  distances of the BBAs  $m_s^\Theta(\cdot)$ ,  $s = 1, 2$  to  $m_{\theta_i}(\cdot)$ , which is expressed by

$$D_{12}(\theta_i) \triangleq |d_{BI}(m_1^\Theta(\cdot), m_{\theta_i}(\cdot)) - d_{BI}(m_2^\Theta(\cdot), m_{\theta_i}(\cdot))|. \quad (8)$$

The disagreement of opinions of  $S \geq 3$  sources about  $\theta_i$ , is defined as

$$D_{1-S}(\theta_i) \triangleq \frac{1}{2} \sum_{i=1}^S \sum_{j=1}^S |d_{BI}(m_i^\Theta(\cdot), m_{\theta_i}(\cdot)) - d_{BI}(m_j^\Theta(\cdot), m_{\theta_i}(\cdot))|, \quad (9)$$

where  $d_{BI}$  distance is defined by<sup>10</sup> [20]

$$d_{BI}^E(m_1, m_2) \triangleq \sqrt{n_c \cdot \sum_{i=1}^{2^n-1} [d^I(BI_1(\theta_i), BI_2(\theta_i))]^2}. \quad (10)$$

Here,  $n_c = 1/2^{n-1}$  is the normalization constant and  $d^I([a, b], [c, d])$  is the Wasserstein's distance defined by  $d^I([a, b], [c, d]) = \sqrt{[\frac{a+b}{2} - \frac{c+d}{2}]^2 + \frac{1}{3}[\frac{b-a}{2} - \frac{d-c}{2}]^2}$ . And  $BI(\theta_i) = [Bel(\theta_i), Pl(\theta_i)]$ .

The disagreement vector  $\mathbf{D}_{1-S}$  is defined by

$$\mathbf{D}_{1-S} \triangleq [D_{1-S}(\theta_1), \dots, D_{1-S}(\theta_n)]. \quad (11)$$

### B. Clustering focal elements

Once  $\mathbf{D}_{1-S}$  is derived, a clustering algorithm is used to coarsen focal elements according to their corresponding values in  $\mathbf{D}_{1-S}$ . In this paper, we have used the k-means algorithm<sup>11</sup> to cluster focal elements. For each source  $s = 1, \dots, S$ , the mass assignments of focal elements in two<sup>12</sup> different clusters are added up according to formulas (12)–(13).

$$m_s^\Omega(\omega_1) = \sum_{\theta_i \in \omega_1} m_s^\Theta(\theta_i), \quad (12)$$

$$m_s^\Omega(\omega_2) = \sum_{\theta_j \in \omega_2} m_s^\Theta(\theta_j). \quad (13)$$

### C. Combination of the BBAs

Based on the disagreement vector and k-means algorithm, a new adaptive bintree structure based on this flexible coarsening decomposition is obtained (see example in the next section) and the elements in FoD  $\Theta$  are grouped more reasonably in each layer of the decomposition. Once the adaptive bintree structure is derived, other steps (multiplications of link weights) can be implemented which are identical to hierarchical (rigid) coarsening method presented in section II to get the final combined Bayesian BBA.

### D. Summary of the method

The fusion method of BBAs to get a combined Bayesian BBA based on hierarchical flexible decomposition of the FoD consists of the four steps below illustrated in Fig. 2.

- **Step 1 (pre-processing):** At first, all input BBAs to combine are approximated to Bayesian BBAs with DSMT transform.
- **Step 2 (disagreement vector):**  $\mathbf{D}_{1-S}(\cdot)$  is calculated using  $d_{BI}$  distances to estimate the degree of disagreement of BBAs  $m_1^\Theta, \dots, m_S^\Theta$  on potential decisions  $\theta_1, \dots, \theta_n$ .
- **Step 3 (adaptive bintree):** The adaptive bintree decomposition of the FoD  $\Theta$  is obtained using k-Means algorithm to get elements of subframes  $\Omega_l$ .
- **Step 4 (assignments and connection weights):** For each source  $m_s^\Theta(\cdot)$  to combine, the mass assignment of

<sup>10</sup>For simplicity, we assume Shafer's model so that  $|2^\Theta| = 2^n$ , otherwise the number of elements in the summation of (10) should be  $|D^\Theta| - 1$  with another normalization constant  $n_c$ .

<sup>11</sup>which is implemented in Matlab™

<sup>12</sup>because we use here the bisection decomposition.

each element of subframe  $\Omega_l$  is computed by (12)–(13). The weight of links between two layers of the bintree decomposition are obtained with PCR6 rule<sup>13</sup>.

- **Step 5 (fusion):** The final result (combined Bayesian BBA) is computed by the product of weights of link paths from root to terminal nodes.

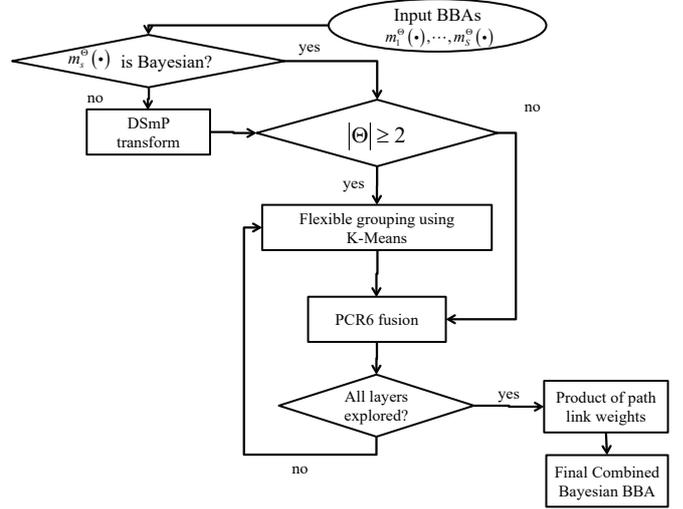

Figure 2: Hierarchical flexible decomposition of FoD for fusion.

## IV. TWO SIMPLE EXAMPLES

### A. Example 1 (fusion of Bayesian BBAs)

Let us revisit example 1 presented in section II-B. It can be verified in applying formula (9) that the disagreement vector  $\mathbf{D}_{1-3}$  for this example is equal to

$$\mathbf{D}_{1-3} = [0.4085, 0.2156, 0.3753, 0.2507, 0.4086]$$

The derivation of  $D_{1-3}(\theta_1)$  is given below for convenience.

$$\begin{aligned} D_{1-3}(\theta_1) &= |d_{BI}(m_1^\Theta(\cdot), m_{\theta_1}(\theta_1)) - d_{BI}(m_2^\Theta(\cdot), m_{\theta_1}(\theta_1))| \\ &\quad + |d_{BI}(m_2^\Theta(\cdot), m_{\theta_1}(\theta_1)) - d_{BI}(m_3^\Theta(\cdot), m_{\theta_1}(\theta_1))| \\ &\quad + |d_{BI}(m_1^\Theta(\cdot), m_{\theta_1}(\theta_1)) - d_{BI}(m_3^\Theta(\cdot), m_{\theta_1}(\theta_1))| \\ &= 0.4085. \end{aligned}$$

Based on the disagreement vector and k-means algorithm, a new adaptive bintree structure is obtained and shown in Fig. 3. Compared to Fig. 1, the elements in FoD  $\Theta$  are grouped more reasonably. In vector  $\mathbf{D}_{1-3}$ ,  $\theta_1$  and  $\theta_5$  lie in similar degree of disagreement so that they are put in the same group. Similarly for  $\theta_2$  and  $\theta_4$ . However, element  $\theta_3$  seems *weird*, which is put alone at the beginning of flexible coarsening. Once this adaptive bintree decomposition is obtained, other steps can be implemented which are identical to hierarchical coarsening method of section II to get the final combined BBA.

The flexible coarsening and fusion of BBAs is obtained from the following steps:

<sup>13</sup>general formula preferred, or applied sequentially to reduce complexity.

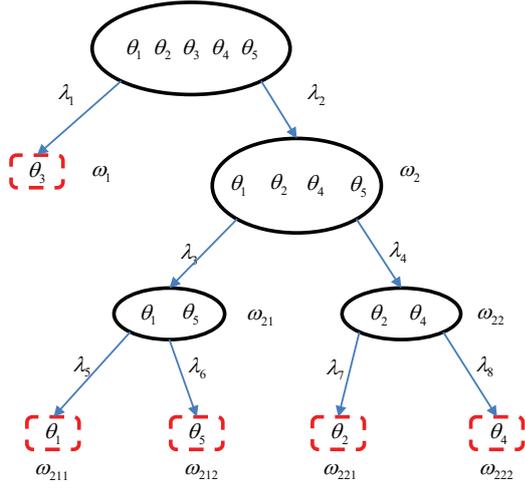

Figure 3: Example 1: Flexible bintree decomposition of FoD.

**Step 1:** According to Fig.3, the elements of the frames  $\Omega_l$  are defined as follows:

- At layer  $l = 1$ :  $\Omega_1 = \{\omega_1 \triangleq \theta_3, \omega_2 \triangleq \theta_1 \cup \theta_2 \cup \theta_4 \cup \theta_5\}$
- At layer  $l = 2$ :  $\Omega_2 = \{\omega_{21} \triangleq \theta_1 \cup \theta_5, \omega_{22} \triangleq \theta_2 \cup \theta_4\}$
- At layer  $l = 3$ :  $\Omega_3 = \{\omega_{211} \triangleq \theta_1, \omega_{212} \triangleq \theta_5, \omega_{221} \triangleq \theta_2, \omega_{222} \triangleq \theta_4\}$

**Step 2:** The BBAs of elements of the (sub-)frames  $\Omega_l$  are obtained as follows:

- At layer  $l = 1$ , we use (12)-(13) and we get

Focal elem.	$m_1^{\Omega_1}(\cdot)$	$m_2^{\Omega_1}(\cdot)$	$m_3^{\Omega_1}(\cdot)$
$\omega_1 \triangleq \theta_3$	0.3	0.1	0.5
$\omega_2 \triangleq \theta_1 \cup \theta_2 \cup \theta_4 \cup \theta_5$	0.7	0.9	0.5

- At layer  $l = 2$ : We use again the proportional redistribution method which gives us:

Focal elem.	$m_1^{\Omega_2}(\cdot)$	$m_2^{\Omega_2}(\cdot)$	$m_3^{\Omega_2}(\cdot)$
$\omega_{21} \triangleq \theta_1 \cup \theta_5$	$\frac{3}{7}$	$\frac{4}{9}$	$\frac{1}{5}$
$\omega_{22} \triangleq \theta_2 \cup \theta_4$	$\frac{4}{7}$	$\frac{5}{9}$	$\frac{4}{5}$

- At layer  $l = 3$ : We work with the two subframes  $\Omega_{31} \triangleq \{\omega_{211}, \omega_{212}\}$  and  $\Omega_{32} \triangleq \{\omega_{221}, \omega_{222}\}$  of  $\Omega_3$  with the BBAs

Focal elem.	$m_1^{\Omega_{31}}(\cdot)$	$m_2^{\Omega_{31}}(\cdot)$	$m_3^{\Omega_{31}}(\cdot)$
$\omega_{211} \triangleq \theta_1$	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$
$\omega_{212} \triangleq \theta_5$	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$
Focal elem.	$m_1^{\Omega_{32}}(\cdot)$	$m_2^{\Omega_{32}}(\cdot)$	$m_3^{\Omega_{32}}(\cdot)$
$\omega_{221} \triangleq \theta_2$	$\frac{2}{5}$	0	$\frac{1}{5}$
$\omega_{222} \triangleq \theta_4$	$\frac{3}{5}$	1	$\frac{4}{5}$

**Step 3:** The connection weights  $\lambda_i$  are computed from the assignments of coarsening elements. Hence, we obtain the following connecting weights in the bintree:

- At layer  $l = 1$ :

$$\lambda_1 = 0.2226; \quad \lambda_2 = 0.7774.$$

- At layer  $l = 2$ :

$$\lambda_3 = 0.2200; \quad \lambda_4 = 0.7800.$$

- At layer  $l = 3$ :

$$\lambda_5 = 0.5; \quad \lambda_6 = 0.5; \quad \lambda_7 = 0.0669; \quad \lambda_8 = 0.9331.$$

**Step 4:** We finally get the following *resulting combined and normalized Bayesian BBA*

$$m^\Theta(\cdot) = \{0.0855, 0.0406, 0.2226, 0.5658, 0.0855\}.$$

**B. Example 2 (with non-Bayesian BBAs)**

**Example 1bis:** Let's consider  $\Theta = \{\theta_1, \theta_2, \theta_3, \theta_4, \theta_5\}$ , and the following BBAs given by

Focal elem.	$m_1^\Theta(\cdot)$	$m_2^\Theta(\cdot)$	$m_3^\Theta(\cdot)$
$\theta_1$	0.1	0.4	0
$\theta_2$	0.2	0	0
$\theta_3$	0.3	0.05	0
$\theta_4$	0.03	0.05	0
$\theta_5$	0.1	0.04	0
$\theta_1 \cup \theta_2$	0.1	0.04	0
$\theta_2 \cup \theta_3 \cup \theta_5$	0	0.02	0.1
$\theta_3 \cup \theta_4$	0.02	0.1	0.2
$\theta_1 \cup \theta_5$	0.1	0.3	0.2
$\Theta$	0.05	0	0.5

**Step 1 (Pre-Processing):** All these three BBAs are transformed into Bayesian BBAs with DSMP transform and the generated BBAs are illustrated as

Focal elem.	$m_1^{\Theta}(\cdot)$	$m_2^{\Theta}(\cdot)$	$m_3^{\Theta}(\cdot)$
$\theta_1$	0.1908	0.7127	0.2000
$\theta_2$	0.2804	0	0.1334
$\theta_3$	0.3387	0.1111	0.2333
$\theta_4$	0.0339	0.1	0.2000
$\theta_5$	0.1562	0.0761	0.2333

It can be verified in applying formula (9) that the disagreement vector  $\mathbf{D}_{1-3}$  for this example is equal to

$$\mathbf{D}_{1-3} = [0.5385, 0.3632, 0.3453, 0.2305, 0.2827].$$

**Step 2:** According to the clustering algorithm, the elements of the frames  $\Omega_l$  are defined as follows:

- At layer  $l = 1$ :  $\Omega_1 = \{\omega_1 \triangleq \theta_1, \omega_2 \triangleq \theta_2 \cup \theta_3 \cup \theta_4 \cup \theta_5\}$
- At layer  $l = 2$ :  $\Omega_2 = \{\omega_{21} \triangleq \theta_2 \cup \theta_3, \omega_{22} \triangleq \theta_4 \cup \theta_5\}$
- At layer  $l = 3$ :  $\Omega_3 = \{\omega_{211} \triangleq \theta_2, \omega_{212} \triangleq \theta_3, \omega_{221} \triangleq \theta_4, \omega_{222} \triangleq \theta_5\}$

**Step 3:** The BBAs of elements of the (sub-)frames  $\Omega_l$  are obtained as follows:

- At layer  $l = 1$ , we use (12)-(13) and we get

Focal elem.	$m_1^{\Omega_1}(\cdot)$	$m_2^{\Omega_1}(\cdot)$	$m_3^{\Omega_1}(\cdot)$
$\omega_1 \triangleq \theta_1$	0.1908	0.7127	0.2000
$\omega_2 \triangleq \theta_2 \cup \theta_3 \cup \theta_4 \cup \theta_5$	0.8092	0.2873	0.8000

- At layer  $l = 2$ : We use again the proportional redistribution method which gives us:

Focal elem.	$m_1^{\Omega_2}(\cdot)$	$m_2^{\Omega_2}(\cdot)$	$m_3^{\Omega_2}(\cdot)$
$\omega_{21} \triangleq \theta_2 \cup \theta_3$	0.7651	0.3867	0.4584
$\omega_{22} \triangleq \theta_4 \cup \theta_5$	0.2349	0.6133	0.5416

- At layer  $l = 3$ : We work with the two subframes  $\Omega_{31} \triangleq \{\omega_{211}, \omega_{212}\}$  and  $\Omega_{32} \triangleq \{\omega_{221}, \omega_{222}\}$  of  $\Omega_3$  with the BBAs:

Focal elem.	$m_1^{\Omega_{31}}(\cdot)$	$m_2^{\Omega_{31}}(\cdot)$	$m_3^{\Omega_{31}}(\cdot)$
$\omega_{211} \triangleq \theta_2$	0.4529	0	0.3638
$\omega_{212} \triangleq \theta_3$	0.5471	1	0.6362
Focal elem.	$m_1^{\Omega_{32}}(\cdot)$	$m_2^{\Omega_{32}}(\cdot)$	$m_3^{\Omega_{32}}(\cdot)$
$\omega_{221} \triangleq \theta_4$	0.1783	0.5679	0.4616
$\omega_{222} \triangleq \theta_5$	0.8217	0.4321	0.5384

**Step 4:** The connection weights  $\lambda_i$  are computed from the assignments of coarsening elements. Hence, we obtain the following connecting weights in the bintree:

- At layer  $l = 1$ :

$$\lambda_1 = 0.2345; \quad \lambda_2 = 0.7655.$$

- At layer  $l = 2$ :

$$\lambda_3 = 0.5533; \quad \lambda_4 = 0.4467.$$

- At layer  $l = 3$ :

$$\lambda_5 = 0.1606; \quad \lambda_6 = 0.8394;$$

$$\lambda_7 = 0.3349; \quad \lambda_8 = 0.6651.$$

**Step 5:** We finally get the following *resulting combined and normalized Bayesian BBA*

$$m^\ominus(\cdot) = \{0.2345, 0.0681, 0.3555, 0.1145, 0.2274\}.$$

## V. SIMULATION RESULTS AND PERFORMANCES

### A. Flexible Grouping of Singletons

1) *Similarity*:<sup>14</sup> Assuming that  $\Theta = \{\theta_1, \theta_2, \theta_3, \theta_4, \theta_5, \theta_6, \theta_7, \theta_8, \theta_9, \theta_{10}, \theta_{11}, \theta_{12}, \theta_{13}, \theta_{14}, \theta_{15}\}$  and first, we randomly generate 2 BBAs, denoted as  $m_1^\ominus(\cdot)$  and  $m_2^\ominus(\cdot)$ , which can be seen in Table I.

Table I: BBAs for Two Sources  $m_1^\ominus(\cdot)$  and  $m_2^\ominus(\cdot)$

	$\theta_1$	$\theta_2$	$\theta_3$	$\theta_4$	$\theta_5$
$m_1^\ominus(\cdot)$	0.1331	0.0766	0.0175	0.0448	0.0229
$m_2^\ominus(\cdot)$	0.1020	0.0497	0.1094	0.0612	0.0612
	$\theta_6$	$\theta_7$	$\theta_8$	$\theta_9$	$\theta_{10}$
$m_1^\ominus(\cdot)$	0.1142	0.0023	0.2254	0.1583	3.4959e-04
$m_2^\ominus(\cdot)$	0.0069	0.0070	0.0128	0.0833	0.0338
	$\theta_{11}$	$\theta_{12}$	$\theta_{13}$	$\theta_{14}$	$\theta_{15}$
$m_1^\ominus(\cdot)$	0.0075	0.0514	0.1121	0.0314	0.0021
$m_2^\ominus(\cdot)$	0.1180	0.1202	0.1351	0.0686	0.0309

In order to fully verify the similarity between hierarchical flexible coarsening method and PCR6 in DSMT, a new strict

<sup>14</sup>Similarity represents the approximate degree between fusion results using flexible coarsening and PCR6.

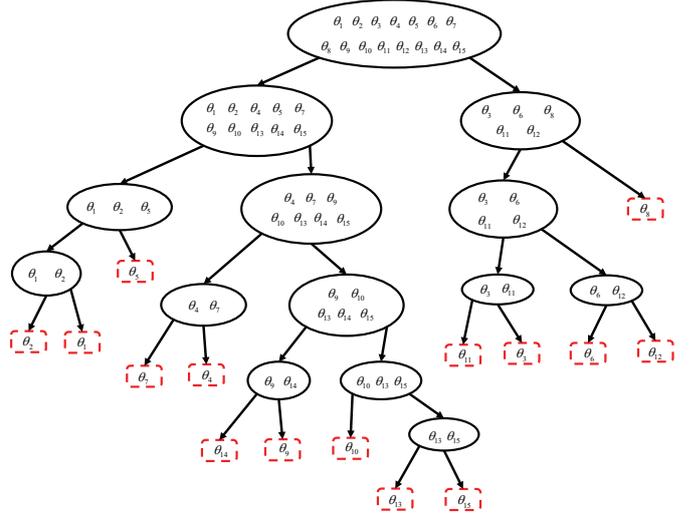

Figure 4: Structure of Hierarchical Flexible Coarsening.

distance metric between two BBAs, denoted  $d_{BI}^E$ , was recently proposed in [20], [16] and it will be used in this paper.

In this paper, we regard  $d_{BI}^E$  as one criteria for evaluating the degree of similarity between the fusion results obtained from flexible coarsening and PCR6.

Based on (8) and (10), the disagreement vector  $\mathbf{D}(\cdot)$  is obtained:

$$\mathbf{D}(\cdot) = (0.0032, 0.0020, 0.0290, 0.0092, 0.0147, 0.0228, 0.0059, 0.0537, 0.0154, 0.0131, 0.0338, 0.0235, 0.0118, 0.0145, 0.0120).$$

Thus, bintree structure of hierarchical flexible coarsening is illustrated in Fig. 4 and the similarity between fusion results of hierarchical flexible coarsening and PCR6 is 0.9783. And the similarity between hierarchical coarsening method and PCR6 is 0.9120. In particular, terminal nodes (the red small box in Fig. 4) of flexible grouping are not in accordance with the original order  $\theta_1, \theta_2, \dots, \theta_{15}$ . This is quite different compared to original hierarchical coarsening method.

From the point of view of statistics, 100 BBAs are randomly generated to be fused with three methods: hierarchical flexible coarsening, hierarchical coarsening and also PCR6. Comparisons are made in Fig. 5, which show the superiority of our new approach proposed in this paper (Average value of new method is **97%** and the old method is **93.5%**).

### B. Flexible Grouping of Conflicting Focal Elements

Assuming that there are five sources of evidence  $m_1^\ominus(\cdot), m_2^\ominus(\cdot), m_3^\ominus(\cdot), m_4^\ominus(\cdot), m_5^\ominus(\cdot)$ , and the restricted hype-power set  $D^\ominus = \{\theta_1, \theta_2, \theta_3, \theta_4, \theta_5, \theta_6, \theta_7, \theta_8, \theta_9, \theta_{10}, \theta_1 \cap \theta_2, \theta_5 \cap \theta_6 \cap \theta_7, \theta_1 \cap \theta_5 \cap \theta_9 \cap \theta_{10}\}$ . And then we randomly generate 1000 BBAs for each source to calculate the similarity using (10). From Fig. 6, we can find that hierarchical flexible coarsening method can also maintain high degree of similarity which performs better than hierarchical coarsening.

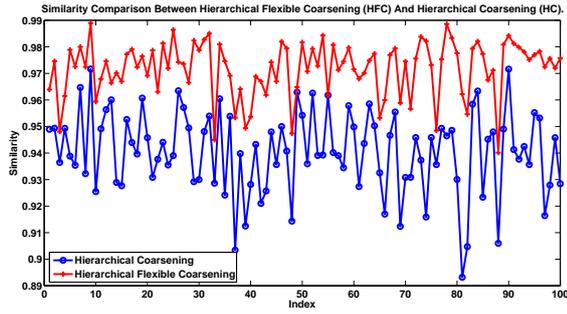

Figure 5: Comparisons Between HFC and HC (Only Singletons).

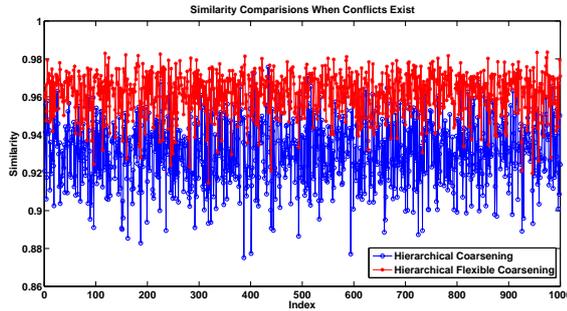

Figure 6: Comparisons Between HFC and HC (Singletons and Conflicting Focal Elements).

### C. Flexible Grouping of Uncertain and Hybrid Focal Elements

We can also deal with uncertain and hybrid focal elements. Assuming that there are also five sources of evidence  $m_1^\ominus(\cdot), m_2^\ominus(\cdot), m_3^\ominus(\cdot), m_4^\ominus(\cdot), m_5^\ominus(\cdot)$  and  $D_1^\ominus = \{\theta_1, \theta_2, \theta_3, \theta_4, \theta_5, \theta_6, \theta_7, \theta_8, \theta_9, \theta_{10}, \theta_1 \cup \theta_2, \theta_5 \cup \theta_6 \cup \theta_7, \theta_1 \cup \theta_5 \cup \theta_9 \cup \theta_{10}\}$ ;  $D_2^\ominus = \{\theta_1, \theta_2, \theta_3, \theta_4, \theta_5, \theta_6, \theta_7, \theta_8, \theta_9, \theta_{10}, \theta_2 \cap \theta_4 \cup \theta_6, \theta_1 \cup \theta_3 \cap \theta_5 \cup \theta_7 \cap \theta_9\}$ <sup>15</sup>. And then we respectively and randomly generate 1000 BBAs for these two cases  $D_1^\ominus$  and  $D_2^\ominus$ . Finally, we calculate the average similarity degree of HFC and HC with PCR6 in Table II, which illustrates HFC performs better than old method. However, there exist the extra time cost of HFC compared to HC due to the clustering steps in coarsening process.

Table II: Similarity Comparisons

	Hierarchical Flexible Coarsening	Hierarchical Coarsening
$D_1^\ominus$	98%	91%
$D_2^\ominus$	97%	93%

## VI. CONCLUSION AND PERSPECTIVES

A novel hierarchical flexible approximate method in DSMT is proposed here. Compared to original hierarchical coarsen-

<sup>15</sup>In this case,  $D_1^\ominus$  represents uncertain focal elements and  $D_2^\ominus$  represents hybrid focal elements.

ing, flexible strategy guarantees higher similarity with PCR6 rules in fusion process. Besides, whether focal elements in hyper power set are singletons, conflicting focal elements, uncertain or even hybrid focal elements, the new method works well. In the future work, we will focus on the general framework of hierarchical coarsening, which could generate final non-Bayesian BBAs in order to avoid loss of information. Furthermore, other advantages or disadvantages of our proposed methods such as computational efficiency and time consumption need to be further investigated.

**Abstract**—The dynamical systems in various science and engineering problems are often governed by nonlinear equations (differential equations). Due to insufficiency and incompleteness of system information, the parameters in such equations may have uncertainty. Interval analysis serves as an efficient tool for handling uncertainties in terms of closed intervals. One of the major problem with interval analysis is handling “dependency problems” for computation of tightest range of solution enclosure or exact enclosure. Such dependency problems are often observed while dealing with complex nonlinear equations. In this regard, initially two test problems comprising of interval nonlinear equations are considered. The Set Inversion via Interval Analysis (SIVIA) along with Monte-Carlo approach is used to compute the exact enclosure of the test problems. Further, the efficiency of the proposed approach has also been verified for solving nonlinear differential equations (Van der Pol oscillator) subject to interval initial conditions.

**Keywords:** uncertain nonlinear equations, nonlinear oscillator, dependency problem, SIVIA Monte-Carlo, contractor.

## I. INTRODUCTION

Various vibration problems in science and engineering disciplines viz. structural mechanics, control theory, seismology, physics, biology etc. may be expressed in terms of nonlinear equations, system of nonlinear equations and nonlinear differential equations. Generally, the parameters in such equations deal with precise variables. But, the insufficiency and incompleteness of the system information often led to parameters or variables with imprecision or uncertainty. For instance, let us consider a nonlinear damped spring-mass system as given in Fig. 1 governed by the equation,

$$m\ddot{x} + c\dot{x} + \alpha x^2 + kx + \beta x^3 = f(t), \quad (1)$$

where,  $m$ ,  $c$  and  $k$  are respectively mass, damping and stiffness of the nonlinear system. Here, the external force applied on the system is  $f(t)$  with damping force  $f_d = c\dot{x} + \alpha x^2$  and spring force  $f_s = kx + \beta x^3$ .

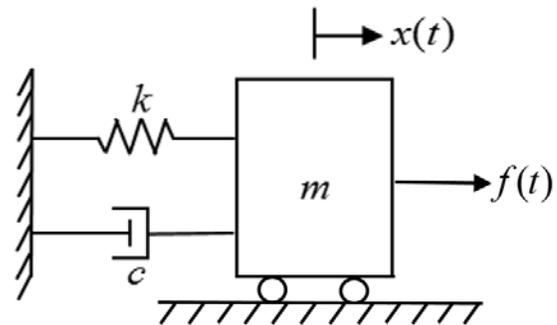

Figure 1. Damped spring-mass system.

The uncertainty of the material properties in Eq. (1) led to uncertain nonlinear differential equation. Such uncertainties may be modeled either using probabilistic approach, interval computation or fuzzy set theory. In case of non-availability of sufficient experimental data, probabilistic methods may not be able to deliver reliable results. Moreover, in fuzzy set theory a fuzzy number is expressed in terms of closed intervals through  $\alpha$ -cut approach. As such, interval analysis have emerged as a powerful tool for various practical problems in handling the uncertainties.

In early 1960s the pioneer concept related to interval computations, functions, matrices, integral and differential equations has been started by R. E. Moore [12]–[14]. System of equations, algebraic eigenvalue problems, second order initial and boundary value problems has been discussed by Alefeld and Herzberger [3]. Guaranteed interval computations with respect to set approximations, parameter and state estimation with applications in robust control and robotics are addressed by Jaulin et al. [10]. While dealing with interval computations, one of the major obstacle is to handle the ‘dependency problems’ effectively such that the tightest enclosure of solution bound may be obtained. Such dependency problems often occur in dealing with systems governed by complex nonlinear equations which often lead to over-estimation of solution bound. The dependency problem due to overestimation (*wrapping effect*) has been studied by Krämer [11] with respect to generalized interval arithmetic proposed by Hansen [9].

Other approach for reduction of overestimation while handling dependency problem may be performed using contractors [10], affine arithmetic [15] and/or parametric forms. As such, the present work proceeds with the introduction section. The preliminaries of classical arithmetic of Interval Analysis (IA) along with its application for two complex nonlinear equations comprising of imprecise variables are considered in Section II. The Set Inversion via Interval Analysis (SIVIA) along with Monte-Carlo approach is then used to compute the exact enclosure of the two test problems in Section III. Further, the proposed approach has also been verified for computing validated enclosure of nonlinear differential equations (Van der Pol oscillator) subject to interval initial conditions in Section IV.

## II. CLASSICAL INTERVAL COMPUTATIONS

Interval analysis deals with interval computations on a set of closed intervals  $\mathbb{IR}$  of real line  $\mathbb{R}$ , in order to obtain the tightest bound or enclosure for uncertain systems. A closed interval  $[x] \subset \mathbb{IR}$  is denoted by  $[x] = [\underline{x}, \bar{x}]$  such that

$$[x] = [\underline{x}, \bar{x}] = \{t \mid \underline{x} \leq t \leq \bar{x}, \text{ where } \underline{x}, \bar{x} \in \mathbb{R}\}.$$

Here,  $\underline{x} = \inf[x]$  is the infimum or lower bound of  $[x]$  and  $\bar{x} = \sup[x]$  is the supremum or upper bound of  $[x]$ . The width and center of  $[x]$  may be referred as  $[x]^w = \bar{x} - \underline{x}$  and  $[x]^c = \frac{\underline{x} + \bar{x}}{2}$  respectively.

Basic operations using classical interval arithmetic given in Moore et al. [14] are illustrated as follows:

- **Addition:**

$$[x] + [y] = [\underline{x} + \underline{y}, \bar{x} + \bar{y}],$$

- **Subtraction:**

$$[x] - [y] = [\underline{x} - \bar{y}, \bar{x} - \underline{y}],$$

- **Multiplication:**

$$[x] \cdot [y] = [\min\{S.([x], [y])\}, \max\{S.([x], [y])\}],$$

where  $S.([x], [y]) = \{\underline{x}\underline{y}, \underline{x}\bar{y}, \bar{x}\underline{y}, \bar{x}\bar{y}\}$ .

- **Division:**

$$[x]/[y] = \begin{cases} [\underline{x}, \bar{x}] \cdot \left[\frac{1}{\bar{y}}, \frac{1}{\underline{y}}\right], & 0 \notin [y, \bar{y}], \\ (-\infty, \infty), & 0 \in [y, \bar{y}] \end{cases}$$

- **Power:**

– If  $n > 0$  is an odd number, then

$$[\mathbf{x}]^n = [\underline{x}^n, \bar{x}^n];$$

– If  $n > 0$  is an even number, then

$$[\mathbf{x}]^n = \begin{cases} [\underline{x}^n, \bar{x}^n], & [\mathbf{x}] > 0, \\ [\bar{x}^n, \underline{x}^n], & [\mathbf{x}] < 0, \\ [0, \max\{\underline{x}^n, \bar{x}^n\}], & 0 \in [\mathbf{x}]. \end{cases}$$

Then, we have illustrated two test examples for the implementation of basic interval arithmetic in Examples 1 and 2.

**Example 1:** Compute the bound  $[z_1]$  satisfying constraint

$$z_1 = x_1y_1 + x_1y_3 + x_3y_1. \quad (2)$$

such that  $x_1 + x_2 + x_3 = 1$  and  $y_1 + y_2 + y_3 = 1$ . Here,  $x_1 \in [x_1] = [0.2, 0.3]$ ,  $x_2 \in [x_2] = [0.1, 0.2]$ ,  $y_1 \in [y_1] = [0.4, 0.6]$  and  $y_2 \in [y_2] = [0.2, 0.3]$ .

Using classical IA, the bounds  $[x_3]$  and  $[y_3]$  are initially estimated as  $[x_3] \sim 1 - [x_1] - [x_2] = [0.5, 0.7]$  and  $[y_3] \sim 1 - [y_1] - [y_2] = [0.1, 0.4]$  respectively with respect to the constraints  $x_1 + x_2 + x_3 = 1$  and  $y_1 + y_2 + y_3 = 1$ . Then, the bound  $[z_1]$  is obtained as

$$[z_1]^{IA} \sim [x_1] \cdot [y_1] + [x_1] \cdot [y_3] + [x_3] \cdot [y_1] = [0.30, 0.72]. \quad (3)$$

Further, we have considered a more complicated nonlinear constraint in Example 2, related to problems of multi-criteria decision-making under imprecise scores given in Dezert et al. [7].

**Example 2:** [7] Compute the bound  $[z_2]$  satisfying constraint given by the imprecise proportional conflict redistribution (PCR) fusion rule

$$z_2 = z_1 + \frac{x_1^2 y_2}{x_1 + y_2} + \frac{y_1^2 x_2}{y_1 + x_2} \quad (4)$$

such that  $x_1 \in [0.2, 0.3]$ ,  $x_2 \in [0.1, 0.2]$ ,  $y_1 \in [0.4, 0.6]$  and  $y_2 \in [0.2, 0.3]$ .

Here, the bound of  $[z_2]$  is obtained as

$$[z_2]^{IA} \sim [z_1]^{IA} + \frac{[x_1]^2 [y_2]}{[x_1] + [y_2]} + \frac{[y_1]^2 [x_2]}{[y_1] + [x_2]} = [0.3333, 0.9315]. \quad (5)$$

The enclosures obtained in Eqs. (3) and (5) have been compared with enclosures obtained using Monte-Carlo simulation in Table I.

Table I  
INTERVAL BOUNDS OF  $z_1$  AND  $z_2$ .

i	Interval bounds	
	$[z_i]^{IA}$	$[z_i]^{MC}$
1	[0.30, 0.72]	[0.3850, 0.5935]
2	[0.3333, 0.9315]	[0.4617, 0.6825]

Here, the Monte-Carlo simulation approach using uniformly distributed 100000 independent random sample values of variables  $x_1, x_2, y_1$  and  $y_2$  have been considered, where  $x_1 \sim U([x_1])$ ,  $x_2 \sim U([x_2])$ ,  $y_1 \sim U([y_1])$  and  $y_2 \sim U([y_2])$ . From Table I, it is worth mentioning that the bounds for  $i = 1, 2$  satisfy

$$[z_i]^{MC} \subset [z_i]^{IA}.$$

In case of more sample values, the Monte-Carlo simulation may yield better interval enclosure with respect to the constraints (2) and (4), but such approach is inefficient with respect to computational time. So, we may consider the

problem in handling interval computations as to interpret the tightest or the exact enclosure  $[z_i]$  of  $z_i$  that satisfies

$$[z_i]^{MC} \subset [z_i] \subset [z_i]^{IA}, \quad (6)$$

such that

$$\begin{cases} \inf [z_i]^{IA} \leq \inf [z_i] \leq \inf [z_i]^{MC}, \\ \sup [z_i]^{MC} \leq \sup [z_i] \leq \sup [z_i]^{IA}. \end{cases} \quad (7)$$

or

$$\begin{cases} \underline{z}_i^{IA} \leq \underline{z}_i \leq \underline{z}_i^{MC}, \\ \bar{z}_i^{MC} \leq \bar{z}_i \leq \bar{z}_i^{IA}. \end{cases} \quad (8)$$

Although in the above computations, interval arithmetic looks simple for basic operations with intervals and seems appealing. But, the ‘‘dependency problem’’ is a major obstacle when complicated expressions have to be computed in order to find tightest enclosure. In this regard, the dependency effect has been discussed in detail in next section.

#### A. Dependency Problem in IA

Variable or parameter dependency problem in IA is generally exhibited when we have more than one occurrence of imprecise parameter in the governing constraint. For instance, in case of the nonlinear constraint

$$z = x^2 + y^2 \text{ for } x \in [0.1, 0.5] \text{ and } y \in [-0.6, 0.1],$$

the occurrence of each imprecise variable  $x$  and  $y$  is once. The computation of enclosure with respect to constraint  $z = x^2 + y^2$  using classical IA results to  $[z]^{IA} = [0.01, 0.61]$  which is found equivalent to the Monte-Carlo simulation of  $x \sim U([0.1, 0.5])$ ,  $y \sim U([-0.6, 0.1])$  for 100000 sample values yield  $[z]^{MC} = [0.01, 0.61]$ . But, the complexity occurs while dealing with complex nonlinear constraints as given in Examples 1 and 2, where the dependency effect is exhibited due to multiple occurrence on imprecise variables.

The dependency effect may be reduced by replacing the constraint given in Eq. (2) with an equivalent simpler constraint having less (or none) redundant variables. For instance, the equivalent constraint

$$z_1 = (1 - x_2)y_2 + x_3y_1 \quad (9)$$

results to a better enclosure approximation  $[z_1]^{IA} = [0.34, 0.66]$ . Here, the interval bound  $[0.34, 0.66]$  is contained in the bound  $[0.30, 0.72]$  obtained using the equivalent constraint given in Eq. (2). But, on the other-hand an equivalent constraint

$$z_1 = (1 - y_2)x_1 + (1 - x_2)y_1 - x_1y_1 \quad (10)$$

results to an overestimated bound  $[z_1]^{IA} = [0.28, 0.70]$ . Due to such dependency, the interval bounds often yield overestimation of the tightest enclosure. Similar, dependency effect is exhibited while computing  $[z_2]^{IA}$  for constraints  $z_2 = z_1 + \left(\frac{1}{x_1y_2} + \frac{1}{x_1^2}\right)^{-1} + \frac{y_1^2x_2}{y_1+x_2}$  and  $z_2 = z_1 + \frac{x_1^2y_2}{x_1+y_2} + \left(\frac{1}{y_1x_2} + \frac{1}{y_1^2}\right)^{-1}$  with respect to (4). As such, identification of constraint yielding tightest enclosure is cumbersome. In this regard, the problem formulation for reduction of dependency effect has been carried out in the next section.

1) *Problem Formulation:* The main aim in the present work is to compute tightest enclosure  $[\underline{z}_i, \bar{z}_i]$  or exact enclosure such that  $[z_i]^{MC} \sim [z_i]^{IA}$  or

$$\begin{cases} \underline{z}_i^{IA} = \underline{z}_i = \underline{z}_i^{MC}, \\ \bar{z}_i^{MC} = \bar{z}_i = \bar{z}_i^{IA}, \end{cases} \quad (11)$$

associated with some nonlinear constraint  $z_i = f(x_1, x_2, y_1, y_2)$ , where  $x_i \in [x_i]$  and  $y_i \in [y_i]$  for  $i = 1, 2$ . In this regard, SIVIA Monte-Carlo approach based on set inversion via interval computations and Monte-Carlo simulation have been proposed to estimate exact bounds in next section.

### III. SIVIA MONTE-CARLO APPROACH

Initially, the general procedure of SIVIA has been incorporated in Section III-A followed by contractors in Section III-B. Finally, the combination of SIVIA with Monte-Carlo approach (i.e SIVIA-MC) has been performed in Section III-C.

#### A. SIVIA

Set inversion of a typical set  $X \subset \mathbb{R}^m$  with respect to function  $f : \mathbb{R}^m \rightarrow \mathbb{R}^n$  is expressed as

$$X = f^{-1}(Y) = \{x \in \mathbb{R}^m \mid f(x) \in Y\},$$

where,  $Y \subset \mathbb{R}^n$ . In case of SIVIA [10], an initial search set  $[x_0]$  is assumed containing the required set  $X$ . Then, using sub-pavings as given in Fig. 2, the desired enclosure of solution set  $X$  is obtained based on the inclusion properties:

- 1) *Case I:*  $[f]([x]) \subset Y \implies [x] \subset X$ , then  $[x]$  is a solution,
- 2) *Case II:*  $[f]([x]) \cap Y = \phi \implies [x] \cap X = \phi$ , then  $[x]$  is not a solution,
- 3) *Case III:*  $[f]([x]) \cap Y \neq \phi$  and  $[f]([x]) \not\subset Y$  then,  $[x]$  is an undetermined solution.

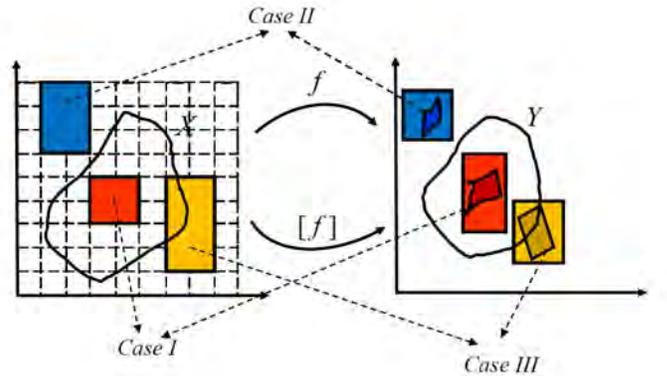

Figure 2. Set inversion via interval analysis.

The detailed illustration of set computation using SIVIA based on regular sub-pavings, bisections etc. may be found in [10]. The sub-pavings in SIVIA may be improved with the usage of contractors discussed in next section.

### B. Contractor

**Contractor:** ([4], [10]) A contractor  $\mathcal{C}$  associated with a set  $\mathbb{X} \subset \mathbb{R}^n$  over domain  $\mathbb{D}$  is an operator

$$\mathcal{C} : \mathbb{R}^n \rightarrow \mathbb{R}^n$$

satisfying the following properties:

- **Contraction:**  $\mathcal{C}([x]) \subset [x], \forall [x] \in \mathbb{R}^n$ ,
- **Completeness:**  $\mathcal{C}([x]) \cap \mathbb{X} = [x] \cap \mathbb{X}, \forall [x] \in \mathbb{R}^n$ .

The pictorial representation of implementation of contractor over set  $\mathbb{X} \subset \mathbb{R}^2$  is illustrated in Fig. 3

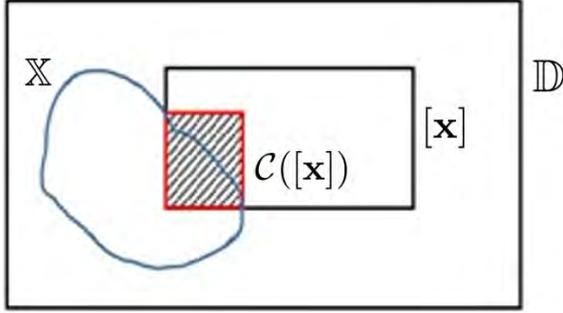

Figure 3. Contraction of  $[x]$ .

There exist various types of contractors viz. fixed-point, forward-backward, Newton, Gauss-Seidel contractors etc. Contractor based set inversion of lemniscate curve  $(x^2 + y^2)^2 + a^2(x^2 - y^2) = 0$  having width  $a \in [2, 3]$  has been obtained based on the PyIbex library [6] and depicted in Fig. 4, where the initial search set is  $[-4, 4] \times [-4, 4]$ .

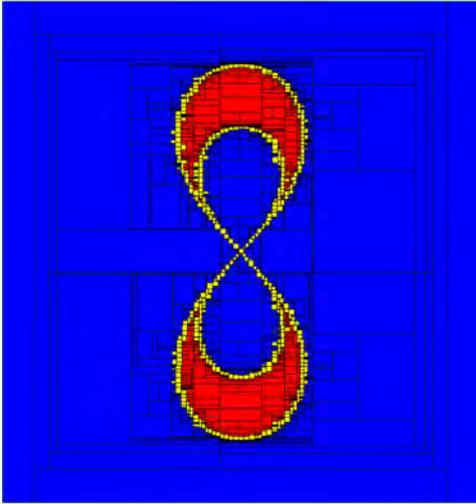

Figure 4. SIVIA of lemniscate curve with width  $[2, 3]$ .

In order to perform SIVIA Monte-Carlo approach, we have used forward-backward and fixed-point contractors. Detailed implementation of forward-backward and fixed-point contractors have been incorporated in Appendix.

### C. SIVIA Monte-Carlo

SIVIA Monte-Carlo (or SIVIA-MC) is two form iterative methodology that includes implementation of SIVIA using contractor programming and the Monte-Carlo simulation till the exact enclosure is obtained satisfying (11). In this regard, the iterative procedure is incorporated in Algorithm 1 with respect to constraint  $z = f(x_1, x_2, \dots, x_n)$  such that each  $x_i \in [x_i] \in \mathbb{R}$  for  $i = 1, 2, \dots, n$ . Here, the initial search set containing the exact enclosure is assumed as  $[z_0]$ .

---

#### Algorithm 1: Implementation of SIVIA-MC approach

---

Input:  $[x_i]$  for  $i = 1, 2, \dots, n$ ; Initial domain  $\mathbb{X} = [x_1], [x_2], \dots, [x_n]$ ;

Initial search set  $[z_0]$

Step 1: Compute enclosure using Monte-Carlo

$$\underline{z}^{\text{MC}} = mcl(\mathbb{X}) \text{ and } \bar{z}^{\text{MC}} = mcu(\mathbb{X})$$

Step 2: Compute enclosure using contractors

$$\underline{z}^{\text{IA}} = Ctcl(\mathbb{X}, [z_0]) \text{ and } \bar{z}^{\text{IA}} = Ctcu(\mathbb{X}, [z_0])$$

Step 3: Improve lower and upper range of  $z$

$$\underline{z} \in [\underline{z}^{\text{IA}}, \underline{z}^{\text{MC}}] \text{ and } \bar{z} \in [\bar{z}^{\text{MC}}, \bar{z}^{\text{IA}}]$$

Step 4: Compute improved lower  $\underline{\mathbb{X}} = [f]^{-1}([\underline{z}^{\text{IA}}, \underline{z}^{\text{MC}}])$  and

upper  $\bar{\mathbb{X}} = [f]^{-1}([\bar{z}^{\text{MC}}, \bar{z}^{\text{IA}}])$  domains using SIVIA

$$\underline{\mathbb{X}}, \bar{\mathbb{X}} = \text{SIVIA}(\mathbb{X}, [f], [z_0], \epsilon)$$

Step 5: Repeat steps 1 to 3 for domains  $\underline{\mathbb{X}}$  and  $\bar{\mathbb{X}}$

Step 6: Repeat step 4 for different domains  $\underline{\mathbb{X}}$  and  $\bar{\mathbb{X}}$

Step 7: Iterate steps 4 and 5 till  $\underline{z} = \underline{z}^{\text{IA}} \sim \underline{z}^{\text{MC}}$  and  $\bar{z} = \bar{z}^{\text{MC}} \sim \bar{z}^{\text{IA}}$

Output:  $[\underline{z}, \bar{z}]$

---

In Algorithm 1,  $mcl(\cdot), mcu(\cdot)$  are functions that compute the minimum and maximum function value with respect to domain  $\mathbb{X}$ . Then,  $Ctcl(\cdot), Ctcu(\cdot)$  uses forward-backward contractor along with fixed-point contractor for computing interval enclosure based on classical IA. Further,  $\text{SIVIA}(\cdot)$  computes the set inversion for domain  $\mathbb{X}$  based on constraint function  $f$  with precision  $\epsilon$ .

Let us again consider the Examples 1 and 2 in order to compute the exact enclosure using SIVIA Monte-Carlo in Example 3.

**Example 3:** Compute the interval bounds for the constraints

$$z_1 = x_1 y_1 + x_1 y_3 + x_3 y_1 \text{ and } z_2 = z_1 + \frac{x_1^2 y_2}{x_1 + y_2} + \frac{y_1^2 x_2}{y_1 + x_2}$$

using SIVIA Monte-Carlo such that  $x_1 + x_2 + x_3 = 1$  and  $y_1 + y_2 + y_3 = 1$ . Again,  $x_1 \in [x_1] = [0.2, 0.3]$ ,  $x_2 \in [x_2] = [0.1, 0.2]$ ,  $y_1 \in [y_1] = [0.4, 0.6]$  and  $y_2 \in [y_2] = [0.2, 0.3]$ . Using Algorithm 1 for SIVIA precision  $\epsilon = 0.001$  and different sample values viz. 100000, 1000, 100, 10, the tightest enclosures with respect to constraints  $z_1 = x_1 y_1 + x_1 y_3 + x_3 y_1$  and  $z_2 = z_1 + \frac{x_1^2 y_2}{x_1 + y_2} + \frac{y_1^2 x_2}{y_1 + x_2}$  for different sample values are obtained and incorporated in Tables II and III respectively.

It may be observed from Table II that the SIVIA Monte-Carlo method iteratively converge to exact enclosure  $[0.38, 0.6]$  (up to two decimals) even for less sample values viz. 100 and 10 respectively. Also, it may be noted that the iterative enclosures converge to exact bound though the computational time increases from 5.1388 to 9.511 seconds for different samples ranging from 100000 to 10 respectively. From Table II, the proposed method seems appealing as even for less sample values the convergent or exact solution bound is achieved. Many practical application problems do not yield sufficient data and sometimes availability of large data are cost effective, in such cases the proposed method may be used to obtain exact enclosure and the increase in computational time may be neglected.

Similar observations of exact enclosure convergence may be found in Table III with respect to different sample values. Moreover, due to complexity of the constraint (4), the required computational time 24.847 seconds for  $[z_2]$  is comparatively higher than time 9.511 seconds required for  $[z_1]$ . Further, a nonlinear differential equations with respect to dynamic

problems has been considered in next section for verification and effectiveness of SIVIA Monte-Carlo approach.

#### IV. NONLINEAR OSCILLATOR

Sometimes, dynamic problems are governed by  $m\ddot{x} + c\dot{x} + kx = f(t)$  having nonlinear stiffness ( $k_1x + k_2x^2 + \dots$ ) which result to nonlinear differential equations (nonlinear oscillators). In case of uncertain nonlinear oscillators, the SIVIA Monte-Carlo method has been implemented using nonlinear equations obtained based on Runge-Kutta 4<sup>th</sup> order [5], [8]. As such, the enclosure obtained in present section yield a validated enclosure rather than the tightest bound. There exists several validated interval methods and solvers viz. DynIbex [16] and CAPD [1] libraries for obtaining validated bounds.

**Example 4:** Consider Van der Pol equation (crisp or precise case given in Akbari et al. [2]),

$$\ddot{x}(t) + 0.15(1 - x^2)\dot{x} + 1.44x = 0, \quad (12)$$

subject to uncertain initial conditions  $x(0) \in [0.1, 0.3]$  and  $\dot{x}(0) = 0$ .

The system of first-order differential equation corresponding to (12) is obtained as

$$\dot{u} = v = f_u(t, u, v), \quad \dot{v} = 0.15(u^2 - 1)v - 1.44u = f_v(t, u, v),$$

subject to initial conditions  $u(0) \in [0.1, 0.3]$  and  $v(0) = 0$ . Using Runge-Kutta fourth-order (RK4), the nonlinear constraints involved in computation of (12) are

$$u_{n+1} = u_n + \frac{h}{6} (k_1 + 2k_2 + 2k_3 + k_4), \quad (13)$$

$$v_{n+1} = v_n + \frac{h}{6} (l_1 + 2l_2 + 2l_3 + l_4), \quad (14)$$

where,

$$k_1 = hf_u(t_n, u_n, v_n), \quad l_1 = hf_v(t_n, u_n, v_n),$$

$$k_2 = hf_u\left(t_n + \frac{h}{2}, u_n + \frac{k_1}{2}, v_n + \frac{l_1}{2}\right),$$

$$l_2 = hf_v\left(t_n + \frac{h}{2}, u_n + \frac{k_1}{2}, v_n + \frac{l_1}{2}\right),$$

$$k_3 = hf_u\left(t_n + \frac{h}{2}, u_n + \frac{k_2}{2}, v_n + \frac{l_2}{2}\right),$$

$$l_3 = hf_v\left(t_n + \frac{h}{2}, u_n + \frac{k_2}{2}, v_n + \frac{l_2}{2}\right),$$

$$k_4 = hf_u(t_n + h, u_n + k_3, v_n + l_3),$$

$$l_4 = hf_v(t_n + h, u_n + k_3, v_n + l_3).$$

Using Algorithm 1 with respect to constraints (13) and (14), the validated enclosure of  $x(t)|_{t=T}$  is obtained and incorporated in Table IV and Fig. 5.

Table IV  
INSTANTANEOUS SOLUTION ENCLOSURE OF  $x(t)|_{t=T}$ .

## V. CONCLUSION

Generally, dynamical systems occurring in various science and engineering problems are governed by nonlinear equations or nonlinear differential equations. An iterative procedure based on set inversion via interval analysis and Monte-Carlo method has been proposed for computation of exact enclosure of nonlinear equations having imprecise or uncertain variables. The effectiveness of SIVIA Monte-Carlo method has also been verified based on the considered test problems that yield exact enclosures even with respect to very less sample values. So, the method may be well implemented in computation of exact enclosures of various nonlinear equations irrespective of the dependency problem. Further, the method has also been implemented to compute validated enclosure in case of Van der Pol oscillator. Accordingly, the method may be applied to other practical nonlinear system of equations involving uncertain parameters.

## APPENDIX

**Forward-backward contractor:** The forward-backward contractor is based on constraint  $f(x) = 0$  where  $x \in [x]$  and  $[x] \in \mathbb{IR}^n$  which is illustrated using an example problem.

**Example A1:** Perform forward-backward contractor subject to constraint  $w = 2u + v$  where,  $[w] = [3, 20]$ ,  $[u] = [-10, 5]$  and  $[v] = [0, 4]$ .

Here, the constraint  $w = 2u + v$  may be expressed in terms of function  $f$  as  $f(u, v, w) = w - 2u - v$ . Further, the possible different forms of the constraint may be written are:

$$u = \frac{w - v}{2},$$

$$v = w - 2u,$$

$$w = 2u + v.$$

The forward-backward steps are then followed with respect to classical interval computations mentioned in Section II as:

$$[u] \cap \left( \frac{[w] - [v]}{2} \right) = [-10, 5] \cap \left( \frac{[3, 20] - [0, 4]}{2} \right) = [-0.5, 5],$$

$$[v] \cap ([w] - 2[u]) = [0, 4] \cap ([3, 20] - 2[-0.5, 5]) = [0, 4],$$

$$[w] \cap (2[u] + [v]) = [3, 20] \cap (2[-0.5, 5] + [0, 4]) = [3, 14].$$

As such, the new interval bounds are  $[z] = [3, 14]$ ,  $[x] = [-0.5, 5]$  and  $[y] = [0, 4]$ .

**Fixed-point contractor:** A fixed-point contraction associated with  $\psi$  is implemented with respect to the constraint  $f(x) = 0$  as  $x = \psi(x)$ , where  $x \in [x] \in \mathbb{IR}^n$ . The fixed-point contractor with respect to constraint  $u^2 + 2u + 1 = 0$  is performed as

$$\begin{aligned} u \in [u] \text{ and } u = \psi(u) &\implies u \in [u] \text{ and } u \in \psi([u]), \\ &\implies u \in [u] \cap [\psi]([u]). \end{aligned}$$

In case of implementation of forward-backward contractor along with fixed point contractor helps in computation of forward-backward contractor until the fixed interval is reached.

**Abstract**—The classifier based on rough sets is widely used in pattern recognition. However, in the implementation of rough set-based classifiers, there always exist the problems of uncertainty. Generally, information decision table in Rough Set Theory (RST) always contains many attributes, and the classification performance of each attribute is different. It is necessary to determine which attribute needs to be used according to the specific problem. In RST, such problem is regarded as attribute reduction problems which aims to select proper candidates. Therefore, the uncertainty problem occurs for the classification caused by the choice of attributes. In addition, the voting strategy is usually adopted to determine the category of target concept in the final decision making. However, some classes of targets cannot be determined when multiple categories cannot be easily distinguished (for example, the number of votes of different classes is the same). Thus, the uncertainty occurs for the classification caused by the choice of classes. In this paper, we use the theory of belief functions to solve two above mentioned uncertainties in rough set classification and rough set classifier based on Dezert-Smarandache Theory (DSMT) is proposed. It can be experimentally verified that our proposed approach can deal efficiently with the uncertainty in rough set classifiers.

**Keywords:** Classification, rough set, uncertainty, evidence reasoning, DSMT, belief functions..

## I. INTRODUCTION

*a) Motivation:* In recent years, we have witnessed the rapid development of Rough Set Theory (RST) [1]. There are many practical applications of this theory [2], [3], [4], [5]. Among these, Rough Set Classifier (RSC) has been widely used in the real classification problems [6], [7], [8], [9].

*b) Challenges:* However, in the practical use of RSC, there always exists uncertainty. In the literature [10] and [11], the discussions of the uncertainty in RST mainly focus on the following points of view: Chen [10] proposed several uncertainty measures of neighborhood granules, which are neighborhood accuracy, information quantity, neighborhood entropy and information granularity in the neighborhood RST; Zheng [11] estimated the uncertainty of rough set originated from two parts of boundary region. Although the uncertainties discussed in the above literature are of certain significance, however, the uncertainties discussed in this paper are shown in two aspects:

1) The choice of attributes: for example, in the decision information table, some attributes are not significant in a representation and deleting of these attributes has no real impact on the classification results. However, such concept of significancy is relative, for different problems, the role of

each attribute is quite different. Thus, the problems of attribute selection are always ad hoc and depending on the user's preference. Obviously, different attribute selections correspond to different strategies, which generally yield different results. For example, in [12], authors attempted to select the most information-rich attributes from a dataset by incorporating a controlled degree of misclassification into approximations of rough sets. Gao et.al [13] proposed a new uncertainty measure, named maximum decision entropy, for attribute reduction in the decision-theoretic rough set model. Although many robust and efficient reduction algorithms have been proposed, most of them concentrate on the properties of data or user preference in the definition of attribute reduction, which result in the difficulties of choosing appropriate attribute reductions for specific applications. For the same data, different users can define different reductions and obtain their interested results according to their applications. Jia et.al [14] reviewed nearly twenty two different attribute reduction methods, but to design of a robust attribute reduction method is not the focus of this paper. We emphasize the uncertainty caused by the choice of attributes, which is not discussed in details in the recent development of RST. For this aim, one typically seeks a policy for avoiding choosing attributes, and we propose to emphasize the importance of each attribute for the specific problems.

2) The choice of classes: besides, in RST, the category of target concept is determined according to the element composition of its corresponding approximate set: if the number of elements belonging to one class is the largest, the concept of target is labelled as this class. However, this kind of voting method often leads to uncertainty in making decisions, which affects the final precision of RSC. In order to illustrate this problem more vividly, we explain it through Figure 1: in case one, the approximate set of target concept (**red five-pointed star**) has four elements (**plus**) belonging to class 1, three elements (**plus**) belonging to class 2 and two elements (**plus**) belonging to class 3. Thus, in case one, we can easily draw the conclusion that the target belongs to class 1. However, in case two or case three, the target cannot be labelled with single category because there are some classes (class 1 and class 2 in case two, class 1, class 2 and class 3 in case three) that have the same number of votes. More specifically, if the approximate set of such target is empty-set (case four), which category should be allocated to the target concept? As aforementioned, for the RSCs, there are two mentioned neglected uncertainty issues. The theory of belief functions

[15] is widely used in uncertainty management and uncertainty reasoning for decision-making. In this paper, we attempt to use it to model and manage the uncertainty incorporated in RSCs.

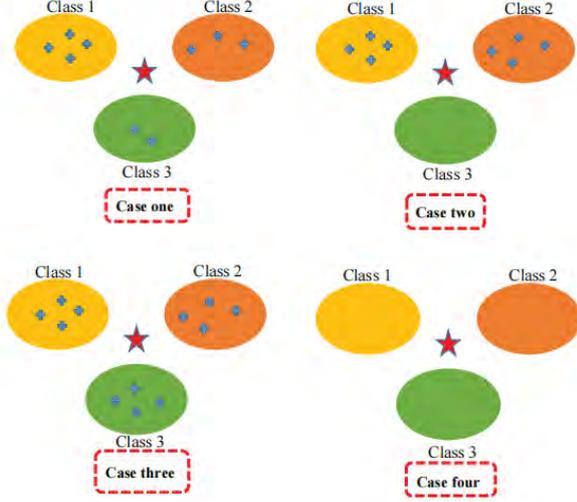

Figure 1: Uncertainty in Voting Strategy.

*c) Contributions:* Because a certain attribute does not have the ability to distinguish items on a particular problem, but there may be a discriminative performance on another problem. Thus, according to the classification performance of each attribute, the corresponding weights of all attributes in information decision table are calculated, which are used as the evaluation index of the importance of an attribute. At the same time, we do not directly delete unimportant attributes which the classical reduction algorithms have done. We just consider all the attributes in the final classification, after all, we consider that all existing attributes must play a role in the decision. For the uncertainty of the voting strategy in traditional RSC, we have no statistics of the number of votes of each class in approximate sets. Instead, we first calculate the coordinate of each class with respect to each attribute and then get the distance between the target concept and each class in every attribute, in order to calculate the Basic Belief Assignment (BBA) of the target in each attribute. Then, we use the classical combination rule (PCR5 is used in this paper) proposed in DSMT [16] to sequentially<sup>1</sup> combine all BBAs (each attribute has a corresponding BBA). Finally, according to the principle of maximum belief mass, we can obtain the final class of the target concept.

This paper is organized as follows. Section II reviews some basic concepts of Dempster-Shafer Theory (DST), and DSMT. The new rough set classifier based on DSMT (RSCD) is proposed in section III. Section IV gives the summary of the

<sup>1</sup>Because PCR5 rule is not associative, which means that the fusion results depend on the order you have chosen. Here, our default way of combination is to combine BBAs in order from small to large. For example, if there are three BBAs:  $m_1, m_2, m_3$ , the way of fusion is  $m_1 = PCR5(m_1, m_2) \rightarrow m_{123} = PCR5(m_{12}, m_3) \rightarrow m_{fusion} = m_{123}$ .

proposed classifier. In section V, we give some experimental results to show the performances of our new method. Also, some meaningful discussions about the extension of RSCD are given in section VI. Section VII concludes the paper with a summary and direction for future.

## II. PRELIMINARIES

This section provides a brief reminder of the basics of DST and DSMT, which is necessary for the presentation and understanding of the more general fusion of evidence.

In DST framework, the Frame of Discernment (FoD)<sup>2</sup>  $\Theta \triangleq \{\theta_1, \dots, \theta_n\}$  ( $n \geq 2$ ) is a set of exhaustive and exclusive elements (hypotheses) which represent the possible solutions of the problem under consideration and thus Shafer's model assumes  $\theta_i \cap \theta_j = \emptyset$  for  $i \neq j$  in  $\{1, \dots, n\}$ . A BBA  $m(\cdot)$  is defined by the mapping:  $2^\Theta \mapsto [0, 1]$ , verifying  $m(\emptyset) = 0$  and  $\sum_{A \in 2^\Theta} m(A) = 1$ . In DSMT, one can abandon Shafer's model (if Shafer's model doesn't fit with the problem) and refute the principle of the third excluded middle. The third excluded middle principle assumes the existence of the complement for any elements/propositions belonging to the power set  $2^\Theta$ . Instead of defining the BBAs on the power set  $2^\Theta \triangleq (\Theta, \cup)$  of the FoD, the BBAs are defined on the so-called *hyper-power set* (or Dedekind's lattice) denoted  $D^\Theta \triangleq (\Theta, \cup, \cap)$  whose cardinalities follows Dedekind's numbers sequence, see [17], Vol.1 for details and examples. A (generalized) BBA, called a mass function,  $m(\cdot)$  is defined by the mapping:  $D^\Theta \mapsto [0, 1]$ , verifying  $m(\emptyset) = 0$  and  $\sum_{A \in D^\Theta} m(A) = 1$ . The DSMT framework encompasses DST framework because  $2^\Theta \subset D^\Theta$ . In DSMT, we can take into account also a set of integrity constraints on the FoD (if known), by specifying all the pairs of elements which are really disjoint. Stated otherwise, Shafer's model is a specific DSMT model where all elements are deemed to be disjoint.  $A \in D^\Theta$  is called a focal element of  $m(\cdot)$  if  $m(A) > 0$ . A BBA is called a Bayesian BBA if all of its focal elements are singletons and Shafer's model is assumed, otherwise it is called non-Bayesian [18]. A full ignorance source is represented by the vacuous BBA  $m_v(\Theta) = 1$ . The belief (or credibility) and plausibility functions are respectively defined by  $Bel(X) \triangleq \sum_{Y \in D^\Theta | Y \subseteq X} m(Y)$  and  $Pl(X) \triangleq \sum_{Y \in D^\Theta | Y \cap X \neq \emptyset} m(Y)$ .  $BI(X) \triangleq [Bel(X), Pl(X)]$  is called the belief interval of  $X$ . Its length  $U(X) \triangleq Pl(X) - Bel(X)$  measures the degree of uncertainty of  $X$ .

In 1976, Shafer did propose Dempster's rule and we use DS index to refer to Dempster-Shafer's rule (DS rule) because Shafer did really promote Dempster's rule in his milestone book [18]) to combine BBAs in DST framework. DS rule for combining two distinct sources of evidence characterized by BBAs  $m_1(\cdot)$  and  $m_2(\cdot)$  is defined by  $m_{DS}(\emptyset) = 0$  and  $\forall A \in 2^\Theta \setminus \{\emptyset\}$ :

$$m_{DS}(A) = \frac{\sum_{B, C \in 2^\Theta | B \cap C = A} m_1(B)m_2(C)}{1 - \sum_{B, C \in 2^\Theta | B \cap C = \emptyset} m_1(B)m_2(C)}. \quad (1)$$

<sup>2</sup>Here, we use the symbol  $\triangleq$  to mean equals by definition.

The DS rule formula is commutative and associative and can be easily extended to the fusion of  $S > 2$  BBAs. Unfortunately, DS rule has been highly disputed during the last decades by many authors because of its counter-intuitive behavior in high or even low conflict situations, and that is why many rules of combination were proposed in literature to combine BBAs [19]. To palliate DS rule drawbacks, the very interesting PCR5 was proposed in DSMT and it is usually adopted<sup>3</sup> in recent applications of DSMT. The fusion of two BBAs  $m_1(\cdot)$  and  $m_2(\cdot)$  by the PCR5 rule is obtained by  $m_{PCR5}(\emptyset) = 0$  and  $\forall A \in D^\ominus \setminus \{\emptyset\}$

$$m_{PCR5}(A) = m_{12}(A) + \sum_{B \in D^\ominus \setminus \{A\} | A \cap B = \emptyset} \left[ \frac{m_1^2(A)m_2(B)}{m_1(A) + m_2(B)} + \frac{m_2^2(A)m_1(B)}{m_2(A) + m_1(B)} \right], \quad (2)$$

where  $m_{12}(A) = \sum_{B,C \in D^\ominus | B \cap C = A} m_1(B)m_2(C)$  is the conjunctive operator, and each element  $A$  and  $B$  are expressed in their disjunctive normal form. If the denominator involved in the fraction is zero, then this fraction is discarded. The general PCR5 formula for combining more than two BBAs altogether is given in [17], Vol. 3. We adopt the generic notation  $m_{12}^{PCR5}(\cdot) = PCR5(m_1(\cdot), m_2(\cdot))$  to denote the fusion of  $m_1(\cdot)$  and  $m_2(\cdot)$  by PCR5 rule. PCR5 is not associative and PCR5 rule can also be applied in DST framework (with Shafer's model of FoD) by replacing  $D^\ominus$  by  $2^\ominus$  in Eq (2).

### III. NEW ROUGH SET CLASSIFIER BASED ON DSMT (RSCD)

#### A. Weights of each attribute

RST is a mathematical tool to deal with vagueness and uncertainty [1], which can effectively analyse the incomplete information and does not need additional data beyond the prior information. Next, we briefly give several relevant definitions to show how to calculate the weights of attributes:

**Definition 1:** An information decision system  $\mathbf{S}$  is  $\mathbf{S} = (U, A, D)$ , where  $U = \{x_1, x_2, \dots, x_n\}$  is non-empty finite set of samples,  $A = \{a_1, a_2, \dots, a_m\}$  is a non-empty finite set of attributes,  $D$  is a non-empty set of finite decision classes.

**Definition 2:** Each attribute  $a \in A$  defines an information function  $f_a : U \rightarrow V_a$ , and  $V_a$  is the set value of the attribute  $a$ . We further extend these notations for a set of attributes  $B \subseteq A$ , an indiscernibility relation  $Ind(B)$  can be defined as follows:

$$Ind(B) = \{(x_i, x_j) \in U^2 \mid f_i(a) = f_j(a), \forall a \in B\}, \quad (3)$$

where  $\mathbf{x}_i$  and  $\mathbf{x}_j$  are indiscernible when  $(\mathbf{x}_i, \mathbf{x}_j) \in Ind(B)$ . Some equivalence classes or elementary sets are generated by  $Ind(B)$ . The elementary set of  $\mathbf{x}_i$  is represented by  $[\mathbf{x}_i]_B$ . Any finite union of elementary sets is called a B-definable set. For pattern classification, elements have the same class

<sup>3</sup>Recently, a new combination rule PCR6 was proposed to combine all the BBAs altogether in a single fusion step, which can be found in [20]. Because PCR6 rule coincides with PCR5 when combining only two BBAs [17], we just use PCR5 rule to combine BBAs in this paper.

label consisting of a concept  $X$  so that  $X \in U/D$ , where  $U/D = \{[\mathbf{x}_i]_D \mid \mathbf{x}_i \in U\}$  and  $[\mathbf{x}_i]_D$  represents the elementary sets of  $\mathbf{x}_i$  with respect to decision attribute  $D$ . Sometimes  $X \subseteq U$  is not B-definable. In other words, there exists elements that are in the same elementary set, but have different class labels, so that  $X$  becomes a vague concept. For this, we give the following definitions of approximation sets of such vague concept:

**Definition 3:** The B-upper approximation  $\overline{B}X$  and the B-lower approximation  $\underline{B}X$  of the vague concept  $X$  is defined as follows:

$$\underline{B}X = \{x_i \in U \mid [x_i]_B \subseteq X\}, \quad (4)$$

$$\overline{B}X = \{x_i \in U \mid [x_i]_B \cap X \neq \emptyset\}. \quad (5)$$

$\underline{B}X \subseteq \overline{B}X$ , and  $\underline{B}X$  consists of elements that certainly belong to  $X$ , whereas  $\overline{B}$  consists of elements that possibly belong to  $X$ . The set  $BN_B(X) = \overline{B}X - \underline{B}X$  is called the B-boundary region of  $X$ , and thus consists of those objects that we cannot decisively classify into  $X$  on the basis of knowledge in  $B$ .

**Definition 4:**  $POS_B(D)$  is a positive region of the partition  $U/D$  with respect to  $B$  and is defined as follows:

$$POS_B(D) = \bigcup_{X \in U/D} \underline{B}X \quad (6)$$

$$= \bigcup \{Y \mid Y \subseteq X, Y \subseteq U/B, X \in U/D\}. \quad (7)$$

**Definition 5:** The degree of support of the condition attributes  $B$  with respect to the decision attribute  $D$  is defined as follows:

$$\zeta_D^B = \frac{|POS_B(D)|}{|U|}. \quad (8)$$

Here,  $\zeta$  is regarded as the degree of importance of each attribute in the information decision table  $\mathbf{S}$ . In order to illustrate how to calculate the weight of a particular attribute based on the aforementioned five definitions, we give a simple example below:

**Example 1:** Table I is an information decision table with  $U = \{x_1, x_2, \dots, x_{12}\}$ ,  $A = \{a_1, a_2, a_3, a_4\}$ ,  $D = \{d_1 = 1, d_2 = 2, d_3 = 3\}$ . According to the decision attribute  $d$  and Eq.(3), if  $\mathbf{x}_i$  is set to  $U$  and  $B$  is equal to  $d$ , we can get the  $[\mathbf{x}_i]_B = [U]_d = U/D = \{\{x_1, x_4, x_7, x_8, x_{12}\}, \{x_2, x_3, x_9, x_{10}, x_{11}\}, \{x_5, x_6\}\}$ . Meanwhile, we can also partition  $U$  by using each attribute  $a_i, i = 1, \dots, m$  based on the indiscernibility relation  $Ind(B)$ , which are illustrated in Table II.

Thus, each element  $X$  in  $[U]_d$  can be approximated by each condition attribute  $a_i, i = 1, \dots, m$ , and then we can obtain  $\underline{a_i}X$  in Table III according to Definition 3. Based on Eq.(7), we can get the positive domain of  $D$  with respect to each attribute  $a_i$ , which is also given in Table IV.

In order to explain how positive domains are calculated in detail, we take  $POS_{a_1}(D)$  as an example:  $U/D = [U]_D = \{\{x_1, x_4, x_7, x_8, x_{12}\}, \{x_2, x_3, x_9, x_{10}, x_{11}\}, \{x_5, x_6\}\}$ ,  $U/a_1 = [U]_{a_1} = \{\{x_1, x_4\}, \{x_2\}, \{x_3\}, \{x_5\}, \{x_6\}, \{x_7\},$

Table I: Information decision table.

U	$a_1$	$a_2$	$a_3$	$a_4$	$a_5$
$x_1$	5.1	3.5	1.4	0.2	1
$x_2$	6.6	2.9	4.6	1.3	2
$x_3$	5.2	2.7	3.9	1.4	2
$x_4$	5.1	3.8	1.5	0.3	1
$x_5$	6.4	2.7	5.3	1.9	3
$x_6$	6.8	3.0	5.5	2.1	3
$x_7$	5.5	4.2	1.4	0.2	1
$x_8$	5.0	3.3	1.4	0.2	1
$x_9$	5.0	2.0	3.5	1.0	2
$x_{10}$	5.9	3.0	4.2	1.5	2
$x_{11}$	5.7	2.6	3.5	1.0	2
$x_{12}$	4.6	3.6	1.0	0.2	1

 Table II: Results of partitioning the domain  $U$  using each attribute.

$a_1\{x_2, x_3, x_9, x_{10}, x_{11}\}$	$\{\{x_2\}, \{x_3\}, \{x_{10}\}, \{x_{11}\}\}$
$a_1\{x_5, x_6\}$	$\{\{x_5\}, \{x_6\}\}$
$a_2\{x_1, x_4, x_7, x_8, x_{12}\}$	$\{\{x_1\}, \{x_4\}, \{x_7\}, \{x_8\}, \{x_{12}\}\}$
$a_2\{x_2, x_3, x_9, x_{10}, x_{11}\}$	$\{\{x_2\}, \{x_9\}, \{x_{11}\}\}$
$a_2\{x_5, x_6\}$	$\emptyset$
$a_3\{x_1, x_4, x_7, x_8, x_{12}\}$	$\{\{x_1, x_7, x_8\}, \{x_4\}, \{x_{12}\}\}$
$a_3\{x_2, x_3, x_9, x_{10}, x_{11}\}$	$\{\{x_2\}, \{x_3\}, \{x_9, x_{11}\}, \{x_{10}\}\}$
$a_3\{x_5, x_6\}$	$\{\{x_5\}, \{x_6\}\}$
$a_4\{x_1, x_4, x_7, x_8, x_{12}\}$	$\{\{x_1, x_7, x_8, x_{12}\}, \{x_4\}\}$
$a_4\{x_2, x_3, x_9, x_{10}, x_{11}\}$	$\{\{x_2\}, \{x_3\}, \{x_9, x_{11}\}, \{x_{10}\}\}$
$a_4\{x_5, x_6\}$	$\{\{x_5\}, \{x_6\}\}$

 Table IV: The positive domain of  $[U]_d$  with respect to each attribute and weights of each attribute according to Eq.(8).

Attribute	Domain	$\zeta$
$POS_{a_1}(D)$	$\{x_1, x_2, x_3, x_4, x_5, x_6, x_7, x_{10}, x_{11}, x_{12}\}$	$\frac{10}{12}$
$POS_{a_2}(D)$	$\{x_1, x_2, x_4, x_7, x_8, x_9, x_{11}, x_{12}\}$	$\frac{10}{12}$
$POS_{a_3}(D)$	$\{x_1, x_2, x_3, x_4, x_5, x_6, x_7, x_8, x_9, x_{10}, x_{11}, x_{12}\}$	$\frac{10}{12}$
$POS_{a_4}(D)$	$\{x_1, x_2, x_3, x_4, x_5, x_6, x_7, x_8, x_9, x_{10}, x_{11}, x_{12}\}$	$\frac{10}{12}$

$\{x_8, x_9\}, \{x_{10}\}, \{x_{11}\}, \{x_{12}\}\}$ , for any elements  $Y$ , where  $Y \in U/a_1$ , if  $Y$  meets the condition:  $Y \subseteq X$ , where  $X \in U/D$ , then  $Y$  belongs to the domain  $POS_{a_1}(D)$ , for

example, when  $Y = \{x_1, x_4\}$  and  $X = \{x_1, x_4, x_7, x_8, x_{12}\}$ , it satisfies  $Y \subseteq X$ , so  $\{x_1, x_4\}$  belongs to  $POS_{a_1}(D)$ . However, if  $Y = \{x_8, x_9\}$ ,  $Y$  is not a subset of any elements in  $U/D$ , so  $\{x_8, x_9\}$  does not belong to  $POS_{a_1}(D)$ . Thus, according to Eq.(8), we can obtain the degree of support of  $a_i$  with respect to the decision attribute  $D$  in Table IV, which will be regarded as the weights of each attribute in the classification problem.

### B. Construction of BBA of Target Concept

As discussed in the introduction section, the traditional way of voting decision will cause uncertainty when using RSC, and directly affect the final classification accuracy. The evidence theory has a good ability to deal with the uncertainty problem, and evidence theory generally describes such concept of uncertainty through BBAs. However, the BBAs in evidence theory are always given by experts depending on their own experience, which cannot be obtained directly in practical problems. Thus, this requires that, when solving such problems, the corresponding BBAs are first constructed and calculated before using them to make decisions. Referring to the construction methods of BBAs in [21], [22], [23], we propose in this paper a new construction method for the BBA based on so-called attribute polygon in RST. Each polygon represents an attribute and each vertex in a polygon represents one category. That is to say, if it is a two-classification problem, the attribute polygon is the line segment; Similarly, if it is the three-classification problem, such polygon is the triangle, and so on. Figure 2 illustrates the corresponding four polygons which represent for two, three, four and five classification problems.

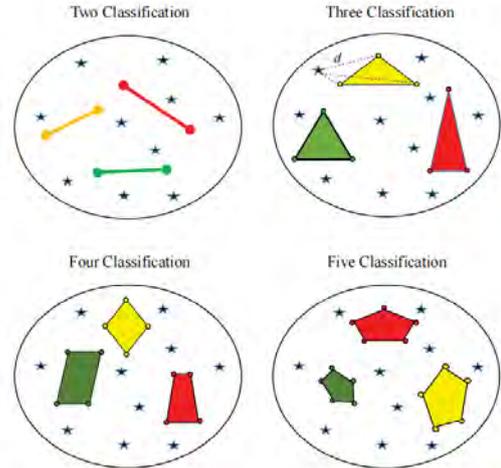

Figure 2: Attribute polygon. Pentagram represents the test example and for example, in three classification, the distances (dotted line) are calculated between the value of one attribute of pentagram and the vertices of one attribute triangle.

Besides, the coordinates of all vertices in all attribute polygons are calculated according to  $[U]_d = \{\{x_1, x_4, x_7, x_8, x_{12}\}, \{x_2, x_3, x_9, x_{10}, x_{11}\}, \{x_5, x_6\}\}$ .

Then, the Euclidean distance is used to calculate the distance between test example and each attribute polygon. Finally, we can get the belief mass value of this example belonging to each class with respect to one attribute by using Eq.(9) and Eq.(10).

$$m_{a_i}^{x^*}(\theta_s) = \alpha e^{\gamma_s d^\beta}, \quad (9)$$

$$m_{a_i}^{x^*}(\Theta) = 1 - \alpha e^{\gamma_s d^\beta}, \quad (10)$$

where  $\alpha$ ,  $\gamma_s$  and  $\beta$  are turning parameters and according to the recommendations given in [24], these parameters are set to  $\alpha = 0.95$ ,  $\gamma_s = -2$  and  $\beta = 1$ . Besides,  $d$  is the distance between the vertices of  $a_i$  attribute polygon and each attribute value of text example  $x^*$ . Next, we will show how to calculate BBAs through Example 1.

### Example 1 revisited:

According to the decision attribute  $d$  in Table I, we know that this simple example is a three-class problem because  $D = \{d_1, d_2, d_3\}$ , so we need to construct the triangles. Because the decision table has four condition attributes, we need to construct four triangles. In order to show how to calculate the coordinates of vertices in each attribute triangle, we give the calculation steps as follows: Based on the partitions of the decision attribute  $d : \{\{x_1, x_4, x_7, x_8, x_{12}\}, \{x_2, x_3, x_9, x_{10}, x_{11}\}, \{x_5, x_6\}\}$ , we can obtain the coordinates of each category with respect to attribute  $a_1$ :

- the coordinate of class one with respect to  $a_1$ :

$$\frac{1}{|X(a_1)|} \sum_{x \in X(a_1)} f(x, a_1) = 5.06,$$

where  $X(a_1) = \{x_1, x_4, x_7, x_8, x_{12}\}$  and  $|\cdot|$  denotes the cardinality;

- the coordinate of class two with respect to  $a_1$ :

$$\frac{1}{|X(a_1)|} \sum_{x \in X(a_1)} f(x, a_1) = 5.6800,$$

where  $X(a_1) = \{x_2, x_3, x_9, x_{10}, x_{11}\}$ ;

- the coordinate of class three with respect to  $a_1$ :

$$\frac{1}{|X(a_1)|} \sum_{x \in X(a_1)} f(x, a_1) = 6.6000,$$

where  $X(a_1) = \{x_5, x_6\}$ .

Here,  $f(x_i, a_j)$  is the value of the cell of the Table I corresponding to value  $x_i$  and attribute  $a_j$ .

Table V: All coordinates of three classes in each attribute.

Attribute	Class 1	Class 2	Class 3
$a_1$	5.0600	5.6800	6.600
$a_2$	3.6800	2.6400	2.8500
$a_3$	1.3400	3.9400	5.4000
$a_4$	0.2200	1.2400	2.0000

Similarly, we can calculate all the coordinates of three classes of four attributes, which is given in Table V as follows. Then, we randomly select a test example, which is denoted as  $x^* = \{5.1000, 3.5000, 1.4000, 0.2000\}$ . Based on the Euclidean distance<sup>4</sup>, the corresponding distances between  $x^*$  and each attribute polygon is given in Table VI.

Table VI: Distances between target  $x^*$  and all vertices of attribute polygons.

Distance	Class 1	Class 2	Class 3
$a_1 \leftrightarrow x^*$	0.0400	0.5800	1.5000
$a_2 \leftrightarrow x^*$	0.1800	0.8600	0.6500
$a_3 \leftrightarrow x^*$	0.0600	2.5400	4.0000
$a_4 \leftrightarrow x^*$	0.0200	1.0400	1.8000

Based on Eq.(9) and Eq.(10), we can transform these values of distances into belief mass so as to obtain the BBAs of each attribute, which is given in Table VII.

Table VII: BBAs of  $x^*$  with respect to each attribute.

$m(\cdot)$	Class 1	Class 2	Class 3	$\Theta$
$m_1(\cdot)$	0.7778	0.0523	0.0005	0.1694
$m_2(\cdot)$	0.3862	0.0129	0.0368	0.5641
$m_3(\cdot)$	0.7038	0.0000	0.0000	0.2962
$m_4(\cdot)$	0.8596	0.0052	0.0043	0.1309

Finally, we use PCR5 formula Eq.(2) to combine the weight of each attribute and the BBAs of each attribute so as to obtain the final BBA of  $x^*$ <sup>5</sup>. According to the fusion result, we can draw a conclusion that  $x^*$  belong to class 1 based on maximum of belief mass principle, which is consistent with the label of  $x^*$  in the original dataset.

$$m_{fusion}(\theta_1) = \mathbf{0.8827}; m_{fusion}(\theta_2) = 0.0009;$$

$$m_{fusion}(\theta_3) = 0.0007; m_{fusion}(\Theta) = 0.1157;$$

## IV. THE SUMMARY OF RSCD

On the next page, we give a brief pseudo-code of RSCD in Algorithm 1. Because RSCD in this paper is a data-driven model, so, first of all, we need to divide original dataset into training datasets and test samples (the experiments in this paper are using ten-fold cross validation). Afterwards, the training datasets are applied to construct attribute polygons and calculate the weights of attributes. Finally, we can obtain the corresponding BBAs of each test samples by calculating the distances between test examples and attribute polygons.

## V. SIMULATIONS

We have tested the different classifiers on real datasets given in the machine learning repository of the University of California Irvine (UCI) [25] and listed in Table VIII.

<sup>4</sup>The Euclidean distance  $d_{ij} = d(\mathbf{x}_i, \mathbf{x}_j) = \sqrt{(\mathbf{x}_i - \mathbf{x}_j)^T (\mathbf{x}_i - \mathbf{x}_j)}$  is used here.

<sup>5</sup>In the final BBA, for the sake of convenience,  $\theta_1$ ,  $\theta_2$ ,  $\theta_3$  and  $\Theta$  represent class 1, class 2, class 3 and unknown; And  $m_{fusion}(\cdot) = [(m_1(\cdot) \oplus m_2(\cdot)) \oplus m_3(\cdot)] \oplus m_4(\cdot)$ , where  $\oplus$  denotes PCR5 rule.

**Algorithm 1** Solving classification problem by RSCD

Dataset,  $\alpha = 0.95$ ,  $\gamma_s = -2$ , and  $\beta = 1$   
 The final BBA of test data:  $m_{fusion}(\cdot)$

- 1) Calculate the weights of attributes  $w_B$ , by

$$POS_B(D) = \bigcup_{X \in U/D} BX; \omega_B = \zeta_B^D = \frac{|POS_B(D)|}{|U|};$$

- 2) Calculate the BBA of each attribute, by

$$m_{a_i}^{x^*}(\theta_s) = \alpha e^{\gamma_s d^\beta}; m_{a_i}^{x^*}(\Theta) = 1 - \alpha e^{\gamma_s d^\beta};$$

- 3) Combine all BBAs of attributes sequentially, by  
 $m_{fusion}(\cdot) = 1 \quad i = 1$

- 4) **while**  $i \leq m$  **do**  $m_{fusion}(\cdot) = PCR5(m_{fusion}(\cdot), \omega_i \cdot m_i(\cdot))$  *Normalization*( $m_{fusion}(\cdot)$ ).

Table VIII: UCI datasets used in the experiments.

Datasets	Class Num.	Feature Dimention	Sample Num.
<i>Iris</i>	3	4	150
<i>Wine</i>	3	13	178
<i>Pima</i>	2	8	768
<i>Bupa</i>	2	6	345
<i>Ionosphere</i>	2	34	351

In our tests, we do not deal with the missing data problem, all the samples with missing values have been eliminated. Features of the samples are normalized by their means and standard deviations before their classification. As with the artificial datasets, we have evaluated the nearest neighbor (NN) classifier, the nearest class centroid (NC) classifier, two k-NN classifiers (one is with big  $k$  ( $k = 40$ ) and the other with a small  $k$  ( $k = 5$ )), and the ER-NN-NC classifier (both with DS+BetP option, and with PCR5+DSmP option) [26]. The results are listed in Table IX. As we can see in Table IX, RSCD performs better in three datasets (Iris, Pima and Bupa) and the classification results are close to ER-NN-NC on the other two datasets (Wine and Ionosphere).

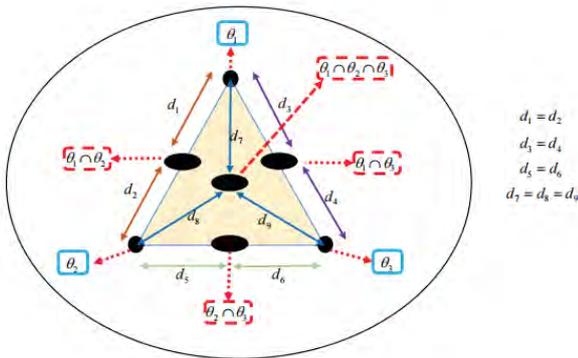

Figure 3: The principle of expanded attribute polygon.

## VI. DISCUSSIONS

In this paper, the Frame of Discernment (FoD) is  $\Theta = \{\theta_1, \theta_2, \dots, \theta_n\}$  where  $\theta_i$  represents the category and here we just consider singletons without compound focal elements<sup>6</sup>. Actually, some examples are difficult to be divided into a single class, and it may be possible to belong to two categories or several categories at the same time. On the basis of constructing attribute polygons in this paper, we can easily expand the mentioned principle above to more complex circumstances so as to ensure the particular target can belong to several classes simultaneously. The principle is illustrated in Figure 3: In this figure, we give a brief description of the expanded principle by using the three classification problem (triangle). In this triangle, three vertices (light blue and solid frame) represent single class, which is denoted by  $\theta_1$ ,  $\theta_2$  and  $\theta_3$ . The difference is that, the centers of the three edges of such triangle and the center of gravity of this triangle are defined as compound focal elements, respectively. Specifically, the center of  $\theta_1$  and  $\theta_2$  is denoted as  $\theta_1 \cap \theta_2$ , in turn, we can define all the centers of all edges of this triangle. Besides, the center of gravity of this triangle is defined as  $\theta_1 \cap \theta_2 \cap \theta_3$ . Then, we can calculate all the coordinates of these centers and also the corresponding distances so as to obtain the BBAs of all attributes. To illustrate the principle of the expanded attribute polygon, we again revisit **Example 1** as follows: Since the extension method is mainly aimed at constructing BBAs, there is no impact on the calculation of attribute weights, so the following steps are only for BBAs calculation.

- Step 1: Calculate all relevant points in expanded polygon which are given in Table X. In Table X,  $\theta_1$ ,  $\theta_2$  and  $\theta_3$  represent Class 1, Class 2 and Class 3.  $\theta_1 \cap \theta_2$  corresponds to the hypothesis for which the target belongs to two categories simultaneously, and so on. The coordinates of  $\theta_1 \cap \theta_2$  and  $\theta_1 \cap \theta_2 \cap \theta_3$  are calculated as for example by:

$$a_1(\theta_1 \cap \theta_2) = \frac{a_1(\theta_1) + a_1(\theta_2)}{2} = 5.37,$$

$$a_1(\theta_1 \cap \theta_2 \cap \theta_3) = \frac{a_1(\theta_1) + a_1(\theta_2) + a_1(\theta_3)}{3} = 5.78.$$

- Step 2: Based on Euclidean distance, we can obtain the corresponding distances between the target concept  $x^*$  and all relevant points in expanded polygon, which is given in Table XI.
- Step 3: According to Eq.(9) and Eq.(10), BBAs of  $x^*$  with respect to each attribute are shown in Table XII.
- Step 4: Sequentially combine all four BBAs with PCR5

<sup>6</sup>Here, we do not regard  $\Theta$  in Eq (10) as a compound focal element even though  $\Theta$  can be defined as  $\Theta = \theta_1 \cup \theta_2 \cup \dots \cup \theta_n$ . Because  $\Theta$  represents the ignorance or unknown of category of target concept, however, compound focal elements here mean that this target belongs to two categories or three categories at the same time.

Table IX: UCI datasets used in the experiments.

Classifiers	Iris(%)	Wine(%)	Pima(%)	Bupa(%)	Ionosphere(%)
<i>NN</i>	93.84	94.76	69.04	60.46	84.41
<i>NN(Center)</i>	92.09	95.68	72.70	56.54	79.25
<i>ER - NN - NC(DSmT + DSmP)</i>	95.15	<b>96.42</b>	73.38	60.96	<b>87.76</b>
<i>k - NN(k = 40)</i>	89.43	95.28	71.60	61.99	67.63
<i>k - NN(k = 5)</i>	95.65	95.28	72.10	59.57	82.41
<i>RSCD</i>	<b>98.00</b>	94.17	<b>74.50</b>	<b>62.87</b>	84.11

rule and then, we can get the final BBA as follows.

$$\begin{aligned}
m_{fusion}(\theta_1) &= \mathbf{0.8763}; m_{fusion}(\theta_2) = 0.0001; \\
m_{fusion}(\theta_3) &= 0.0000; m_{fusion}(\theta_1 \cap \theta_2) = 0.0240; \\
m_{fusion}(\theta_2 \cap \theta_3) &= 0.0000; m_{fusion}(\theta_1 \cap \theta_3) = 0.0006; \\
m_{fusion}(\theta_1 \cap \theta_2 \cap \theta_3) &= 0.0004; m_{fusion}(\Theta) = 0.0985.
\end{aligned}$$

Thus, we can also get the result that  $x^*$  belongs to Class 1 ( $\theta_1$ ). The biggest difference between the extension method and the RSCD is that the possible category of target is further divided so as to reduce the uncertainty in classification problem, which can be embodied in  $m_2(\cdot)$  in Table VII and Table XII. In RSCD, the assignment of  $x^*$  to  $\Theta$  with respect to  $a_2$  is 0.5640 (see the BBA  $m_2(\cdot)$  of Table VII), which means the class of  $x^*$  cannot be determined if the principle of maximum belief mass is applied. However, in expanded strategy,  $\Theta$  is further divided into  $\theta_1 \cap \theta_2$ ,  $\theta_2 \cap \theta_3$ ,  $\theta_1 \cap \theta_3$ ,  $\theta_1 \cap \theta_2 \cap \theta_3$ , which ensure the target can be labelled with the correct class.

## VII. CONCLUSION

In this paper, a new rough set classifier based on DSMT has been proposed to manage uncertainties using belief function theory. Our simulation results show clearly that RSCD performs well and its implementation is relatively simple since the attribute reduction in traditional rough set is avoided. In the implementation of RSCD, different types of combination rules can be used which give some flexibility to the users. In this paper, only one combination rule in DSMT (PCR5) has been tested. Of course many more could be implemented and tested, especially globally combing all BBAs in a single fusion step with PCR6 rule, which is left for future investigations. Also, The way of the attribute weights and BBAs' calculation used in RSCD is an open question and we plan to make investigations on this question, and evaluate the robustness of RSCD in future research works.

**Abstract**—In this paper, we prove that any dichotomous basic belief assignment (BBA)  $m$  can be expressed as the combination of two simple belief assignments  $m_p$  and  $m_c$  called respectively the pros and cons BBAs thanks to the proportional conflict redistribution rule no 5 (PCR5). This decomposition always exists and is unique and we call it the canonical decomposition of the BBA  $m$ . We also show that canonical decompositions do not exist in general if we use the conjunctive rule, the disjunctive rule, Dempster’s rule, Dubois and Prade’s or Yager’s rules, or even the averaging rule of combination. We give some numerical examples of canonical decompositions and discuss of the potential interest of this canonical decomposition for applications in information fusion.

**Keywords:** Belief Functions, Contra-evidence, Pro-evidence, PCR5, Canonical Decomposition.

## I. INTRODUCTION

The belief functions (BF) introduced by Shafer in the mid of 1970’s [1] from Dempster’s works are well known and used in the artificial intelligence community to model epistemic uncertainty and to reason with it for information fusion. In Dempster-Shafer theory, the combination of basic belief assignments (BBAs) provided by distinct sources of evidence is done with Dempster’s rule of combination which suffers of serious drawbacks in high conflict situation as discussed by Zadeh [16], [17], but also in very low conflict situations [4]. As a matter of fact many rules of combination have been proposed in the literature [2] (Vol. 2), among them the combination of two sources of evidence based on the proportional conflict redistribution principle no5 (PCR5 rule) [8] has been shown successful in applications, and well justified theoretically. However its complexity remains one of its limitations to prevent its use in large fusion problems.

In this study, we show how the fusion of dichotomous BBAs could be done thanks to their PCR5-based canonical decomposition which is always possible. Such decomposition of dogmatic or nondogmatic BBA has never been presented in the literature so far. Only a canonical decomposition based on conjunctive rule involving improper BBA has been proposed by Smets in 1995 [3] and extended later by Denœux [12] to develop the cautious rule of combination. Here the canonical decomposition we present is done differently, and we show that any dichotomous BBA is always the result of the PCR5 fusion of a simple proper pro-evidence BBA  $m_p$  with a

simple proper contra-evidence BBA  $m_c$ , and we show that this decomposition is unique.

This paper is organized as follows. After a brief recall of basics of belief functions in section II, we present the canonical decomposition problem (CDP) in section III and we show the impossibility to realize the CDP of a non dogmatic BBA with conjunctive rule, disjunctive rule, Yager’s and Dubois & Prade rules, and even with the averaging rule of combination. In section IV, we analyze the CDP based on Dempster’s rule of combination and we show that it cannot be done for a dogmatic BBA. In section V, we prove that the canonical decomposition based on PCR5 rule always exist for all the cases. In section VI, we present some particular decompositions of a dichotomous BBA (including dogmatic BBA). Some numerical examples are presented in section VII, and potential interests of this PCR5-based canonical decomposition are discussed in section VIII. The last section concludes this paper and opens a challenging question for application of this new approach.

## II. BASICS OF BELIEF FUNCTIONS

BF have been introduced by Shafer in [1] to model epistemic uncertainty. We assume that the answer<sup>1</sup> of the problem under concern belongs to a known (or given) finite discrete frame of discernment (FoD)  $\Theta = \{\theta_1, \theta_2, \dots, \theta_n\}$ , with  $n > 1$ , and where all elements of  $\Theta$  are mutually exclusive<sup>2</sup>. The set of all subsets of  $\Theta$  (including empty set  $\emptyset$  and  $\Theta$ ) is the power-set of  $\Theta$  denoted by  $2^\Theta$ . A proper Basic Belief Assignment (BBA) associated with a given source of evidence is defined [1] as a mapping  $m(\cdot) : 2^\Theta \rightarrow [0, 1]$  satisfying  $m(\emptyset) = 0$  and  $\sum_{A \in 2^\Theta} m(A) = 1$ . In some BF related frameworks, like in Smets Transferable Belief Model (TBM) [3],  $m(\emptyset)$  is allowed to take a positive value. In this case,  $m(\cdot)$  is said improper because it does not satisfy Shafer’s definition [1]. The quantity  $m(A)$  is called the mass of  $A$  committed by the source of evidence. Belief and plausibility functions are respectively defined from a proper BBA  $m(\cdot)$  by

$$Bel(A) = \sum_{B \in 2^\Theta | B \subseteq A} m(B), \quad (1)$$

<sup>1</sup>That is, the solution, or the decision to take.

<sup>2</sup>This is so-called Shafer’s model of FoD [2].

and

$$Pl(A) = \sum_{B \in 2^\Theta | A \cap B \neq \emptyset} m(B) = 1 - Bel(\bar{A}), \quad (2)$$

where  $\bar{A}$  is the complement of  $A$  in  $\Theta$ .

$Bel(A)$  and  $Pl(A)$  are usually interpreted, respectively, as lower and upper bounds of an unknown (subjective) probability measure  $P(A)$ .  $A$  is called a focal element (FE) of  $m(\cdot)$  if  $m(A) > 0$ . When all FEs are singletons then  $m(\cdot)$  is called a *Bayesian BBA* [1] and its corresponding  $Bel(\cdot)$  function is equal to  $Pl(\cdot)$ , and they are homogeneous to a (subjective) probability measure  $P(\cdot)$ . The vacuous BBA, or VBBA for short, representing a totally ignorant source is defined as<sup>3</sup>  $m_v(\Theta) = 1$ . A dogmatic BBA is a BBA such that  $m(\Theta) = 0$ . If  $m(\Theta) > 0$  the BBA  $m(\cdot)$  is nondogmatic. A simple BBA is a BBA that has at most two focal sets and one of them is  $\Theta$ . A dichotomous non dogmatic mass of belief is a BBA having three focal elements  $A$ ,  $\bar{A}$  and  $A \cup \bar{A}$  with  $A$  and  $\bar{A}$  subsets of  $\Theta$ .

In his Mathematical Theory of Evidence [1], Shafer proposed to combine  $s \geq 2$  distinct sources of evidence represented by BBAs  $m_1(\cdot), \dots, m_s(\cdot)$  over the same FoD  $\Theta$  with Dempster's rule (i.e. the normalized conjunctive rule). The justification and behavior of Dempster's rule have been disputed over the years from many counter-examples involving high and low conflicting sources (from both theoretical and practical standpoints) as reported in [4]–[7].

Many rules of combination exist in the literature<sup>4</sup>, among them we recommend the rule based on the proportional conflict redistribution principle no5 (PCR5 rule) [8] which has been shown successful in applications and well justified theoretically. That is why we analyze it in details for solving the BF canonical decomposition problem (BF-CDP). PCR5 transfers the conflicting mass only to the elements involved in the conflict and proportionally to their individual masses, so that the specificity of the information is entirely preserved in this fusion process. (see [2], Vol. 2 and Vol. 3 for full justification and examples). The PCR5 combination of two BBAs  $m_1$  and  $m_2$  defined on the same FoD  $\Theta$ , denoted by  $m_{PCR5} = PCR5(m_1, m_2)$ , is mathematically defined as  $m_{PCR5}(\emptyset) = 0$ , and  $\forall X \in 2^\Theta \setminus \{\emptyset\}$

$$m_{PCR5}(X) = \sum_{\substack{x_1, x_2 \in 2^\Theta \\ x_1 \cap x_2 = X}} m_1(x_1)m_2(x_2) + \sum_{\substack{X_2 \in 2^\Theta \\ X_2 \cap X = \emptyset}} \left[ \frac{m_1(X)^2 m_2(X_2)}{m_1(X) + m_2(X_2)} + \frac{m_2(X)^2 m_1(X_2)}{m_2(X) + m_1(X_2)} \right], \quad (3)$$

where all denominators in (3) are different from zero. If a denominator is zero, that fraction is discarded. The properties of PCR5 can be found in [9]. Extension of PCR5 for combining qualitative BBA's can be found in [2], Vol. 2 and 3. All propositions/sets are in a canonical form. A variant

<sup>3</sup>The complete ignorance is denoted  $\Theta$  in Shafer's book [1].

<sup>4</sup>see [2], Vol. 2 for a detailed list of fusion rules.

of PCR5, called PCR6 has been proposed by Martin and Osswald in [2], Vol. 2, for combining  $s > 2$  sources. The general formulas for PCR5 and PCR6 rules are also given in [2], Vol. 2. PCR6 coincides with PCR5 when one combines two sources. The difference between PCR5 and PCR6 lies in the way the proportional conflict redistribution is done as soon as three (or more) sources are involved in the fusion. From the implementation point of view, PCR6 is simpler to implement than PCR5. For convenience, very basic (not optimized) Matlab codes of PCR5 and PCR6 fusion rules can be found in [2], [10] and from the toolboxes repository on the web [11]. In the sequel we work with PCR5 rule because only two BBAs are involved in the canonical decomposition process we present.

### III. THE CANONICAL DECOMPOSITION PROBLEM

We consider a dichotomous (simplest) FoD  $\Theta$  made of only two exclusive elements  $A$  and  $\bar{A}$ , that is  $\Theta = \{A, \bar{A}\}$  and we consider a given proper<sup>5</sup> BBA  $m(\cdot) : 2^\Theta \rightarrow [0, 1]$  of the form

$$m(A) = a, \quad m(\bar{A}) = b, \quad m(A \cup \bar{A}) = 1 - a - b, \quad (4)$$

with  $0 < a < 1$ ,  $0 < b < 1$ , and  $a + b < 1$ .

The conditions  $0 < a < 1$  and  $0 < b < 1$  mean that  $A$  and  $\bar{A}$  are FEs of the BBA. The restriction  $a + b < 1$  means that the BBA is nondogmatic. This assumption of nondogmaticity of the BBA  $m(\cdot)$  can be justified because most (if not all) states of belief, being based on imperfect and not entirely conclusive evidence, should be represented by nondogmatic BFs, even if the mass  $m(\Theta)$  is very small as argued by Denœux in [12] (p. 240). In fact, we can always slightly modify a dogmatic BBA  $m(\cdot)$  in a nondogmatic BBA by discounting it with some small discount rate  $\epsilon > 0$ , and letting  $\epsilon$  tend towards 0 [3]. The case of dogmatic belief, as well as degenerate cases with  $a = 0$  and  $b = 0$  will be discussed in Section VI. Note that his assumption of nondogmaticity of the BBA  $m(\cdot)$  is necessary for Smets canonical decomposition [3], but it is not essential for our PCR5-based canonical decomposition because it also works with a dogmatic BBA as discussed in section VI.

The belief function canonical decomposition problem can be expressed as follows:

Given a nondogmatic BBA  $m(\cdot)$  as in (4) and a chosen rule of combination, find the two following simple proper BBAs  $m_p$  and  $m_c$  of the form

$$m_p(A) = x, \quad m_p(A \cup \bar{A}) = 1 - x, \quad (5)$$

$$m_c(\bar{A}) = y, \quad m_c(A \cup \bar{A}) = 1 - y, \quad (6)$$

with  $(x, y) \in [0, 1] \times [0, 1]$ , such that  $m = Fusion(m_p, m_c)$ , for a chosen rule of combination denoted  $Fusion(\cdot, \cdot)$ .

$m_p(\cdot)$  is called the *pro-BBA* (or pro-evidence) of  $A$ , and  $m_c(\cdot)$  the *contra-BBA* (or contra-evidence) of  $A$ . In the section V we prove that this decomposition is always possible and unique and we call it the (PCR5-based) canonical decomposition of the BBA  $m(\cdot)$ . The BBA  $m_p(\cdot)$  is interpreted as

<sup>5</sup>which means that  $m(\emptyset) = 0$ .

a source of evidence providing uncertain evidence in favor of  $A$ , whereas  $m_c(\cdot)$  is interpreted as a source of evidence providing uncertain evidence against  $A$ . The BBA  $m(\cdot)$  can be interpreted as the result of the PCR5 fusion of these two (pros and cons) aspects of evidence about  $A$ .

It is worth noting that this BF-CDP must not be confused with canonical decomposition problem addressed by Smets in [3] in his TBM framework, which is based on conjunctive rule of combination and which involves, in general, improper BBAs, called generalized simple BBA (GSBBA) in Smets terminology.

#### A. Impossibility of decompositions by some well-known rules

Here we analyze briefly the impossibility of a canonical decomposition for some well-known rules of combination.

1) **Conjunctive rule:** We consider  $x > 1$  and  $y > 1$  so that the two BBAs are really informative (otherwise they become vacuous and useless from decision-making standpoint). In this case we always have a conflict between  $m_p(\cdot)$  and  $m_c(\cdot)$  resulting of the conjunctive rule of combination. That is

$$m_{conj}(\emptyset) = m_p(A)m_c(\bar{A}) = x \cdot y > 0 \quad (7)$$

Hence  $m_{conj}(\emptyset) \neq 0$  is incompatible with the constraint  $m(\emptyset) = 0$ . Therefore, the canonical decomposition of the BBA  $m(\cdot)$  expressed as the conjunctive fusion of pros and cons BBAs  $m_p(\cdot)$  and  $m_c(\cdot)$  is impossible to get in general<sup>6</sup>, but in the very degenerate cases where  $a = 0$ , or  $b = 0$ , or  $a = 0$  and  $b = 0$  which would involve vacuous BBAs in the decomposition and of course will be useless.

2) **Disjunctive rule:** If we consider the disjunctive rule of combination of  $m_p(\cdot)$  and  $m_c(\cdot)$  we will always obtain the vacuous BBA because  $m_p(A)m_c(\bar{A})$ ,  $m_p(A)m_c(A \cup \bar{A})$ ,  $m_p(A \cup \bar{A})m_c(\bar{A})$  and  $m_p(A \cup \bar{A})m_c(A \cup \bar{A})$  will all be committed to the uncertainty  $A \cup \bar{A}$ . Therefore the combination result is nothing but the vacuous belief assignment  $m_v$ , that is  $Disj(m_p, m_c) = m_v$ . In conclusion, we cannot make a decomposition of the BBA  $m(\cdot)$  based on the disjunctive rule in general because if  $m(\cdot)$  is informative (e.g. not vacuous) one always has  $a + b < 1$  so that  $m(A \cup \bar{A}) < 1$  whereas the disjunctive rule of  $m_p(\cdot)$  and  $m_c(\cdot)$  will always provide  $m(A \cup \bar{A}) = 1$ .

3) **Yager's and Dubois & Prade rules:** Due to the particular simple form of BBAs  $m_p(A)$  and  $m_c(\cdot)$ , Yager's rule [13] and Dubois-Prade rule [14] coincide. Based on these rules we are searching  $x$  and  $y$  in  $[0, 1]$  such that

$$m(A) = a = x(1 - y) \quad (8)$$

$$m(\bar{A}) = b = (1 - x)y \quad (9)$$

$$m(A \cup \bar{A}) = 1 - a - b = (1 - x)(1 - y) + xy \quad (10)$$

Because the third equation is dependent of the two first, we have only to solve the following system of equations

<sup>6</sup>that is for any  $a$  and  $b$  values of mass of FEs  $A$  and  $\bar{A}$  of the BBA  $m(\cdot)$ .

$x - xy = a$  and  $y - xy = b$ . Assuming<sup>7</sup>  $y < 1$ , one gets from the first equation  $x = \frac{a}{1-y}$ . By replacing  $x$  by its expression in the second equation  $y - xy = b$  we have to find  $y$  in  $[0, 1]$  such that (after basic algebraic simplifications)

$$y^2 + (a - b - 1)y + b = 0 \quad (11)$$

This second-order equation admits one or two real solutions  $y_1$  and  $y_2$  if and only if the discriminant is null or positive respectively, that is if  $(a - b - 1)^2 - 4b \geq 0$ . However this discriminant can become negative depending on the values of  $a$  and  $b$ . For instance, for  $a = 0.4$  and  $b = 0.5$ , we have  $(a - b - 1)^2 - 4b = -0.79$  which means that there is no real solution for the equation  $y^2 - 1.1 \cdot y + 0.5 = 0$ . Therefore, in general, the canonical decomposition of the BBA  $m(\cdot)$  cannot be accomplished from Yager's and Dubois & Prade rules of combination.

4) **Averaging rule:** Suppose we combine  $m_p(\cdot)$  and  $m_c(\cdot)$  with the averaging rule. Then we are searching  $x$  and  $y$  in  $[0, 1]$  such that

$$m(A) = a = (x + 0)/2 \quad (12)$$

$$m(\bar{A}) = b = (0 + y)/2 \quad (13)$$

$$m(A \cup \bar{A}) = 1 - a - b = ((1 - x) + (1 - y))/2 \quad (14)$$

This means that  $x = 2a$  and  $y = 2b$  with  $x$  and  $y$  in  $[0, 1]$ . So, if  $a > 0.5$  or  $b > 0.5$  the canonical decomposition is impossible to make with the averaging rule of combination. Therefore, in general, the averaging rule is not able to provide a canonical decomposition of the BBA  $m(\cdot)$ .

#### IV. DECOMPOSITION BASED ON DEMPSTER'S RULE

Let consider a nondogmatic BBA  $m(A) = a$ ,  $m(\bar{A}) = b$  and  $m(A \cup \bar{A}) = 1 - a - b$  with  $0 \leq a, b \leq 1$  and  $1 - a - b > 0$ , and let's see if a decomposition of  $(\cdot)$  is possible based on Dempster's rule of combination [1]. For this, we are searching  $x$  and  $y$  in  $[0, 1]$  such that  $xy \neq 1$  and

$$m(A) = a = \frac{x(1 - y)}{1 - xy}, \quad (15)$$

$$m(\bar{A}) = b = \frac{y(1 - x)}{1 - xy}, \quad (16)$$

$$m(A \cup \bar{A}) = 1 - a - b = \frac{(1 - x)(1 - y)}{1 - xy}. \quad (17)$$

Because the third equality is redundant with the two first, we just have to solve the system of two equations expressed as

$$(1 - xy)a = x(1 - y), \quad (18)$$

$$(1 - xy)b = y(1 - x). \quad (19)$$

That is, one should have

$$x - xy + axy = a, \quad (20)$$

$$y - xy + bxy = b, \quad (21)$$

<sup>7</sup>taking  $y = 1$  would mean that  $x(1 - y) = 0$  but  $m(A) = a$  with  $a \neq 0$  in general, so that the choice of  $y = 1$  is not possible.

with the constraints  $0 < x < 1$  and  $0 < y < 1$ . So one must have

$$x = \frac{a}{1-y+ay}, \quad y \neq \frac{1}{1-a}, \quad (22)$$

and solve the equation  $y - xy + bxy = b$  with  $x$  expressed as function of  $y$  as above. We get the equation for  $a \neq 1$

$$(a-1)y^2 + (1+b-a)y - b = 0, \quad (23)$$

whose solutions have the form

$$y = \frac{-(1+b-a) \pm \sqrt{\Delta}}{2(a-1)}, \quad (24)$$

where the discriminant  $\Delta$  is given by

$$\begin{aligned} \Delta &= (1+b-a)^2 - 4(1-a)b \\ &= 1 + b^2 + a^2 + 2b - 2a - 2ab + 4ab - 4b \\ &= a^2 + b^2 + 1 - 2b + 2ab - 2a \\ &= (a+b-1)^2 = (1-a-b)^2. \end{aligned}$$

One sees that  $\Delta$  is strictly positive because  $a + b < 1$  ( $m$  being a nondogmatic BBA). So, there exist two real solutions  $y_1$  and  $y_2$  of (23) of the form

$$y_1 = \frac{-(1+b-a) + \sqrt{\Delta}}{2(a-1)} = \frac{b}{1-a}, \quad (25)$$

$$y_2 = \frac{-(1+b-a) - \sqrt{\Delta}}{2(a-1)} = \frac{1-a}{1-a} = 1. \quad (26)$$

For the case  $a \neq 1$ , the second ‘‘solution’’  $y_2 = 1$  implies  $x = \frac{a}{1-y_2+ay_2} = \frac{a}{a} = 1$  which is not an acceptable solution<sup>8</sup> because one must have  $xy \neq 1$ . The solution  $(x, y)$  of the decomposition problem for  $a \neq 1$  is actually given by the first solution  $y_1$ , that is

$$y = y_1 = \frac{b}{1-a} \in [0, 1) \quad (27)$$

$$x = \frac{a}{1-y+ay} = \frac{a}{1-b} \in [0, 1) \quad (28)$$

The case  $a = 1$  corresponding to the dogmatic BBA given by  $m(A) = a = 1$ ,  $m(\bar{A}) = b = 0$ ,  $m(A \cup \bar{A}) = 1 - a - b = 0$  is analyzed in details in Section VI - See lemma right after Theorem 4.

In summary, the unique solution of decomposition of a nondogmatic BBA with  $0 < a < 1$ ,  $0 < b < 1$  and  $a + b < 1$  using Dempster’s rule is  $x = \frac{a}{1-b}$  and  $y = \frac{b}{1-a}$ .

**Example 1:** Consider  $m(A) = a = 0.6$ ,  $m(\bar{A}) = b = 0.2$  and  $m(A \cup \bar{A}) = 1 - a - b = 0.2$ . The solution  $(x, y)$  of the decomposition of  $m(\cdot)$  based on Dempster’s rule is  $x = \frac{a}{1-b} = \frac{0.6}{1-0.2} = 0.75$  and  $y = \frac{b}{1-a} = \frac{0.2}{1-0.6} = 0.5$ . Therefore,  $m_p(A) = x = 0.75$ ,  $m_p(A \cup \bar{A}) = 1 - x = 0.25$  and  $m_c(\bar{A}) = y = 0.5$ ,  $m_c(A \cup \bar{A}) = 1 - y = 0.5$ . It can be verified that  $m_p \oplus m_c = m$ , where  $\oplus$  represents symbolically Dempster’s rule of combination [1].

<sup>8</sup>otherwise the denominators of Eqs. (15)–(17) will be equal to zero.

## V. DECOMPOSITION BASED ON PCR5 RULE

In this section we prove that the decomposition of a dichotomous nondogmatic BBA  $m(\cdot)$  based on PCR5 rule of combination is always possible and unique. Suppose we combine  $m_p(\cdot)$  and  $m_c(\cdot)$  with the PCR5 rule of combination. Then we are searching  $(x, y) \in [0, 1]^2$  satisfying

$$m(A) = a = x(1-y) + \frac{x^2y}{x+y} = \frac{x^2 + xy - xy^2}{x+y}, \quad (29)$$

$$m(\bar{A}) = b = (1-x)y + \frac{xy^2}{x+y} = \frac{y^2 + xy - x^2y}{x+y}, \quad (30)$$

$$m(A \cup \bar{A}) = 1 - a - b = 1 - x - y + xy, \quad (31)$$

under the constraints  $(a, b) \in [0, 1]^2$ , and  $0 < a + b < 1$ .

The equations (29) and (30) can be rewritten as

$$x - \frac{xy^2}{x+y} = a, \quad (32)$$

$$y - \frac{x^2y}{x+y} = b, \quad (33)$$

from which (31) is redundant because (29) + (30) gives

$$x + y - xy = a + b. \quad (34)$$

Therefore  $(1-x)(1-y) = 1 - (a+b)$  and that is why the constraint  $a + b \leq 1$  is necessary<sup>9</sup> for the existence of the solution  $(x, y)$ .

With  $x$  and  $y$  in  $[0, 1]$  the solutions of (32) and (33) verify

$$x \geq a, \quad (35)$$

$$y \geq b. \quad (36)$$

Moreover, the equality (34) implies

$$x(1-y) = a + b - y \Rightarrow y \leq a + b, \quad (37)$$

$$y(1-x) = a + b - x \Rightarrow x \leq a + b. \quad (38)$$

For  $x \neq 1$ , from (34) one gets  $y = \frac{a+b-x}{1-x}$  and from (32) one has

$$x^2 + xy - xy^2 = ax + ay. \quad (39)$$

Putting this expression of  $y$  in (39), yields the equation

$$x^2 + (x-a)\frac{a+b-x}{1-x} - x\left(\frac{a+b-x}{1-x}\right)^2 - ax = 0, \quad (40)$$

which can be expressed after elementary algebraic calculation as

$$\begin{aligned} x^4 + (-a-2)x^3 + (2a+b)x^2 \\ + (a+b-ab-b^2)x + (-a^2-ab) = 0. \end{aligned} \quad (41)$$

This equation of degree 4 has at most four real solutions. We have to take only the solution  $x$  from the open interval  $(0, 1)$  and  $y = (a+b-x)/(1-x)$  with  $y \in [0, 1]$ .

The general expression of the solutions of this quartic equation [15] is very complicate to obtain analytically even

<sup>9</sup>In fact we use the constraint  $a + b < 1$  because in this section we consider only nondogmatic BBA. The canonical decomposition of a dichotomous dogmatic BBA will be analyzed in the section VI.

with modern symbolic computing systems like Maple™, or Mathematica™, but the solutions can be easily calculated numerically by these computing systems, and even with Matlab™system (thanks to the *fsolve* command) as soon as the numerical values are committed to  $a$  and to  $b$ . Another method to make the decomposition consists to solve numerically the system of equations  $\frac{x^2+xy-xy^2}{x+y} = a$  and  $\frac{y^2+xy-x^2y}{x+y} = b$  for numerical values committed to  $a$  and  $b$  thanks to Mathematica™, Maple™, or Matlab™computing systems for instance. Of course the solutions provided by the two methods are the same.

**Example 2:** Let consider  $m(A) = 0.6$ ,  $m(\bar{A}) = 0.3$  and  $m(A \cup \bar{A}) = 0.1$ , therefore  $a = 0.6$  and  $b = 0.3$ . The quartic equation (41) becomes

$$x^4 - 2.6x^3 + 1.5x^2 + 0.63x - 0.54 = 0. \quad (42)$$

The four solutions of this quartic equation provided by the computing system<sup>10</sup> are approximately

$$\begin{aligned} x_1 &\approx 0.7774780438, \\ x_2 &\approx 0.9297589637, \\ x_3 &\approx 1.419151582, \\ x_4 &\approx -0.5263885898, \end{aligned}$$

which are shown on the graph of figure 1 obtained easily from Desmos online tool<sup>11</sup>.

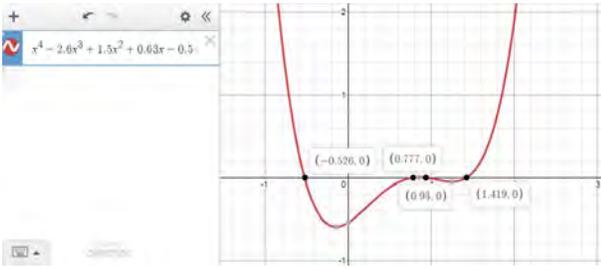

Figure 1. Plot of the quartic function.

Clearly  $x_3$  and  $x_4$  are not acceptable solutions because they do not belong to  $[0, 1]$ . If we take  $x_1 \approx 0.7774780438$  then will get  $y_1 = (a + b - x_1)/(1 - x_1) = (0.9 - x_1)/(1 - x_1) \approx 0.5506061437$ , so the pair  $(x_1, y_1) \in [0, 1]^2$  is a solution of the decomposition problem of the BBA  $m(\cdot)$ . If we take  $x_2 \approx 0.9297589637$  then will get  $y_2 = (a + b - x_2)/(1 - x_2) = (0.9 - x_2)/(1 - x_2) \approx -0.4236692006$ , so we see that  $y_2 \notin [0, 1]$  and therefore the pair  $(x_2, y_2)$  cannot be a solution of the decomposition problem of the BBA  $m(\cdot)$ . Therefore the canonical masses  $m_p(\cdot)$  and  $m_c(\cdot)$  are given by

$$\begin{aligned} m_p(A) &\approx 0.7774780438, & m_p(A \cup \bar{A}) &\approx 0.2225219562, \\ m_c(\bar{A}) &\approx 0.5506061437, & m_c(A \cup \bar{A}) &\approx 0.4493938563. \end{aligned}$$

<sup>10</sup>We did also obtain the same solutions with Maple™, and also with Matlab™.

<sup>11</sup><https://www.desmos.com/calculator>

It can be verified that the PCR5 combination of the BBAs  $m_p$  and  $m_c$ , denoted  $PCR5(m_p, m_c)$ , is equal to the BBA  $m(\cdot)$ . The following important theorem holds.

**Theorem 1:** Consider a dichotomous FoD  $\Theta = \{A, \bar{A}\}$  with  $A \neq \Theta$  and  $A \neq \emptyset$  and a nondogmatic BBA  $m(\cdot) : 2^\Theta \rightarrow [0, 1]$  defined on  $\Theta$  by  $m(A) = a$ ,  $m(\bar{A}) = b$ , and  $m(A \cup \bar{A}) = 1 - a - b$ , where  $a, b \in [0, 1]$  and  $a + b < 1$ . Then the BBA  $m(\cdot)$  has a unique canonical decomposition using PCR5 rule of combination of the form  $m = PCR5(m_p, m_c)$  with pro-evidence  $m_p(A) = x$ ,  $m_p(A \cup \bar{A}) = 1 - x$  and contra-evidence  $m_c(\bar{A}) = y$ ,  $m_c(A \cup \bar{A}) = 1 - y$ , where  $x, y \in [0, 1]$ .

**Proof:** Based on (29)-(30), we have to prove that the following system  $S_{a,b}$  of equations always admits one and only one solution  $(x, y) \in [0, 1] \times [0, 1]$

$$S_{a,b} : \begin{cases} h(x, y) = a, \\ h(y, x) = b, \end{cases} \quad (43)$$

with  $h(x, y) = \frac{x^2+xy-xy^2}{x+y} = x - \frac{xy^2}{x+y}$ . The  $h$  function can be prolonged in  $(0, 0)$  by continuity by setting  $h(0, 0) = 0$ .

One has to prove the existence of a unique  $x \in [a, a + b] \subset [0, 1]$  and  $y \in [b, a + b] \subset [0, 1]$  solutions of  $S_{a,b}$ , or equivalently solutions of  $y = \frac{a+b-x}{1-x}$  and of (41)  $P(x) = 0$  with

$$\begin{aligned} P(x) \triangleq &x^4 + (-a - 2)x^3 + (2a + b)x^2 \\ &+ (a + b)(1 - b)x - a(a + b). \end{aligned} \quad (44)$$

Because<sup>12</sup>  $\lim_{x \rightarrow -\infty} P(x) = +\infty$  and<sup>13</sup>  $P(a) < 0$ , there exists  $x_1 \in (-\infty, a)$  such that  $P(x_1) = 0$ . The solution  $x_1$  is not acceptable because  $x_1 \notin [a, a + b]$ . Because<sup>14</sup>  $P(1) < 0$  and  $\lim_{x \rightarrow +\infty} P(x) = +\infty$ , there exists also  $x_4 \in (1, +\infty)$  such that  $P(x_4) = 0$ . The solution  $x_4$  is not acceptable because  $x_4 \notin [a, a + b]$ . For  $a + b \neq 1$ , one has<sup>15</sup>  $P(a + b) > 0$  and  $P(1) < 0$ . Therefore there exists  $x_3 \in (a + b, 1)$  such that  $P(x_3) = 0$  but this solution  $x_3$  is also not acceptable because  $x_3 \notin [a, a + b]$ . Because  $P(a) < 0$  and  $P(a + b) > 0$  there exists  $x_2 \in [a, a + b]$  such that  $P(x_2) = 0$  which is the only satisfactory solution. The value  $y_2$  is given by  $y_2 = \frac{a+b-x_2}{1-x_2}$ , and one has  $y_2 > 0$  because  $x_2 < a + b$  and  $y_2 < 1$  because  $a + b < 1$ . Moreover, from (33),  $y_2 - b = \frac{x_2 y_2}{x_2 + y_2}$  which is always positive, therefore  $y_2 > b$ , and from (34)  $y_2 - (a + b) = x_2(y_2 - 1)$  which is always negative, therefore  $y_2 < a + b$ . This completes the proof of Theorem 1.

<sup>12</sup> $P(x)$  being polynomial, it is continuous and if  $P(c)P(d) < 0$  there exist at least one solution between  $[c, d]$ . Therefore, we are not sure a priori there is only one solution between  $[c, d]$ . In our case, the signs of  $P(x)$  for  $x = -\infty, a, a + b, 1, +\infty$  are respectively  $+, -, +, -$  and  $+$ . But because one has four intervals, into each interval it is not possible to have more than one solution (because otherwise will get five or more solutions, while this equation has only up to four real solutions). Therefore in each interval there exists only one real solution.

<sup>13</sup>because  $P(a) = a^2b - ab(a + b) = -ab^2$ .

<sup>14</sup>because  $P(1) = -1 + a + b + (a + b)(1 - b - a) = -(a + b - 1)^2$ .

<sup>15</sup>because from (40),  $P(a + b) = (a + b)/(1 - a - b)^2 = (a + b)^2 - a(a + b) \Rightarrow P(a + b) = b(a + b)(1 - a - b)^2 > 0$ .

## VI. PARTICULAR CASES OF DECOMPOSITIONS

Here we examine the canonical decomposition of particular cases, including dogmatic BBA.

A. *Dogmatic BBA*:  $a + b = 1$

**Theorem 2:** Any dogmatic BBA defined by  $m(A) = a$  and  $m(\bar{A}) = b$ , where  $a, b \in [0, 1]$  and  $a + b = 1$ , has a canonical decomposition using PCR5 rule of combination of the form  $m = PCR5(m_p, m_c)$  with  $m_p(A) = x$ ,  $m_p(A \cup \bar{A}) = 1 - x$  and  $m_c(\bar{A}) = y$ ,  $m_c(A \cup \bar{A}) = 1 - y$  where  $x, y \in [0, 1]$ .

**Proof:** Any solution of  $S_{a,b}$  verifies

$$x - a = \frac{xy^2}{x + y}, \quad (45)$$

$$y - b = \frac{x^2y}{x + y}, \quad (46)$$

and therefore from (45)+(46) one has

$$(x - y) - (a - b) = \frac{xy(y - x)}{x + y}, \quad (47)$$

which can be rewritten as

$$(x - y)\left[1 + \frac{xy}{x + y}\right] = (a - b). \quad (48)$$

This means that differences  $(x - y)$  and  $(a - b)$  have the same sign. Moreover from (34) with  $a + b = 1$  one has  $x + y - xy = 1$ , or equivalently  $(1 - x)(1 - y) = 0$  which is satisfied if  $x = 1$ , or if  $y = 1$  or both equal one. We must distinguish three cases as follows:

- If  $a < b$  then<sup>16</sup>  $x < y$  therefore  $y = 1$  and  $h(x, 1) = a$ . Solving  $h(x, 1) = a$  is equivalent to solve  $x^2 - ax - a = 0$  which admits only one positive solution  $x \in [a, a + b = 1]$  given by  $x = \frac{a + \sqrt{a^2 + 4a}}{2}$ . Note if  $a + b = 1$  and  $a < b$ , then necessarily  $a < 0.5$ .
- If  $a > b$  then  $x > y$  therefore  $x = 1$  and  $h(1, y) = b$ . Solving  $h(1, y) = b$  is equivalent to solve  $y^2 - by - b = 0$  which admits only one positive solution  $y \in [b, a + b = 1]$  given by  $y = \frac{b + \sqrt{b^2 + 4b}}{2}$ . Note if  $a + b = 1$  and  $a > b$ , then necessarily  $b < 0.5$ .
- If  $a = b$  and  $a + b = 1$  then  $a = b = 0.5$  and  $x = y = 1$ .

So we have proved that a decomposition based on PCR5 always exists and it is unique also for any dogmatic dichotomous BBA. Therefore, this decomposition of dogmatic dichotomous BBA is canonical, which completes the proof of Theorem 2.

**Theorem 3:** Any dogmatic BBA  $m(A) = a$ ,  $m(\bar{A}) = b$  with  $a + b = 1$  and  $0 < a < 1$  is not decomposable from Yager's rule and Dubois-Prade rule of combination.

**Proof:** We have the following system of equations to solve

$$x - xy = a, \quad (49)$$

$$y - xy = b. \quad (50)$$

From (49) and (50), we get  $a - b = x - xy - (y - xy) = x - y$ , so  $y = x - a + b$ . After replacing this expression of  $y$  into (49) and algebraic manipulations, we have to solve

$$x^2 - 2ax + a = 0,$$

whose solutions are of the form

$$x = a \pm \sqrt{a(a - 1)}.$$

For  $0 < a < 1$  the system has no real solutions because  $a(a - 1) < 0$ , which completes the proof of Theorem 3.

**Theorem 4:** Any dogmatic BBA  $m(A) = a$ ,  $m(\bar{A}) = b$  with  $a + b = 1$  is not decomposable from Dempster's rule of combination for the case when  $(a, b) \neq (1, 0)$  and  $(a, b) \neq (0, 1)$ .

**Proof:** We have the following system of equations to solve with  $0 \leq x, y \leq 1$  and  $1 - xy \neq 0$

$$\frac{x - xy}{1 - xy} = a, \quad (51)$$

$$\frac{y - xy}{1 - xy} = b. \quad (52)$$

After adding the two equations (51) and (52) and because  $a + b = 1$ , we obtain  $\frac{x - xy + y - xy}{1 - xy} = a + b = 1$ , whence  $x + y - 2xy = 1 - xy$ , or  $x + y - xy = 1$ , or  $x + y(1 - x) = 1$ , or  $y(1 - x) = 1 - x$ , or  $\frac{1 - x}{1 - x} = 1$  when  $x \neq 1$ . From (52), one should have  $\frac{y - xy}{1 - xy} = b$  with  $y = 1$ , that is  $\frac{1 - x \cdot 1}{1 - x \cdot 1} = b$ , or  $1 = b$  which is false because if  $0 < a < 1$  then  $b = 1 - a \neq 1$ . This completes the proof of theorem 4.

**Lemma:** The dogmatic BBAs  $m(A) = 1$ ,  $m(\bar{A}) = 0$  (case  $(a, b) = (1, 0)$ ), or  $m(A) = 0$ ,  $m(\bar{A}) = 1$  (case  $(a, b) = (0, 1)$ ) have infinitely many decompositions based on Dempster's rule of combination.

**Proof:** For the case  $(a, b) = (1, 0)$  one has to solve with  $0 \leq x, y \leq 1$  and  $1 - xy \neq 0$  the system of equations

$$\frac{x - xy}{1 - xy} = 1, \quad \text{and} \quad \frac{y - xy}{1 - xy} = 0. \quad (53)$$

This system is satisfied for  $x = 1$  and  $y \in [0, 1)$ , that is any value in  $[0, 1)$  can be chosen for  $y$ .

For the case  $(a, b) = (0, 1)$  one has to solve with  $0 \leq x, y \leq 1$  and  $1 - xy \neq 0$  the system of equations

$$\frac{x - xy}{1 - xy} = 0, \quad \text{and} \quad \frac{y - xy}{1 - xy} = 1. \quad (54)$$

This system is satisfied for  $y = 1$  and  $x \in [0, 1)$ , that is any value in  $[0, 1)$  can be chosen for  $x$ . Therefore one sees that for the case  $(a, b) = (1, 0)$  and the case  $(a, b) = (0, 1)$  there is no unique decomposition of these BBAs from Dempster's rule of combination, which completes the proof of the lemma.

<sup>16</sup>because  $(x - y)$  and  $(a - b)$  have the same sign.

*B. Case when  $a = 0$  and  $b = 0$  (i.e.,  $m$  is the vacuous BBA)*

This is the most degenerate case where the BBA  $m(\cdot)$  corresponds to the vacuous BBA. For averaging rule, conjunctive rule, Yager's, Dubois-Prade's, Dempster's and PCR5 rules one has  $x = 0$  and  $y = 0$  (conflict between canonical masses is zero). In fact the vacuous BBA  $m(\cdot)$  can always be interpreted as the fusion of  $m_p$  and  $m_c$ , where  $m_p$  and  $m_c$  are also vacuous BBAs. This degenerate case has no particular interest in practice but to model the total ignorant state of knowledge.

*C. Case when  $a = 0$ , or  $b = 0$*

In the case  $a = 0$  and  $0 < b \leq 1$ , then for conjunctive rule, Yager's, Dubois-Prade's, Dempster's and PCR5 rules one has  $x = 0$  and  $y = b$  (conflict between canonical masses is zero) and  $m(\cdot)$  corresponds to the fusion of vacuous pro-evidence  $m_p = m_v$  with the contra-evidence  $m_c = m$ . In the case  $0 < a \leq 1$  and  $b = 0$ , then for conjunctive rule, Yager's, Dubois-Prade's, Dempster's and PCR5 rules one has  $x = a$  and  $y = 0$  (conflict between canonical masses is zero) and  $m(\cdot)$  corresponds to the fusion of the pro-evidence  $m_p = m$  with the vacuous contra-evidence  $m_c = m_v$ . These cases have no particular interest because they can be seen just as the combination of pros (or cons) BBA with the vacuous BBA

*D. Case when  $a = b \in (0, 0.5)$*

**Theorem 5:** In the case  $a = b \in (0, 0.5)$ , the BBA  $m(A) = m(\bar{A}) = a$  and  $m(A \cup \bar{A}) = 1 - 2a$  can be canonically decomposed from PCR5 rule with the BBAs  $m_p(A) = 1 - \sqrt{1 - 2a}$ ,  $m_p(A \cup \bar{A}) = \sqrt{1 - 2a}$  and  $m_c(\bar{A}) = 1 - \sqrt{1 - 2a}$ ,  $m_c(A \cup \bar{A}) = \sqrt{1 - 2a}$ .

**Proof:** From (29) and (30), one has  $\frac{x^2 + xy - xy^2}{x + y} = a$  and one has also in this case  $\frac{y^2 + xy - x^2y}{x + y} = b = a$ . Therefore  $x^2 + xy - xy^2 = y^2 + xy - x^2y$ , or  $x^2 - xy^2 - y^2 + x^2y = 0$ , or  $(x - y)(x + y + xy) = 0$ .  $x \geq 0$  and  $y \geq 0$  because they represent the masses. Therefore  $x + y + xy \geq 0$ . The sum  $x + y + xy = 0$  if and only if  $x = y = 0$ , but this produces the degenerate case, which is corresponding to  $a = b = 0$  (i.e. the vacuous BBA). Yet, in our theorem's hypothesis we assumed  $a, b \in (0, 0.5)$ , so  $a > 0$ , and  $b > 0$ . Therefore  $x + y + xy > 0$ . Hence  $x = y$ . Therefore the canonical BBAs must be of the form  $m_p(A) = x$ ,  $m_p(A \cup \bar{A}) = 1 - x$  and  $m_c(\bar{A}) = x$ ,  $m_c(A \cup \bar{A}) = 1 - x$ . So one must solve the equation<sup>17</sup>  $x - x^2 + \frac{x^2}{2} = m(A) = a$ , or equivalently  $\frac{1}{2}x^2 - x + a = 0$ , whose solutions are  $x_1 = 1 + \sqrt{1 - 2a}$ , and  $x_2 = 1 - \sqrt{1 - 2a}$ . For  $0 < a < 0.5$ , the solution  $x_1 > 1$  is not admissible because  $x_1 \notin [0, 1]$ . The solution  $x_2$  is acceptable because if  $0 < a < 0.5$ , then  $0 < 2a < 1$ , or  $-1 < -1 + 2a < 0$ , or (by multiplying by -1 the inequalities)  $1 > 1 - 2a > 0$ , or  $0 < 1 - 2a < 1$ , or  $\sqrt{0} < \sqrt{1 - 2a} < \sqrt{1}$ , or  $0 > -\sqrt{1 - 2a} > -1$ , or  $1 > 1 - \sqrt{1 - 2a} > 0$  hence  $x_2 \in (0, 1)$ . This completes the proof of Theorem 5.

<sup>17</sup>In fact, we have also the second equation  $x - x^2 + \frac{x^2}{2} = m(\bar{A}) = b = a$  to solve which is the same as the first one.

VII. EXAMPLES

We give in Tables I-IX some numerical examples of PCR5-based canonical decompositions of BBA  $m(\cdot)$  for different sampled values of  $a$  and  $b$  for convenience. These numerical examples may be useful for researchers working with belief functions and interested by this new type of decomposition in their own examples. The values have been approximated at the 10th digit.

Figures 2 and 3 show the shapes of the pro-evidence  $x = f(a, b)$  and the contra-evidence  $y = g(a, b)$  surfaces proving graphically the existence of canonical decomposition based on PCR5 at the sampling rate of 0.025. The values  $(a, b)$  for which  $a + b > 1$  are not acceptable and  $f(a, b)$  and  $g(a, b)$  have been set to zero in the figures.

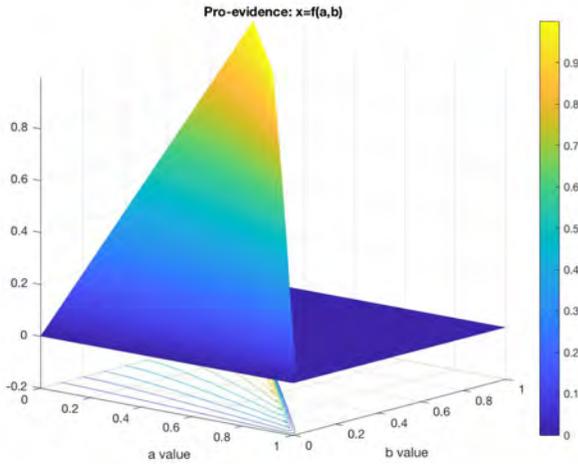

Figure 2. Plot of  $x = f(a, b)$  pro-evidence surface.

### VIII. INTEREST OF CANONICAL DECOMPOSITION

The canonical decomposition based on PCR5 offers several practical interests and advantages that are briefly listed here.

- 1) From the theoretical standpoint, one has proved that the canonical decomposition based on PCR5 rule always

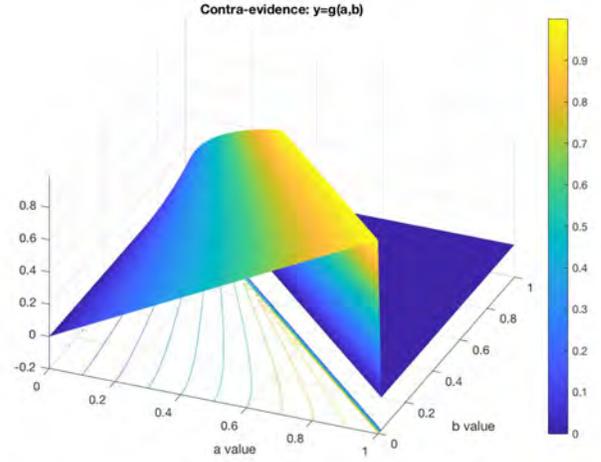

Figure 3. Plot of  $y = g(a, b)$  contra-evidence surface.

exists in all the cases for nondogmatic or dogmatic BBAs contrariwise to other rules of combination that only work in some restrictive cases. Therefore this decomposition is more general and mathematically well justified.

- 2) This canonical decomposition of any dichotomous BBA  $m(\cdot)$  into the pro-evidence  $m_p(\cdot)$  and the contra-evidence  $m_c(\cdot)$  allows to define now the notion of internal conflict of a (dichotomous) source of evidence, denoted  $K_{int}(m)$ , by

$$K_{int}(m) \triangleq m_p(A)m_c(\bar{A}), \quad (55)$$

where  $m_p(A) = x$  and  $m_c(\bar{A}) = y$  are the canonical factors of the BBA  $m(\cdot)$  based on PCR5 rule of combination. It is worth noting that the BBA  $m(\cdot)$  has no internal conflict, if and only if at least one of its factor is the vacuous belief mass, that is if  $x = 0$  or  $y = 0$ , or both, which makes sense. For instance the BBA  $m(A) = 0.3$  and  $m(A \cup \bar{A}) = 0.7$  does not carry internal conflict because  $m_p = m$  and  $m_c = m_v$  (the vacuous BBA) so that its internal conflict  $K_{int}(m) \triangleq m_p(A)m_c(\bar{A}) = 0.3 \cdot 0 = 0$ . In fact in this example the BBA  $m(\cdot)$  carries only uncertain pro-evidence, and vacuous contra-evidence. This internal conflict measure should contribute somehow in the definition of the information content carried by a (dichotomous) source of evidence. This aspect however is not detailed in this paper and is left for future research works. It is clear that the maximum of internal conflict  $K_{int}(m) = 1$  is obtained for the dogmatic BBA  $m(A) = m(\bar{A}) = 0.5$  whose canonical decomposition by PCR5 is  $m_p(A) = 1$  and  $m_c(\bar{A}) = 1$  which shows the full conflict between the pro-evidence  $m_p(\cdot)$  and the contra-evidence  $m_c(\cdot)$  of the source. Of course, there is no internal conflict for the vacuous BBA. More precisely,  $K_{int}(m_v) = 0$  because

if  $a = b = 0$  then one has  $x = y = 0$  calculated from PCR5-based decomposition. Figure 4 shows the internal conflict  $K_{int}(m)$  of a dichotomous BBA  $m$ .

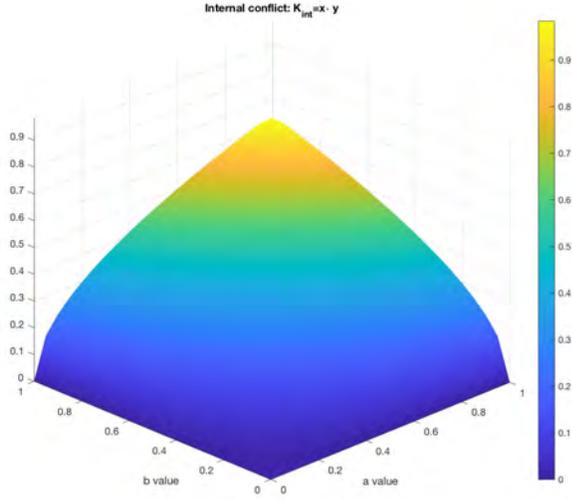

Figure 4. Internal conflict  $K_{int}(m)$ .

- 3) This canonical decomposition allows also to define the notion of level of uncertainty  $U(m)$  of a dichotomous source of evidence  $m(\cdot)$  as the conjunction of the uncertainties of pro and contra evidences, that is

$$\begin{aligned} U(m) &\triangleq m_p(A \cup \bar{A})m_c(A \cup \bar{A}) \\ &= (1-x)(1-y) = 1-x-y+xy \\ &= 1-x-y+K_{int}(m). \end{aligned} \quad (56)$$

Because of PCR5-based decomposition one gets (as already shown in (31))  $U(m) = 1 - a - b$  which always belongs to  $[0, 1]$ . The formula (56) is interesting because it clearly shows the link between the pro-evidence value  $x$ , the contra-evidence value  $y$  and the internal conflict  $K_{int}(m) = xy$ . Clearly, if  $x = 0$  and  $y = 0$ , then  $K_{int}(m) = 0$  and the uncertainty is maximal (i.e.  $U(m) = 1$ ) because the dichotomous BBA  $m$  is the vacuous BBA  $m(A \cup \bar{A}) = 1$ . It can be verified that a dichotomous BBA  $m$  has no uncertainty ( $U(m) = 0$ ) if and only if  $x = 1$ , or  $y = 1$ , or both which means that  $m(\cdot)$  is a Bayesian dichotomous BBA.

- 4) The canonical decomposition allows also to adjust/revise easily a dichotomous source of evidence (if needed) according the knowledge one has on it. For instance, suppose one knows that the source which provides the BBA  $m(\cdot)$  usually over estimates with a reinforcement factor of  $\beta_p = 20\%$  the belief mass committed to hypothesis  $A$  but is always fair (unbiased) when committing its mass to  $\bar{A}$ . Under this condition, we make the canonical decomposition of  $m(\cdot)$  to get  $m_p(\cdot)$

and  $m_c(\cdot)$  and we have to discount<sup>18</sup> the pro-evidence  $m_p(\cdot)$  with the discounting rate of  $\alpha_p = 1/(1 + \beta_p)$  to get the new unbiased BBA  $m'_p(\cdot)$  and keep the contra-evidence  $m_c(\cdot)$  unchanged, so that the corrected (unbiased) BBA  $m'(\cdot)$  will be obtained by the PCR5 combination of  $m'_p(\cdot)$  with  $m_c(\cdot)$ . Of course similar principles can be applied to discount (or reinforce)  $m_c(\cdot)$  as we prefer (and when necessary) by choosing the adequate discounting (or reinforcing) factors.

- 5) This canonical decomposition opens the door to new rules of combination for the fusion of  $S \geq 2$  (dichotomous) distinct<sup>19</sup> BBAs  $m_s(\cdot)$ ,  $s = 1, 2, \dots, S$ . After making their canonical decompositions to get  $S$  pro-evidences  $m_{p,s} = (m_{p,s}(A), m_{p,s}(\bar{A}), m_{p,s}(A \cup \bar{A}))$  equal to  $(x_s, 0, 1 - x_s)$ , and  $S$  contra-evidences  $m_{c,s} = (m_{c,s}(A), m_{c,s}(\bar{A}), m_{c,s}(A \cup \bar{A}))$  equal to  $(0, y_s, 1 - y_s)$  for  $s = 1, 2, \dots, S$ , one can for instance combine the  $S$  informative non-conflicting pro-evidences  $m_{p,s}$  altogether by the conjunctive rule (or any rule one prefers) to get the combined pro-evidence  $m_p(\cdot)$ , and do similarly to combine altogether the non conflicting contra-evidences  $m_{c,s}$  to get the combined contra-evidence  $m_c(\cdot)$ . Once  $m_p(\cdot)$  and  $m_c(\cdot)$  are calculated, we combine them with PCR5 to get the final resulting BBA. Processing this way will greatly simplify the combination of many dichotomous BBAs. Once the decomposition of each dichotomous BBA is done, we could also consider to apply some importance discounting [10] with rates  $\beta_s$  to combine separately the set of BBAs  $\{m_{p,s}, s = 1, \dots, S\}$  and the set of BBAs  $\{m_{c,s}, s = 1, \dots, S\}$  before making their PCR5 combination.

## IX. CONCLUSIONS

In this study, we have proved that any dichotomous basic belief assignment (nondogmatic, or dogmatic) can be decomposed into two simpler proper belief assignments called the pro-evidence and contra-evidence that can be combined with PCR5 rule to retrieve the original BBA. This canonical decomposition is unique and is always possible. No simple explicit form of the expression of the solution exists but the solution can be found quite easily with numerical solvers (Matlab, Maple, etc). We have also shown that the decomposition of any dichotomous basic belief assignment cannot be done in all the cases with other well-known rules of combination, which reinforce the interest of PCR5 principle for BF combination. This PCR5-based canonical decomposition allows also to establish the notion of internal conflict of a dichotomous source of evidence which could be helpful in some applications. It offers the possibility to combine several dichotomous sources of evidence based on the fusion of their canonical components. This will be presented in details in a forthcoming publication. The open challenging question is how to extend this notion of

<sup>18</sup>We use classical Shafer's discounting method [1].

<sup>19</sup>i.e., cognitively independent.

canonical decomposition for working with more general basic belief assignments to make their combination more effective (if possible), and how could we define a measure of (uncertain) information thanks to this canonical decomposition.

#### ACKNOWLEDGMENT

**Abstract**—We present a new methodology for decision-making support based on belief functions thanks to a new theoretical canonical decomposition of dichotomous basic belief assignments (BBAs) that has been developed recently. This decomposition based on proportional conflict redistribution rule no 5 (PCR5) always exists and is unique. This new PCR5-based decomposition method circumvents the exponential complexity of the direct fusion of BBAs with PCR5 rule and it allows to fuse quickly many sources of evidences. The method we propose in this paper provides both a decision and an estimation of the quality of the decision made, which is appealing for decision-making support systems.

**Keywords:** Decision-Making, Belief Functions, PCR5.

## I. INTRODUCTION

This paper deals with the decision-making support problem from many sources of evidence characterized by belief functions (BF) defined over a same frame of discernment. Belief functions introduced by Shafer [1] are appealing to model epistemic uncertainty. They are well-known and used in the artificial intelligence community to fuse uncertain information and to make a decision. However, many debates in scientific community started with Zadeh’s criticism [2], [3] - see additional references in [4] - have bloomed on the validity of Dempster’s rule of combination and its counter-intuitive behavior (not only in high conflicting situations, but also in low conflicting situations as well). That is why many rules of combination have been developed by different researchers [5] (Vol. 2) over the last decades. In this work we consider only the rule based on the proportional conflict redistribution principle no 5 (PCR5 rule) to combine basic belief assignments (BBAs). This choice is motivated not only by its conflict redistribution principle, but also by its ability to generate a unique canonical decomposition of any dichotomous BBA that will be convenient for decision-making from many sources of evidence.

This paper is organized as follows. After a brief recall of basics of belief functions in Section II, we present succinctly the canonical decomposition of a (dichotomous) BBA in Section III based on [6]. Then we propose a new decision-making support methodology that exploits this canonical decomposition in Section IV for working in a general framework with many (non dichotomous) sources of evidences, with basic illustrative examples. Conclusions are given in Section V.

## II. BASICS OF BELIEF FUNCTIONS

### A. Definitions

The answer<sup>1</sup> of the problem under concern is supposed to belong to a given finite discrete frame of discernment (FoD)  $\Theta = \{\theta_1, \theta_2, \dots, \theta_n\}$ , with  $n > 1$ . All elements of  $\Theta$  are mutually exclusive<sup>2</sup>. The set of all subsets of  $\Theta$  (including empty set  $\emptyset$  and  $\Theta$ ) is the power-set of  $\Theta$  denoted by  $2^\Theta$ . A Basic Belief Assignment (BBA) given by a source of evidence is defined [1] as  $m(\cdot) : 2^\Theta \rightarrow [0, 1]$  satisfying  $m(\emptyset) = 0$  and  $\sum_{A \in 2^\Theta} m(A) = 1$ . The quantity  $m(A)$  is the mass of belief of  $A$ . Belief and plausibility functions are respectively defined from  $m(\cdot)$  by

$$Bel(A) = \sum_{B \in 2^\Theta | B \subseteq A} m(B), \quad (1)$$

and

$$Pl(A) = \sum_{B \in 2^\Theta | A \cap B \neq \emptyset} m(B) = 1 - Bel(\bar{A}). \quad (2)$$

where  $\bar{A}$  is the complement of  $A$  in  $\Theta$ .

$Bel(A)$  and  $Pl(A)$  are usually interpreted respectively as lower and upper bounds of an unknown (subjective) probability measure  $P(A)$ .  $A$  is called a Focal Element (FE) of  $m(\cdot)$  if  $m(A) > 0$ . When all focal elements are singletons then  $m(\cdot)$  is called a *Bayesian BBA* [1] and its corresponding  $Bel(\cdot)$  function is equal to  $Pl(\cdot)$  and they are homogeneous to a (subjective) probability measure  $P(\cdot)$ . The vacuous BBA (VBBA for short) representing a totally ignorant source is defined as<sup>3</sup>  $m_v(\Theta) = 1$ . A dogmatic BBA is a BBA such that  $m(\Theta) = 0$ . If  $m(\Theta) > 0$  the BBA  $m(\cdot)$  is nondogmatic. A simple BBA is a BBA that has at most two focal sets and one of them is  $\Theta$ . A FoD is a dichotomous FoD if it has only two elements, say  $\Theta = \{A, \bar{A}\}$  with  $A \neq \emptyset$  and  $A \neq \Theta$ . A dichotomous BBA is a BBA defined over a dichotomous FoD.

### B. PCR5 Rule of Combination

The combination of distinct sources of evidence characterized by their BBAs is done by Dempster’s rule of combination in Shafer’s mathematical theory of evidence [1]. The

<sup>1</sup>I.e. the solution, or the decision to take.

<sup>2</sup>This is so-called Shafer’s model of FoD [5].

<sup>3</sup>The complete ignorance is denoted  $\Theta$  in Shafer’s book [1].

justification and behavior of Dempster's rule (corresponding to the normalized conjunctive rule) have been disputed from many counter-examples involving high and low conflicting sources (from both theoretical and practical standpoints) as reported in [4]. Many alternatives to Dempster's rule are now available [5], Vol. 2. Among them, we consider in the sequel the PCR5 rule which transfers the conflicting mass only to the elements involved in the conflict and proportionally to their individual masses, so that a more sophisticated and precise distribution is done with the PCR5 fusion process. The PCR5 rule is presented in details (with justification and examples) in [5], Vol. 2 and Vol. 3. We only briefly recall for convenience its formula for the fusion of two BBAs, which is symbolically noted as  $m_{PCR5} = PCR5(m_1, m_2)$ , where  $PCR5(\cdot, \cdot)$  represents the PCR5 fusion rule for two BBAs. With this PCR5 rule, one has  $m_{PCR5}(\emptyset) = 0$ , and  $\forall X \in 2^\Theta \setminus \{\emptyset\}$

$$m_{PCR5}(X) = m_{Conj}(X) + \sum_{\substack{X_2 \in 2^\Theta \\ X_2 \cap X = \emptyset}} \left[ \frac{m_1(X)^2 m_2(X_2)}{m_1(X) + m_2(X_2)} + \frac{m_2(X)^2 m_1(X_2)}{m_2(X) + m_1(X_2)} \right], \quad (3)$$

where  $m_{Conj}(X) = \sum_{\substack{X_1, X_2 \in 2^\Theta \\ X_1 \cap X_2 = X}} m_1(X_1) m_2(X_2)$  is the conjunctive rule, and where all denominators in (3) are different from zero. If a denominator is zero, that fraction is discarded. Extension of PCR5 for combining qualitative BBA's can be found in [5], Vols. 2 & 3. All propositions/sets are in a canonical form. A variant of PCR5, called PCR6 has been proposed by Martin and Osswald in [5], Vol. 2, for combining  $s > 2$  sources. The general formulas for PCR5 and PCR6 rules are also given in [5], Vol. 2. PCR6 coincides with PCR5 when one combines two sources. The difference between PCR5 and PCR6 lies in the way the proportional conflict redistribution is done as soon as three (or more) sources are involved in the fusion.

### III. CANONICAL DECOMPOSITION OF A DICHOTOMOUS BASIC BELIEF ASSIGNMENT

Because the canonical decomposition of a dichotomous BBA has been presented in details in [6], we only make a succinct presentation here. A FoD is a dichotomous FoD if it is made of only two elements, say  $\Theta = \{A, \bar{A}\}$  with  $A \cup \bar{A} = \Theta$  and  $A \cap \bar{A} = \emptyset$ .  $A$  is different from  $\Theta$  and from Empty-Set because we want to work with informative FoD. A dichotomous BBA  $m(\cdot) : 2^\Theta \rightarrow [0, 1]$  has the general form

$$m(A) = a, \quad m(\bar{A}) = b, \quad m(A \cup \bar{A}) = 1 - a - b, \quad (4)$$

with  $a, b \in [0, 1]$  and  $a + b \leq 1$ .

The canonical decomposition problem consists in finding the two following simpler BBAs  $m_p$  and  $m_c$  of the form

$$m_p(A) = x, \quad m_p(A \cup \bar{A}) = 1 - x, \quad (5)$$

$$m_c(\bar{A}) = y, \quad m_c(A \cup \bar{A}) = 1 - y, \quad (6)$$

with  $(x, y) \in [0, 1] \times [0, 1]$ , such that  $m = Fusion(m_p, m_c)$ , for a chosen rule of combination denoted by  $Fusion(\cdot, \cdot)$ . The simple BBA  $m_p(\cdot)$  is called the *pro-BBA* (or pro-evidence) of  $A$ , and the simple BBA  $m_c(\cdot)$  the *contra-BBA* (or contra-evidence) of  $A$ . The BBA  $m_p(\cdot)$  is interpreted as a source of evidence providing an uncertain evidence in favor of  $A$ , whereas  $m_c(\cdot)$  is interpreted as a source of evidence providing an uncertain contrary evidence about  $A$ . In [6], we proved that this decomposition always exists and is unique if we use the PCR5 fusion rule. In the vacuous BBA case when  $a = 0$  and  $b = 0$ , the BBA  $m(\cdot)$  can be interpreted as the PCR5 fusion of two degenerate pro- and contra-evidences BBAs  $m_p(\cdot)$  and  $m_c(\cdot)$  which coincide with the vacuous BBA with  $x = 0$  and  $y = 0$ . Hence any (Bayesian, or non Bayesian) dichotomous BBA  $m(\cdot)$  can be always interpreted as the result of the PCR5 fusion of these two (pros and cons) aspects of evidence about  $A$ . It is worth noting that this type of canonical decomposition is different of Smets' canonical decomposition problem [7] which needs to work with generalized simple BBA which are not *stricto sensu* valid BBAs as defined by Shafer [1].

For the case of dichotomous dogmatic BBA, the expression of solutions  $x$  and  $y$  of canonical decomposition are as follows [6]:

- if  $a = b$  and  $a + b = 1$  then  $a = b = 0.5$  and  $x = y = 1$ ;
- if  $a < b$  then  $x < y$ , and we have

$$\begin{cases} y = 1, \\ x = \frac{a + \sqrt{a^2 + 4a}}{2}; \end{cases}$$

- if  $a > b$  then  $x > y$ , and we have

$$\begin{cases} x = 1, \\ y = \frac{b + \sqrt{b^2 + 4b}}{2}. \end{cases}$$

For the case of dichotomous non-dogmatic BBA, the expression of solutions  $x$  and  $y$  of the canonical decomposition do not have simple analytical expression because one has to find  $x$  and  $y$  solutions of the system

$$a = x(1 - y) + \frac{x^2 y}{x + y} = \frac{x^2 + xy - xy^2}{x + y}, \quad (7)$$

$$b = (1 - x)y + \frac{xy^2}{x + y} = \frac{y^2 + xy - x^2 y}{x + y}, \quad (8)$$

under the constraints  $(a, b) \in [0, 1]^2$ , and  $0 < a + b < 1$ . In fact, we have proved in [6] that  $x \in [a, a + b] \subset [0, 1]$  and  $y \in [b, a + b] \subset [0, 1]$ , but the explicit expression of  $x$  and  $y$  are very complicated to obtain analytically (even with modern symbolic computing systems like Mathematica™, or Maple™) because after algebraic calculation, and for  $x \neq 1$ , one has to solve the following quartic equation which has at most four real solutions with only a valid one in  $[a, a + b]$

$$x^4 + (-a - 2)x^3 + (2a + b)x^2 + (a + b - ab - b^2)x + (-a^2 - ab) = 0, \quad (9)$$

and then compute  $y$  by  $y = (a + b - x)(1 - x)$ .

Once the numerical values are committed to  $a$  and to  $b$  the numerical (approximate) solutions  $x$  and then  $y$  can be easily obtained by a standard numerical solver. For instance, with Matlab™ we can use the `fsolve` command, and this is what we use to make the canonical decomposition of dichotomous non-dogmatic BBA.

### A. Canonical Decompositions From Other Well-Known Rules

In [6] we did prove that this type of canonical decomposition cannot be obtained by the conjunctive rule only, because if  $m_p$  and  $m_c$  exist and if  $x > 0$  and  $y > 0$  then  $m_{Conj}(\emptyset) = x \cdot y > 0$  which means that  $m = Conj(m_p, m_c)$  is not a proper BBA as defined by Shafer's. If we use the disjunctive rule of combination we will always obtain the vacuous BBA as the result<sup>4</sup> of  $Disj(m_p, m_c)$  because  $m_p(A)m_c(\bar{A})$ ,  $m_p(A)m_c(A \cup \bar{A})$ ,  $m_p(A \cup \bar{A})m_c(\bar{A})$  and  $m_p(A \cup \bar{A})m_c(A \cup \bar{A})$  will all be committed to the uncertainty  $A \cup \bar{A}$ . So for any choice of  $m_p$  and  $m_c$  we always get same result (the vacuous BBA) when using the disjunctive rule making the canonical decomposition of non vacuous dichotomous BBA  $m$  just impossible. Due to the particular simple form of BBAs  $m_p(\cdot)$  and  $m_c(\cdot)$ , Yager's rule [8] and Dubois-Prade rule [9] coincide, and we have to search  $x$  and  $y$  in  $[0, 1]$  such that  $m(A) = a = x(1 - y)$  and  $m(\bar{A}) = b = (1 - x)y$ . Assuming<sup>5</sup>  $y < 1$ , one gets from the first equation  $x = a/(1 - y)$ . By replacing  $x$  by its expression in the second equation  $y - xy = b$  we have to find  $y$  in  $[0, 1]$  such that (after basic algebraic simplifications)  $y^2 + (a - b - 1)y + b = 0$ . This 2nd order equation admits one or two real solutions  $y_1$  and  $y_2$  if and only if the discriminant is null or positive respectively, that is if  $(a - b - 1)^2 - 4b \geq 0$ . However this discriminant can become negative depending on the values of  $a$  and  $b$ . For instance, for  $a = 0.3$  and  $b = 0.6$ , we have  $(a - b - 1)^2 - 4b = -0.71$  which means that there is no real solution for the equation  $y^2 - 1.3 \cdot y + 0.6 = 0$ . Therefore, in general (that is for all possible values  $a$  and  $b$  of the BBA  $m$ ), the canonical decomposition of the BBA  $m(\cdot)$  cannot be obtained from Yager's and Dubois & Prade rules of combination. If we use the averaging rule, we are searching  $x$  and  $y$  in  $[0, 1]$  such that  $m(A) = a = (x + 0)/2$  and  $m(\bar{A}) = b = (0 + y)/2$ , which means that  $x = 2a$  and  $y = 2b$  with  $x$  and  $y$  in  $[0, 1]$ . So, if  $a > 0.5$  or  $b > 0.5$  the canonical decomposition is impossible to make with the averaging rule of combination. Therefore, in general, the averaging rule is not able to provide a canonical decomposition of the BBA  $m(\cdot)$ .

If we consider the canonical decomposition of a dichotomous non-dogmatic BBA ( $a + b < 1$ ) using Dempster's rule of combination [1], denoted  $DS(m_p, m_c)$ , we have to obtain

<sup>4</sup> $Disj(m_p, m_c)$  denotes the disjunctive fusion of  $m_p$  with  $m_c$ .

<sup>5</sup>Taking  $y = 1$  would mean that  $x(1 - y) = 0$  but  $m(A) = a$  with  $a \neq 0$  in general, so the choice of  $y = 1$  is not possible.

$x$  and  $y$  in  $[0, 1]$  such that<sup>6</sup>  $xy \neq 1$  and

$$m(A) = a = \frac{x(1 - y)}{1 - xy}, \quad (10)$$

$$m(\bar{A}) = b = \frac{y(1 - x)}{1 - xy}, \quad (11)$$

with the constraints  $0 < x < 1$  and  $0 < y < 1$ .

Therefore,

$$x = \frac{a}{1 - y + ay}, \quad y \neq \frac{1}{1 - a}, \quad (12)$$

and we solve the equation  $y - xy + bxy = b$  with  $x$  expressed as function of  $y$  as above. We get the equation for  $a \neq 1$

$$(a - 1)y^2 + (1 + b - a)y - b = 0, \quad (13)$$

whose two solutions are  $y_1 = b/(1 - a)$  and  $y_2 = 1$  - see [6] for details.

For the case  $a \neq 1$ , the second "solution"  $y_2 = 1$  implies  $x = \frac{a}{1 - y_2 + ay_2} = \frac{a}{a} = 1$  which is not an acceptable solution<sup>7</sup> because one must have  $xy \neq 1$ . The solution  $(x, y)$  of the decomposition problem for  $a \neq 1$  is actually given by the first solution  $y_1$ , that is

$$y = y_1 = \frac{b}{1 - a} \in [0, 1), \quad (14)$$

$$x = \frac{a}{1 - y + ay} = \frac{a}{1 - b} \in [0, 1). \quad (15)$$

The analysis of the case  $a = 1$  corresponding to the dogmatic BBA given by  $m(A) = a = 1$ ,  $m(\bar{A}) = b = 0$ ,  $m(A \cup \bar{A}) = 1 - a - b = 0$  shows that this BBA is not canonically decomposable by Dempster's rule. Why? Because one has to solve with  $0 \leq x, y \leq 1$  and  $1 - xy \neq 0$  the system of equations  $(x - xy)/(1 - xy) = 1$  and  $(y - xy)(1 - xy) = 0$  which is satisfied for  $x = 1$  and  $y \in [0, 1)$ , that is any value in  $[0, 1)$  can be chosen for  $y$ . Similarly, for the case  $(a, b) = (0, 1)$  one has to solve with  $0 \leq x, y \leq 1$  and  $1 - xy \neq 0$  the system of equations  $(x - xy)/(1 - xy) = 0$  and  $(y - xy)/(1 - xy) = 1$  which is satisfied for  $y = 1$  and  $x \in [0, 1)$ , that is any  $x$  value in  $[0, 1)$  can be chosen. Therefore one sees that for the case  $(a, b) = (1, 0)$  and the case  $(a, b) = (0, 1)$  there is no unique decomposition of these dogmatic BBAs from Dempster's rule of combination. More generally, any dogmatic BBA  $m(A) = a$ ,  $m(\bar{A}) = b$  with  $a + b = 1$  is not decomposable from Dempster's rule of combination for the case when  $(a, b) \neq (1, 0)$  and  $(a, b) \neq (0, 1)$  - See Theorem 4 with its proof in [6].

In summary, the canonical decomposition based on Dempster's rule of combination is possible only for nondogmatic BBA with  $0 < a < 1$ ,  $0 < b < 1$  and  $a + b < 1$  and we have  $x = \frac{a}{1 - b}$  and  $y = \frac{b}{1 - a}$ . Dempster's rule does not allow to obtain a canonical decomposition if the BBA is a Bayesian (dogmatic) dichotomous BBA.

<sup>6</sup>The third equality  $m(A \cup \bar{A}) = 1 - a - b = \frac{(1 - x)(1 - y)}{1 - xy}$  being redundant with (10) and (11) is useless.

<sup>7</sup>Otherwise the denominator of (10) and (11) will equal zero.

### Example where Dempster's canonical decomposition is possible

Consider  $m(A) = a = 0.6$ ,  $m(\bar{A}) = b = 0.2$  and  $m(A \cup \bar{A}) = 1 - a - b = 0.2$ . The solution  $(x, y)$  of the decomposition of  $m(\cdot)$  based on Dempster's rule is

$$x' = \frac{a}{1-b} = \frac{0.6}{1-0.2} = 0.75,$$

and

$$y' = \frac{b}{1-a} = \frac{0.2}{1-0.6} = 0.50.$$

Therefore, the pro- and contra- evidential BBAs  $m_p$  and  $m_c$  are given by

$$\begin{aligned} m_p(A) &= x = 0.75, & m_p(A \cup \bar{A}) &= 1 - x = 0.25, \\ m_c(\bar{A}) &= y = 0.50, & m_c(A \cup \bar{A}) &= 1 - y = 0.50. \end{aligned}$$

It can be verified that  $DS(m_p, m_c) = m$ .

If we make the PCR5-based canonical decomposition, we will obtain in this example  $x \approx 0.6861$  and  $y \approx 0.3628$ . Therefore, the pro- and contra- evidential BBAs  $m_p$  and  $m_c$  based on the PCR5-based canonical decomposition are

$$\begin{aligned} m_p(A) &= x = 0.6861, & m_p(A \cup \bar{A}) &= 1 - x = 0.3139, \\ m_c(\bar{A}) &= y = 0.3628, & m_c(A \cup \bar{A}) &= 1 - y = 0.6372. \end{aligned}$$

It can be verified that  $PCR5(m_p, m_c) = m$ .

In the case where Dempster's rule can be applied for making the canonical decomposition (that is when  $a + b < 1$ ) we see that the canonical values (parameters)  $x$  and  $y$  can be very different from those obtained with PCR5 rule as shown in the previous example. This is normal because the principles of conflicting information redistribution of Dempster's rule and PCR5 rule are very different, and there is no link between parameters  $x$  and  $y$  obtained with Dempster's rule versus those obtained from PCR5. In PCR5 rule the conflict is a refined conflict, i.e. the conflict is split into partial conflicts, so in PCR5 the total conflict is more accurately redistributed than in Dempster's rule because each partial conflict is redistributed only to the elements involved into it, while in Dempster's rule the total conflict is redistributed to all focal elements, therefore even the elements that were not involved in the conflict receive conflicting mass, which is inaccurate.

It is worth noting that the internal conflict of  $m$  based on Dempster's rule will be in this example  $xy = 0.75 \cdot 0.5 = 0.375$ , whereas the internal conflict of  $m$  based on PCR5 rule will be only  $xy \approx 0.6861 \cdot 0.3628 \approx 0.2489$ . In fact we can attest that the internal conflict obtained from PCR5-based canonical decomposition is always lesser (or equal) to the internal conflict obtained from Dempster-based canonical decomposition. Although such claim cannot be proved algebraically<sup>8</sup>, we can always make a fine sampling of  $(a, b)$  values in  $[0, 1)$  satisfying  $a + b < 1$  to evaluate numerically

<sup>8</sup>Because there is no simple analytical expressions for solutions  $x$  and  $y$  of PCR5-based canonical decomposition.

$x$  and  $y$  and compare the internal conflict  $xy$  to the internal conflict, denoted  $x'y' = \frac{a}{1-b} \cdot \frac{b}{1-a}$ , obtained with Dempster-based canonical decomposition. In doing this we see that the difference  $\Delta = x'y' - xy$  is always greater (or equal) to zero as clearly shown in Figure 1. This means that the PCR5-based canonical decomposition is more efficient than Dempster-based canonical decomposition because it always yield pro- and contra-evidences which are less conflicting when using PCR5 rule than when using Dempster's rule, which is normal.

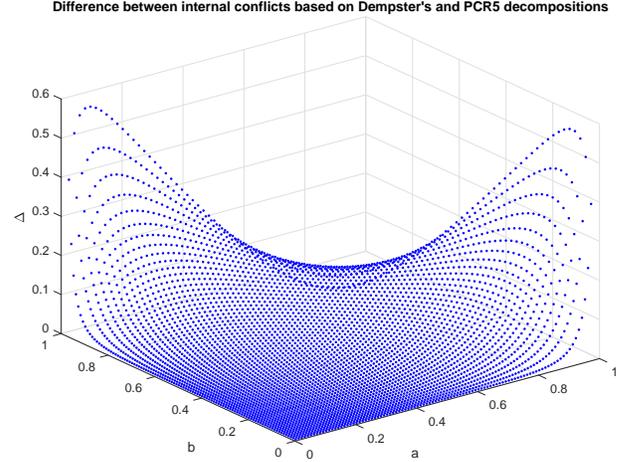

Figure 1. Plot of  $\Delta = x'y' - xy$  as function of  $a$  and  $b$ .

It is important to keep in mind that Dempster-based canonical decomposition is only possible for non-dogmatic BBAs (when  $a + b < 1$ ) but cannot be obtained with dogmatic BBAs, whereas PCR5-based canonical decomposition works for all types of dichotomous BBAs (dogmatic and non-dogmatic ones).

### B. Simple Example of PCR5-Based Canonical Decomposition

Let consider  $m(A) = 0.3$ ,  $m(\bar{A}) = 0.4$  and  $m(A \cup \bar{A}) = 1 - m(A) - m(\bar{A}) = 0.3$ , therefore  $a = 0.3$  and  $b = 0.4$ . The quartic equation (9) becomes

$$x^4 - 2.3x^3 + x^2 + 0.42x - 0.21 = 0. \quad (16)$$

The four solutions of this quartic equation are approximately<sup>9</sup>

$$\begin{aligned} x_1 &\approx 1.5203, \\ x_2 &\approx -0.4243, \\ x_3 &\approx 0.7942, \\ x_4 &\approx 0.4099. \end{aligned}$$

One sees that  $x_1$  and  $x_2$  are not acceptable solutions because they do not belong to  $[0, 1]$ . If we take  $x_3 \approx 0.7942$  then will get  $y_3 = (a + b - x_3)/(1 - x_3) = (0.7 - x_3)/(1 - x_3) \approx -0.4576$ . We see that  $y_3 \notin [0, 1]$  and therefore the pair  $(x_3, y_3)$  cannot be a solution of the PCR5-based canonical

<sup>9</sup>The solutions can be easily obtained with the `roots` command of Matlab™.

decomposition problem for the BBA  $m(\cdot)$  of this example. If we take  $x_4 \approx 0.4099$  then will get  $y_4 = (a+b-x_4)/(1-x_4) = (0.7-x_4)/(1-x_4) \approx 0.4916$  which belongs to  $[0, 1]$ . So the pair  $(x_4, y_4) \in [0, 1]^2$  is the unique solution of the canonical decomposition problem. Therefore the canonical masses  $m_p(\cdot)$  and  $m_c(\cdot)$  are given by

$$m_p(A) \approx 0.4099, \quad m_p(A \cup \bar{A}) \approx 0.5901,$$

and

$$m_c(\bar{A}) \approx 0.4916, \quad m_c(A \cup \bar{A}) \approx 0.5084.$$

It can be verified that  $PCR5(m_p, m_c) = m$ .

### C. Advantages and Limitation of PCR5-Based Decomposition

The PCR5-based canonical decomposition offers the following advantages:

- 1) It is well justified theoretically.
- 2) It gives us access to the simpler pro- and contra-evidences  $m_p(\cdot)$  and  $m_c(\cdot)$  which are unique and always exist for any possible (dogmatic, or non-dogmatic) dichotomous BBA  $m(\cdot)$ .
- 3) It allows to define clearly the notion of internal conflict of a dichotomous source of evidence simply as  $K_{int}(m) \triangleq m_p(A)m_c(\bar{A})$ .
- 4) It always provides less conflicting pro- and contra-evidences than what we would obtain with Dempster's rule when considering non-dogmatic dichotomous BBA  $m(\cdot)$ . This proves the superiority of PCR5-based canonical decomposition over Dempster's-based canonical decomposition in general.
- 5) It allows also to adjust or revise<sup>10</sup> quite easily a dichotomous source of evidence (if needed) according to the knowledge one has on it by reinforcing or discounting its pro- or contra-evidential BBA.
- 6) It can be easily achieved with classical numerical solvers on the shelf.
- 7) The decomposition can be done off-line for many sampled  $(a, b)$  values at any precision we want, and stored in computer memory for working directly with  $m_p(\cdot)$  and  $m_c(\cdot)$  instead of making the decomposition on the fly. This is of prime importance for real-time applications where this method could be used.
- 8) It allows to establish efficient fast<sup>11</sup> suboptimal PCR5 fusion scheme, see [10] for details, examples and evaluations.

The only important limitation of this PCR5-based canonical decomposition is that it applies only to dichotomous BBAs, and it seems very difficult (maybe impossible) to use or to extend it for making directly some new canonical decomposition of non dichotomous BBAs. Because of this limitation the use of PCR5-based canonical decomposition appears, at first glance, quite restrictive for being really useful in applications involving non dichotomous BBAs. Of course

in applications working with dichotomous BBAs (like those in robotics or for autonomous vehicle navigation using belief-based perception based on grid occupancy) this PCR5-based canonical decomposition may have a great interest. In fact we have already used it for belief-based inter-criteria analysis in [11] and that is why we do not present our results in this work. Nevertheless we will show in the next section how this PCR5-based canonical decomposition could be used for the decision-making support in a more general context involving many non-dichotomous BBAs. This is a problem which has not been addressed in [6].

## IV. DECISION-MAKING USING PCR5-BASED DECOMPOSITION

In this section we propose a new simple general decision-making scheme based on PCR5-based canonical decomposition of dichotomous BBA. We consider  $S > 2$  distinct sources of evidence characterized by their BBAs<sup>12</sup>  $m_s^\Theta(\cdot)$  defined over the same (possibly non dichotomous) FoD  $\Theta = \{\theta_1, \dots, \theta_n\}$ , with  $n > 1$ .

Can we exploit the PCR5-based canonical decomposition in this context to make a decision? How? We answer positively to the first question and explain in details how we can proceed. For this, we need to express the problem in the framework of dichotomous BBAs that has been presented in the previous section. More precisely, suppose one has a BBA  $m^\Theta(\cdot)$  defined on  $2^\Theta$  with  $|\Theta| \geq 2$ , then based on Bel and Pl formulas (1)-(2), it is always possible to calculate  $Bel^\Theta(X)$  and  $Pl^\Theta(X)$  for any  $X \in 2^\Theta$ . From  $Bel^\Theta(X)$  and  $Pl^\Theta(X)$  one can always build a simpler coarsened dichotomous BBA on the dichotomous (coarsened) FoD  $\Theta_X \triangleq \{X, \bar{X}\}$  if  $X \neq \emptyset$  and  $X \neq \Theta_X$  as follows

$$m^{\Theta_X}(X) = Bel^\Theta(X), \quad (17)$$

$$m^{\Theta_X}(\bar{X}) = 1 - Pl^\Theta(X), \quad (18)$$

$$m^{\Theta_X}(X \cup \bar{X}) = Pl^\Theta(X) - Bel^\Theta(X). \quad (19)$$

Hence,  $Bel^{\Theta_X}(X) = m^{\Theta_X}(X) = Bel^\Theta(X)$  and  $Pl^{\Theta_X}(X) = m^{\Theta_X}(X) + m^{\Theta_X}(X \cup \bar{X}) = Bel^\Theta(X) + Pl^\Theta(X) - Bel^\Theta(X) = Pl^\Theta(X)$ . This dichotomous BBA  $m^{\Theta_X}(\cdot)$  can always be decomposed canonically into its pro- and contra-evidences  $m_p^{\Theta_X}(\cdot)$  and  $m_c^{\Theta_X}(\cdot)$ .

Therefore, instead of combining  $S > 1$  non dichotomous BBAs  $m_s^\Theta(\cdot)$  for  $s = 1, 2, \dots, S$  altogether from which a decision is classically drawn, we propose to make the decision from the set of all combined coarsened BBAs relatively to each possible dichotomous frame of discernment  $\Theta_X$ . Of course this decision-scheme is only suboptimal because the whole information is not processed (combined) altogether, but separately using only the coarsened (less informative) BBAs  $m_s^{\Theta_X}(X)$ . However, this method allows to use fast suboptimal PCR5 fusion of  $m_s^{\Theta_X}(X)$  thanks to PCR5-based canonical decomposition as presented in [10] which can be applied with many (hundreds or even thousands) sources of dichotomous

<sup>10</sup>This point is not detailed here because is out of the scope of this paper.

<sup>11</sup>Where the complexity is linear with the number of dichotomous BBAs to fuse.

<sup>12</sup>For clarity, we need to introduce in the notations a superscript to indicate the FoD we are working on.

BBAs. With this simple suboptimal decision-scheme we can easily restrict the domain  $\mathcal{D}$  on which the decisions can be made, for instance  $\mathcal{D}$  can be chosen as the set of singletons of  $2^\Theta$ , or any other subset of  $2^\Theta$  depending on the application under concern as it will be shown in the next section. The generic steps of the method we propose are as follows:

- **Inputs:** BBAs  $m_s^\Theta(\cdot)$ ,  $s = 1, \dots, S$ , and the decision domain  $\mathcal{D} \subset 2^\Theta$ .
- **Step 1:** For  $s = 1, \dots, S$ , coarsening of  $m_s^\Theta(\cdot)$  into dichotomous BBA  $m_s^{\Theta_X}(\cdot)$ , for each  $X \in \mathcal{D}$  based on (17)-(19).
- **Step 2:** For  $s = 1, \dots, S$ , PCR5-based canonical decomposition of  $m_s^{\Theta_X}(\cdot)$  to get pro- and contra-evidences  $m_{p,s}^{\Theta_X}(\cdot)$  and  $m_{c,s}^{\Theta_X}(\cdot)$ .
- **Step 3:** Conjunctive fusion of all the pro-evidences  $m_{p,s}^{\Theta_X}(\cdot)$  to get  $m_p^{\Theta_X}(\cdot)$ .
- **Step 4:** Conjunctive fusion of all the contra-evidences  $m_{c,s}^{\Theta_X}(\cdot)$  to get  $m_c^{\Theta_X}(\cdot)$ .
- **Step 5:** PCR5 fusion of  $m_p^{\Theta_X}(\cdot)$  with  $m_c^{\Theta_X}(\cdot)$  to get  $m_{PCR5}^{\Theta_X}(\cdot)$  for  $X \in \mathcal{D}$ .
- **Step 6:** Decision-making from the set of the combined coarsened dichotomous BBAs  $\{m_{PCR5}^{\Theta_X}(\cdot), X \in \mathcal{D}\}$  to get the final decision  $\hat{X} \in \mathcal{D}$ .
- **Output:** the final decision  $\hat{X} \in \mathcal{D}$

In steps 3 and 4 we use the conjunctive fusion because there is no conflict between all pro-evidences  $m_{p,s}^{\Theta_X}(\cdot)$ , and there is also no conflict between all contra-evidences  $m_{c,s}^{\Theta_X}(\cdot)$ ,  $s = 1, \dots, S$ . The steps 1 to 5 do not require high computational burden and they can be done very quickly, specially if PCR5-based decompositions have been done off-line (as they should be) [10].

We must detail a bit more the principle of the decision-making for the step 6. Actually, the decision-making for step 6 can be interpreted as a decision-making problem from a set or coarsened BBAs  $m_{PCR5}^{\Theta_X}(\cdot)$  defined over different dichotomous FoD  $\Theta_X$  which are all the different coarsenings of the whole (refined original) FoD  $\Theta$ . In this paper we propose two methods to make the decision from the set of coarsened BBAs  $\{m_{PCR5}^{\Theta_X}(\cdot), X \in \mathcal{D}\}$ .

#### A. Method 1 for Step 6

This method is very simple. We take the decision  $\hat{X}$  corresponding to the largest value of  $m_{PCR5}^{\Theta_X}(X)$ , that is

$$\hat{X} = \arg \max_{X \in \mathcal{D}} (m_{PCR5}^{\Theta_X}(X)) \quad (20)$$

If there exist several arguments having the largest value (i.e. there is a tie), we select the one whose  $m_{PCR5}^{\Theta_X}(\bar{X})$  is smaller.

**Example 1 (without tie):** Suppose  $\Theta = \{A, B, C, D, E\}$  and we want to make a decision/choice only among the elements

of  $\mathcal{D} = \{A, B, C\}$ . Suppose after applying steps 1-5 we get the following 3 BBAs

$$\begin{aligned} m_{PCR5}^{\Theta_A}(A) &= 0.3, m_{PCR5}^{\Theta_A}(\bar{A}) = 0.2, m_{PCR5}^{\Theta_A}(A \cup \bar{A}) = 0.5, \\ m_{PCR5}^{\Theta_B}(B) &= 0.1, m_{PCR5}^{\Theta_B}(\bar{B}) = 0.5, m_{PCR5}^{\Theta_B}(B \cup \bar{B}) = 0.4, \\ m_{PCR5}^{\Theta_C}(C) &= 0.4, m_{PCR5}^{\Theta_C}(\bar{C}) = 0.3, m_{PCR5}^{\Theta_C}(C \cup \bar{C}) = 0.3. \end{aligned}$$

The decision will be  $\hat{X} = C$  because

$$m_{PCR5}^{\Theta_C}(C) > m_{PCR5}^{\Theta_A}(A) > m_{PCR5}^{\Theta_B}(B).$$

**Example 2 (with tie)** We consider same  $m_{PCR5}^{\Theta_B}(\cdot)$  and  $m_{PCR5}^{\Theta_C}(\cdot)$  as in example 1 but  $m_{PCR5}^{\Theta_A}(\cdot)$  is given by

$$m_{PCR5}^{\Theta_A}(A) = 0.4, m_{PCR5}^{\Theta_A}(\bar{A}) = 0.2, m_{PCR5}^{\Theta_A}(A \cup \bar{A}) = 0.4.$$

In this case, there is a tie between  $A$  and  $C$  because  $m_{PCR5}^{\Theta_A}(A) = m_{PCR5}^{\Theta_C}(C) = 0.4$ . But because  $m_{PCR5}^{\Theta_A}(\bar{A}) < m_{PCR5}^{\Theta_C}(\bar{C})$  we will take  $\hat{X} = A$  as the final decision.

The interest of this method is above all its simplicity, but it does not allow to quantify the quality (trustfulness) of the decision which is often useful and required in decision-making support systems, and that is why we propose a second method for the decision-making of step 6.

#### B. Method 2 for Step 6

This second method is a bit more sophisticated but it circumvents the exponential complexity of the direct PCR6 fusion of  $S \geq 2$  BBAs defined on non dichotomous FoD  $\Theta$ . Once the step 5 is accomplished we propose to fuse altogether the (coarsened) dichotomous  $m_{PCR5}^{\Theta_X}(\cdot)$  and to apply the decision-making method based on the distance between the belief intervals [12]. Because the fusion must operate on the same common frame, we need just to express each BBA  $m_{PCR5}^{\Theta_X}(\cdot)$  as a dichotomous BBA on  $\Theta$  which is denoted  $m_{PCR5}^{\Theta_X \uparrow \Theta}(\cdot)$ . This is done very easily by just expressing each  $\bar{X}$  as the disjunction of all elements of  $\Theta$  included in  $\bar{X}$ . The fusion of BBAs  $m_{PCR5}^{\Theta_X \uparrow \Theta}(\cdot)$  is done by the weighted averaging rule of combination, where each weighting factor depends on the decision-making easiness of the BBA  $m_{PCR5}^{\Theta_X}(\cdot)$  to fuse. The easier the decision-making, the higher the weighting factor. We summarize this method 2:

- 1) For each  $X \in \mathcal{D}$ , establish  $m_{PCR5}^{\Theta_X \uparrow \Theta}(\cdot)$  from  $m_{PCR5}^{\Theta_X}(\cdot)$
- 2) For each  $X \in \mathcal{D}$ , compute the weighting factor  $w(X)$  of  $m_{PCR5}^{\Theta_X \uparrow \Theta}(\cdot)$  by

$$w(X) = \frac{1}{C} (1 - h(m_{PCR5}^{\Theta_X \uparrow \Theta})), \quad (21)$$

where  $C$  is a normalization factor given by  $C = \sum_{X \in \mathcal{D}} (1 - h(m_{PCR5}^{\Theta_X \uparrow \Theta}))$ , and where  $h(m_{PCR5}^{\Theta_X \uparrow \Theta}) = H(m_{PCR5}^{\Theta_X \uparrow \Theta}) / H_{\max} \in [0, 1]$  is the normalized pignistic entropy of the BBA  $m_{PCR5}^{\Theta_X \uparrow \Theta}$  defined by  $H(m_{PCR5}^{\Theta_X \uparrow \Theta}) = - \sum_{X \in 2^\Theta} \text{BetP}(X) \log_2(\text{BetP}(X))$  and  $\text{BetP}(X)$  is the pignistic probability of  $X$  [13], and  $H_{\max} = \log_2 |\Theta|$ .

- 3) Make the weighting average of  $m_{PCR5}^{\Theta_X \uparrow \Theta}(\cdot)$  for all  $X \in \mathcal{D}$  to get the BBA

$$m^\Theta(\cdot) = \sum_{X \in \mathcal{D}} w(X) m_{PCR5}^{\Theta_X \uparrow \Theta}(\cdot). \quad (22)$$

- 4) From  $m^\Theta(\cdot)$  make the decision based on minimum of belief-interval distance [12], that is

$$\hat{X} = \arg \min_{X \in \mathcal{D}} d_{BI}(m^\Theta, m_X^\Theta), \quad (23)$$

where  $m_X^\Theta$  is the BBA focused on  $X$  that is  $m_X^\Theta(X) = 1$  and  $m_X^\Theta(Y) = 0$  if  $Y \neq X$ , and where  $d_{BI}(\cdot, \cdot)$  is the belief-interval distance defined by (see [12] for details, justification and examples)

$$d_{BI}(m_1, m_2) \triangleq \sqrt{N_c \cdot \sum_{X \in 2^\Theta} d_W^2(BI_1(X), BI_2(X))}, \quad (24)$$

where  $N_c = 1/2^{|\Theta|-1}$  is a normalization factor to have  $d_{BI}(m_1, m_2) \in [0, 1]$ , and  $d_W(BI_1(X), BI_2(X))$  is the Wassertein's distance between belief intervals

$$BI_1(X) \triangleq [Bel_1(X), Pl_1(X)] = [a_1, b_1],$$

and

$$BI_2(X) \triangleq [Bel_2(X), Pl_2(X)] = [a_2, b_2],$$

given by

$$d_W([a_1, b_1], [a_2, b_2]) \triangleq \left[ \left[ \frac{a_1 + b_1}{2} - \frac{a_2 + b_2}{2} \right]^2 + \frac{1}{3} \left[ \frac{b_1 - a_1}{2} - \frac{b_2 - a_2}{2} \right]^2 \right]^{\frac{1}{2}}.$$

- 5) The quality (or trustfulness) of the decision is given by

$$q(\hat{X}) \triangleq 1 - \frac{d_{BI}(m, m_{\hat{X}})}{\sum_{X \in \mathcal{D}} d_{BI}(m, m_X)}. \quad (25)$$

$q(\hat{X}) \in [0, 1]$  becomes maximum (equal to one) when  $d_{BI}(m^\Theta, m_{\hat{X}}^\Theta)$  is zero, which means that  $m^\Theta(\cdot)$  is focused only on  $\hat{X}$ . The higher  $q(\hat{X})$  is, the more confident in the decision  $\hat{X}$  we are. When there exists a tie between multiple decisions  $\{\hat{X}_j, j > 1\}$ , then the prudent decision corresponding to their disjunction  $\hat{X} = \cup_j \hat{X}_j$  should be preferred (if allowed), or we can apply the method 1 to resolve the tie, or in desperation select randomly  $\hat{X}$  among the elements  $\hat{X}_j$  involved in the tie.

Of course we could adopt a more complicate method where the averaging fusion could operate on all the possible dichotomous BBAs related with each element  $X \in 2^{\Theta \setminus \{\theta, \Theta\}}$  instead of  $X \in \mathcal{D}$ , but this would substantially increase the computational burden. Because the decision  $\hat{X}$  must be constrained to belong to  $\mathcal{D}$ , we restrict the fusion to be applied only for the dichotomous BBAs related to these elements only. By doing this we can reduce substantially the computational burden if  $|\mathcal{D}|$  is much lesser than  $2^{|\Theta|}$ .

For convenience, we show how works the method 2 in the previous Example 1 using the same  $\Theta$  and  $\mathcal{D} = \{A, B, C\}$ .

We have to make the weighted average of the three following BBAs

$$\begin{cases} m_{PCR5}^{\Theta_A \uparrow \Theta}(A) = 0.3, \\ m_{PCR5}^{\Theta_A \uparrow \Theta}(B \cup C \cup D \cup E) = 0.2, \\ m_{PCR5}^{\Theta_A \uparrow \Theta}(A \cup \bar{A} = \Theta) = 0.5, \end{cases}$$

$$\begin{cases} m_{PCR5}^{\Theta_B \uparrow \Theta}(B) = 0.1, \\ m_{PCR5}^{\Theta_B \uparrow \Theta}(A \cup C \cup D \cup E) = 0.5, \\ m_{PCR5}^{\Theta_B \uparrow \Theta}(B \cup \bar{B} = \Theta) = 0.4, \end{cases}$$

$$\begin{cases} m_{PCR5}^{\Theta_C \uparrow \Theta}(C) = 0.4, \\ m_{PCR5}^{\Theta_C \uparrow \Theta}(A \cup B \cup D \cup E) = 0.3, \\ m_{PCR5}^{\Theta_C \uparrow \Theta}(C \cup \bar{C} = \Theta) = 0.3, \end{cases}$$

with  $B \cup C \cup D \cup E = \bar{A}$ ,  $A \cup C \cup D \cup E = \bar{B}$  and  $A \cup B \cup D \cup E = \bar{C}$ . The pignistic entropies are respectively equal to  $H(m_{PCR5}^{\Theta_A \uparrow \Theta}) \approx 2.1710$ ,  $H(m_{PCR5}^{\Theta_B \uparrow \Theta}) \approx 2.3201$  and  $H(m_{PCR5}^{\Theta_C \uparrow \Theta}) \approx 2.0754$ , and their normalized values are  $h(A) \approx 2.1710/2.3219 = 0.9350$ ,  $h(B) \approx 2.3201/2.3219 = 0.9992$  and  $h(C) \approx 2.0754/2.3219 = 0.8938$ . From Eq. (21) we get the weighting factors  $w(A) \approx 0.37803$ ,  $w(B) \approx 0.00463$  and  $w(C) \approx 0.61734$ , and the weighted average BBA is

$$\begin{aligned} m^\Theta(A) &= w(A)m_{PCR5}^{\Theta_A \uparrow \Theta}(A) + w(B) \cdot 0 + w(C) \cdot 0 \approx 0.1134, \\ m^\Theta(B) &= w(A) \cdot 0 + w(B)m_{PCR5}^{\Theta_B \uparrow \Theta}(B) + w(C) \cdot 0 \approx 0.0005, \\ m^\Theta(C) &= w(A) \cdot 0 + w(B) \cdot 0 + w(C)m_{PCR5}^{\Theta_C \uparrow \Theta}(C) \approx 0.2469, \\ m^\Theta(B \cup C \cup D \cup E) &= w(A)m_{PCR5}^{\Theta_A \uparrow \Theta}(B \cup C \cup D \cup E) \\ &\quad + w(B) \cdot 0 + w(C) \cdot 0 \approx 0.0756, \\ m^\Theta(A \cup C \cup D \cup E) &= w(A) \cdot 0 \\ &\quad + w(B)m_{PCR5}^{\Theta_B \uparrow \Theta}(A \cup C \cup D \cup E) \\ &\quad + w(C) \cdot 0 \approx 0.0023, \\ m^\Theta(A \cup B \cup D \cup E) &= w(A) \cdot 0 + w(B) \cdot 0 \\ &\quad + w(C)m_{PCR5}^{\Theta_C \uparrow \Theta}(A \cup B \cup D \cup E) \\ &\quad \approx 0.1852, \\ m^\Theta(\Theta) &= w(A)m_{PCR5}^{\Theta_A \uparrow \Theta}(\Theta) + w(B)m_{PCR5}^{\Theta_B \uparrow \Theta}(\Theta) \\ &\quad + w(C)m_{PCR5}^{\Theta_C \uparrow \Theta}(\Theta) = 0.3761. \end{aligned}$$

From Eq. (24) we get

$$\begin{cases} d_{BI}(m^\Theta, m_A^\Theta) \approx 0.6818, \\ d_{BI}(m^\Theta, m_B^\Theta) \approx 0.7541, \\ d_{BI}(m^\Theta, m_C^\Theta) \approx 0.5874. \end{cases}$$

Because  $d_{BI}(m^\Theta, m_C^\Theta) < d_{BI}(m^\Theta, m_A^\Theta) < d_{BI}(m^\Theta, m_B^\Theta)$ , the final decision must be  $\hat{X} = C$  because it corresponds to the smallest  $d_{BI}$  distance value. This decision is the same as with method 1. Based on Eq. (25) one has  $q(\hat{X} = C) \approx 0.7096$  indicating a pretty good trustful decision because it is much greater than 0.5. If one have preferred  $\hat{X} = A$  (the second best choice) then  $q(\hat{X} = A) \approx 0.6630$  which is a bit worse, and for  $\hat{X} = B$  one gets the least trustful decision because  $q(\hat{X} = B) \approx 0.6273$ . Note that a

more optimistic attitude (if preferred) could be obtained by replacing the BetP probability by the DSMP probability [5] (Chap. 3 of Vol. 3) in the entropy derivation.

## V. CONCLUSIONS

In this work we have presented a very new methodology for decision-making under uncertainty in the framework of belief functions thanks to the unique PCR5-based canonical decomposition of any (dogmatic or non-dogmatic) dichotomous BBAs. We have shown that this new canonical decomposition provides less conflicting contra- and pro-evidences with respect to the decomposition based on Dempster's rule when the latter can be applied. Any BBAs defined on a general (non dichotomous) frame of discernment can be transformed into a set of coarsened dichotomous BBAs that can always be decomposed canonically and combined easily and quickly in one PCR5 fusion step to get a suboptimal fusion result for each element of the decision space under consideration. The final decision can be made in two ways: either by a simple comparative analysis of masses of elements of the decision space, or on the minimization of belief-interval distance which also offers the advantage of quantifying the quality of the decision. The evaluation of this new methodology for real applications is under progress and it will be reported in forthcoming publications.

**Abstract**—In this paper, we propose a new fusion approach to combine basic belief assignments (BBAs) defined on a dichotomous frame of discernment based on their canonical decomposition. In a companion paper, we have already proved that the canonical decomposition of this type of BBA (called dichotomous BBA) is always possible and unique thanks to the proportional conflict redistribution rule No 5 (PCR5). More precisely, any dichotomous BBA is always the PCR5 combination of two simpler basic belief assignments named respectively the pro-evidence, and the contra-evidence. From this interesting canonical decomposition, we present a new way of combining many dichotomous BBAs and we show that the computational time for fusing these dichotomous BBAs based on their canonical decomposition is quasi-linear with the number of sources to combine, contrary to the direct fusion of the dichotomous BBAs altogether.

**Keywords:** Information fusion, canonical decomposition, belief functions, PCR5 rule, PCR6 rule.

## I. INTRODUCTION

The belief functions (BF) introduced by Shafer in the mid of 1970's [1] from Dempster's works are well known and used in the artificial intelligence community to model epistemic uncertainty and to reason with it for information fusion and decision-making support. Dempster's rule to combine distinct sources of evidence characterized by their basic belief assignments (BBAs) defined on the same frame of discernment (FoD) is the historical and emblematic rule of combination in Dempster-Shafer Theory (DST). Unfortunately, Dempster's rule (denoted by DS rule for short) suffers of serious drawbacks in high conflict evidences as pointed out by Zadeh [2], [3], but more importantly also in some very low conflict situations [4] as well. That is why many rules have been proposed in the literature [5] (Vol.2), among them the combination of two sources of evidence based on the proportional conflict redistribution principle No. 5<sup>1</sup> (PCR5 rule) justified theoretically in [6], which has been shown successful in applications. However its complexity remains

<sup>1</sup>Actually PCR6 rule is preferentially used for the combination of more than two sources altogether. For two sources, PCR5 and PCR6 rules coincide and because canonical decomposition involved only two sources, we only need to work with PCR5 rule to combine the pro-evidence with its contra-evidence.

one of its limitations which prevents its use in fusion problems involving many sources of evidence to combine, and its non associativity property<sup>2</sup> which make it not so appealing because the fusion order matters when sequential PCR5 fusion is applied instead of global combination of the sources altogether.

In this work, we show how the fusion of many sources of evidences represented by BBAs defined on a same dichotomous frame of discernment can be easily done based on the PCR5-based canonical decomposition of the BBAs. Such decomposition of BBA has been proposed recently in [7].

We recall that another canonical decomposition based on conjunctive rule (but involving improper<sup>3</sup> BBA) had been proposed in 1995 by Smets [8], and extended later by Denœux [11] to develop the so-called cautious rule of combination. In this new approach we use our well justified canonical decomposition based on PCR5 which is strictly based on a proper (i.e. normal) BBAs as defined by Shafer himself. We have shown that any dichotomous BBA is always the result of the PCR5 fusion of a simple proper pro-evidence BBA  $m_p$  with a simple proper contra-evidence BBA  $m_c$ , and that this decomposition is unique. Based on this important result, we address in this work the problem of combination of many dichotomous BBAs based on their canonical decomposition.

This paper is organized as follows. After a brief recall of basics of belief functions in section II, we present briefly the canonical decomposition for any dichotomous BBA based on PCR5 rule of combination in section III which is explained in more details with proofs, and examples in [7]. The fusion of dichotomous BBAs based on the principle of canonical decompositions is detailed in section IV. Concluding remarks with perspectives are given in the last section.

## II. BASICS OF BELIEF FUNCTIONS

Belief functions (BF) have been introduced by Shafer in [1] to model epistemic uncertainty. We assume that the answer<sup>4</sup> of the problem under concern belongs to a known (or given) finite

<sup>2</sup>PCR5 is only quasi-associative.

<sup>3</sup>We call a BBA improper when it does not satisfy Shafer's original definition. Smets called it a generalized simple BBA (GSBBA).

<sup>4</sup>i.e. the solution, or the decision to take.

discrete frame of discernment (FoD)  $\Theta = \{\theta_1, \theta_2, \dots, \theta_n\}$ , with  $n > 1$ , and where all elements of  $\Theta$  are mutually exclusive and exhaustive<sup>5</sup>. The FoD is said dichotomous when it involves only two elements (one subset and its complement), that is  $\Theta = \{A, \bar{A}\}$  where  $\bar{A}$  is the complement of  $A$  in  $\Theta$ . The set of all subsets of  $\Theta$  (including empty set  $\emptyset$  and  $\Theta$ ) is the power-set of  $\Theta$  denoted by  $2^\Theta$ . A proper Basic Belief Assignment (BBA) associated with a given source of evidence is defined [1] as a mapping  $m(\cdot) : 2^\Theta \rightarrow [0, 1]$  satisfying  $m(\emptyset) = 0$  and  $\sum_{A \in 2^\Theta} m(A) = 1$ . In some BF related frameworks, like in Smets Transferable Belief Model (TBM) [8],  $m(\emptyset)$  is allowed to take a positive value. In this case,  $m(\cdot)$  is said improper because it does not satisfy Shafer's definition [1]. The quantity  $m(A)$  is called the mass of  $A$  committed by the source of evidence. Belief and plausibility functions are respectively defined from a proper BBA  $m(\cdot)$  by

$$Bel(A) = \sum_{B \in 2^\Theta | B \subseteq A} m(B), \quad (1)$$

and

$$Pl(A) = \sum_{B \in 2^\Theta | A \cap B \neq \emptyset} m(B) = 1 - Bel(\bar{A}), \quad (2)$$

where  $\bar{A}$  is the complement of  $A$  in  $\Theta$ .

$Bel(A)$  and  $Pl(A)$  are interpreted respectively as lower and upper bounds of an unknown (subjective) probability measure  $P(A)$  in original Dempster's works [9], [10]. The quantities  $m(\cdot)$  and  $Bel(\cdot)$  are one-to-one and the following Möbius inverse formula holds (see [1], p. 39)

$$m(A) = \sum_{B \subseteq A \subseteq \Theta} (-1)^{|A-B|} Bel(B). \quad (3)$$

$A$  is called a Focal Element (FE) of  $m(\cdot)$  if  $m(A) > 0$ . When all focal elements are singletons,  $m(\cdot)$  is called a *Bayesian BBA* [1] and its corresponding  $Bel(\cdot)$  function is equal to  $Pl(\cdot)$  and they are homogeneous to a (subjective) probability measure  $P(\cdot)$ . The vacuous BBA, or VBBA for short, representing a totally ignorant source is defined as<sup>6</sup>  $m_v(\Theta) = 1$ . A dichotomous BBA is a BBA defined on a dichotomous FoD. A dogmatic BBA is a BBA such that  $m(\Theta) = 0$ . If  $m(\Theta) > 0$  the BBA  $m(\cdot)$  is nondogmatic. A simple BBA is a BBA that has at most two focal sets and one of them is  $\Theta$ . A dichotomous non dogmatic mass of belief is a BBA having three focal elements  $A$ ,  $\bar{A}$  and  $A \cup \bar{A}$  with  $A$  and  $\bar{A}$  subsets of  $\Theta$ .

In his *Mathematical Theory of Evidence* [1], Shafer proposed to combine  $s \geq 2$  distinct sources of evidence represented by BBAs  $m_1(\cdot), \dots, m_s(\cdot)$  over the same FoD  $\Theta$  with Dempster's rule (i.e. the normalized conjunctive rule).

For the combination of two BBAs, Dempster's rule formula [1] is given by  $m_{DS}(\emptyset) = 0$  and  $\forall X \in 2^\Theta \setminus \{\emptyset\}$

$$m_{DS}(X) = \frac{1}{K_{12}} \sum_{\substack{X_1, X_2 \in 2^\Theta \\ X_1 \cap X_2 = X}} m_1(X_1)m_2(X_2), \quad (4)$$

with  $K_{12} = 1 - \sum_{X_1, X_2 \in 2^\Theta | X_1 \cap X_2 = \emptyset} m_1(X_1)m_2(X_2)$ .

The justification and behavior of Dempster's rule have been disputed over the years from many counter-examples involving high and low conflicting sources (from both theoretical and practical standpoints) as reported in [4], [12]–[14]. Many rules of combination exist in the literature<sup>7</sup>, among them we recommend the rule based on the proportional conflict redistribution principle No. 5 (PCR5 rule) [6] which has been shown to be successful in applications and well justified theoretically. That is why we analyze it in details for solving the BF canonical decomposition problem (BF-CDP). PCR5 transfers the conflicting mass only to the elements involved in the conflict and proportionally to their individual masses, so that the specificity of the information is entirely preserved in this fusion process (see [5], Vol. 2 and Vol. 3 for full justification and examples):  $m_{PCR5}(\emptyset) = 0$  and  $\forall X \in 2^\Theta \setminus \{\emptyset\}$

$$m_{PCR5}(X) = \sum_{\substack{X_1, X_2 \in 2^\Theta \\ X_1 \cap X_2 = X}} m_1(X_1)m_2(X_2) + \sum_{\substack{X_2 \in 2^\Theta \\ X_2 \cap X = \emptyset}} \left[ \frac{m_1(X)^2 m_2(X_2)}{m_1(X) + m_2(X_2)} + \frac{m_2(X)^2 m_1(X_2)}{m_2(X) + m_1(X_2)} \right], \quad (5)$$

where all denominators in (5) are different from zero. If a denominator is zero, that fraction is discarded. The properties of PCR5 can be found in [15]. Extension of PCR5 for combining qualitative BBA's can be found in [5], Vol. 2 & 3. A variant of PCR5, called PCR6 has been proposed by Martin and Osswald in [5], Vol. 2, for combining  $s > 2$  sources. The general formulas for PCR5 and PCR6 rules are also given in [5], Vol. 2. PCR6 coincides with PCR5 when one combines two sources. The difference between PCR5 and PCR6 lies in the way the proportional conflict redistribution is done as soon as three (or more) sources are involved in the fusion. From the implementation point of view, PCR6 is simpler to implement than PCR5. For convenience, very basic (not optimized) Matlab<sup>TM</sup> codes of PCR5 and PCR6 fusion rules can be found in [5], [16] and from the toolboxes repository on the web [17]. The main drawback of PCR5 and PCR6 rules is their combinatorial complexity when the number of source is big. Even for combining BBAs defined on a simple dichotomous frame of discernment, the computational time for combining more than 20 sources can take several hours<sup>8</sup>.

Our main motivation and contribution is to propose a faster fusion method to combine many dichotomous BBAs in order

<sup>7</sup>see [5], Vol. 2 for a detailed list of fusion rules.

<sup>8</sup>due to the exponential complexity of the PCR6 rule (as shown in Figure 4). For our simulations, we did use a MacBook Pro 2.8 GHz Intel Core i7 with 16 Go 1600 MHz DDR3 memory running Matlab<sup>TM</sup> R2018a.

<sup>5</sup>This is so-called Shafer's model of FoD [5].

<sup>6</sup>The complete ignorance is denoted  $\Theta$  in Shafer's book [1].

to overcome the combinatorial complexity problem by establishing a new effective (approximating) fusion method based on the new PCR5-based canonical decomposition principle. It is worth noting that our new method is very different of the method based on the clustering of non conflicting BBAs followed by a discounting step and the conjunctive rule presented in [18].

### III. CANONICAL DECOMPOSITION OF DICHOTOMOUS BBA

A FoD  $\Theta = \{A, \bar{A}\}$  is called dichotomous if it consists of only two elements  $A$  and  $\bar{A}$  with  $A \cup \bar{A} = \Theta$  and  $A \cap \bar{A} = \emptyset$ .  $A$  is different from  $\Theta$  and from Empty-Set because we want to work with informative FoD. Indeed, the very special frame  $\{\Theta, \emptyset\}$  does not bring any useful information since the only possible BBA with such frame is the vacuous BBA. So, we consider a given proper<sup>9</sup> BBA  $m(\cdot) : 2^\Theta \rightarrow [0, 1]$  of the form

$$m(A) = a, \quad m(\bar{A}) = b, \quad m(A \cup \bar{A}) = 1 - a - b, \quad (6)$$

with  $0 < a < 1$ ,  $0 < b < 1$  and  $a + b < 1$ .

The conditions  $0 < a < 1$  and  $0 < b < 1$  mean that  $A$  and  $\bar{A}$  are focal elements of the BBA. The restriction  $a + b < 1$  means that the BBA is nondogmatic.

This assumption of nondogmaticity of the BBA  $m(\cdot)$  is necessary for Smets canonical decomposition [8], but it is not essential for our PCR5-based canonical decomposition (as we will show in the sequel) because our decomposition also works directly with a dogmatic BBA. Of course any dogmatic BBA can always be modified as a non-dogmatic BBA by using a very small discounting number ( $\epsilon > 0$ ) so that, in practice, Smets' decomposition can always be applied, but this is not sufficient to prove that Smets approach always provides relevant results. Why? just because we know (and we have proved) that Dempster's (normalized conjunctive rule) and even the conjunctive rule in Smets' TBM suffers of serious drawbacks - see justifications in our aforementioned references. That is why we explore in this work another way of making a canonical decomposition, which is, for now, limited to dichotomous BBA.

Our canonical decomposition problem consists in finding the two following simple proper BBAs  $m_p$  and  $m_c$  of the form

$$m_p(A) = x, \quad m_p(A \cup \bar{A}) = 1 - x, \quad (7)$$

$$m_c(\bar{A}) = y, \quad m_c(A \cup \bar{A}) = 1 - y, \quad (8)$$

with  $(x, y) \in [0, 1] \times [0, 1]$ , such that  $m = \text{Fusion}(m_p, m_c)$ , for a chosen rule of combination denoted by  $\text{Fusion}(\cdot, \cdot)$ . The simple BBA  $m_p(\cdot)$  is called the *pro-BBA* (or pro-evidence) of  $A$ , and the simple BBA  $m_c(\cdot)$  the *contra-BBA* (or contra-evidence) of  $A$ . The BBA  $m_p(\cdot)$  is interpreted as a source of evidence providing an uncertain evidence in favor of  $A$ , whereas  $m_c(\cdot)$  is interpreted as a source of evidence providing an uncertain contrary evidence about  $A$ .

This decomposition is possible with Dempster's rule only if  $0 < a < 1$ ,  $0 < b < 1$  and  $a + b < 1$ , and in this case we

have  $x = \frac{a}{1-b}$  and  $y = \frac{b}{1-a}$ . However, any dogmatic BBA  $m(A) = a$ ,  $m(\bar{A}) = b$  with  $a + b = 1$  is not decomposable from Dempster's rule for the case when  $(a, b) \neq (1, 0)$  and  $(a, b) \neq (0, 1)$  (see Theorem 4 in [7]), and the dogmatic BBAs  $m(A) = 1$ ,  $m(\bar{A}) = 0$  (case  $(a, b) = (1, 0)$ ), or  $m(A) = 0$ ,  $m(\bar{A}) = 1$  (case  $(a, b) = (0, 1)$ ) have infinitely many decompositions based on Dempster's rule of combination (see Lemma in [7]). In [7], we have shown that our canonical decomposition cannot be achieved from conjunctive, disjunctive, Yager's [19] or Dubois-Prade [20] rules of combination, neither from averaging rule. However, such type of decomposition is unique and is always possible in all cases of dichotomous BBA  $m(\cdot)$  using the PCR5 rule of combination. In [7], we did prove the following Theorem.

**Theorem 1:** Consider a dichotomous FoD  $\Theta = \{A, \bar{A}\}$  with  $A \neq \Theta$  and  $A \neq \emptyset$  and a nondogmatic BBA  $m(\cdot) : 2^\Theta \rightarrow [0, 1]$  defined on  $\Theta$  by  $m(A) = a$ ,  $m(\bar{A}) = b$ , and  $m(A \cup \bar{A}) = 1 - a - b$ , where  $a, b \in [0, 1]$  and  $a + b < 1$ . Then the BBA  $m(\cdot)$  has a unique canonical decomposition using PCR5 rule of combination of the form  $m = \text{PCR5}(m_p, m_c)$  with pro-evidence  $m_p(A) = x$ ,  $m_p(A \cup \bar{A}) = 1 - x$  and contra-evidence  $m_c(\bar{A}) = y$ ,  $m_c(A \cup \bar{A}) = 1 - y$  where  $x, y \in [0, 1]$ .

Moreover, we also proved in [7] that the canonical decomposition also exists even if the dichotomous BBA is dogmatic (i.e. Bayesian) and the following theorem also holds.

**Theorem 2:** Any dogmatic BBA defined by  $m(A) = a$  and  $m(\bar{A}) = b$ , where  $a, b \in [0, 1]$  and  $a + b = 1$ , has a canonical decomposition using PCR5 rule of combination of the form  $m = \text{PCR5}(m_p, m_c)$  with  $m_p(A) = x$ ,  $m_p(A \cup \bar{A}) = 1 - x$  and  $m_c(\bar{A}) = y$ ,  $m_c(A \cup \bar{A}) = 1 - y$  where  $x, y \in [0, 1]$ .

Theorems 1 & 2 prove that the decomposition based on PCR5 always exists and it is unique for any dichotomous (nondogmatic, or dogmatic) BBA.

For the case of dichotomous dogmatic BBA considered in Theorem 2, the expression of solutions  $x$  and  $y$  can be established explicitly as follows - see [7] for details

- If  $a < b$  then  $x < y$ , and we have  $y = 1$  and  $x = \frac{a + \sqrt{a^2 + 4a}}{2}$ .
- If  $a > b$  then  $x > y$ , and we have  $x = 1$  and  $y = \frac{b + \sqrt{b^2 + 4b}}{2}$ .
- If  $a = b$  and  $a + b = 1$  then  $a = b = 0.5$  and  $x = y = 1$ .

For the case of dichotomous nondogmatic BBA considered in Theorem 1, one has to find  $x$  and  $y$  solutions of the system

$$a = x(1 - y) + \frac{x^2 y}{x + y} = \frac{x^2 + xy - xy^2}{x + y}, \quad (9)$$

$$b = (1 - x)y + \frac{xy^2}{x + y} = \frac{y^2 + xy - x^2 y}{x + y}. \quad (10)$$

under the constraints  $(a, b) \in [0, 1]^2$ , and  $0 < a + b < 1$ . In fact, it has been proved in [7] that  $x \in [a, a + b] \subset [0, 1]$  and  $y \in [b, a + b] \subset [0, 1]$ , but the explicit expression of  $x$  and  $y$  are very complicated to obtain analytically (even with modern symbolic computing systems like Mathematica<sup>TM</sup>, or

<sup>9</sup>which means that  $m(\emptyset) = 0$ .

Maple™) because after algebraic calculation, and for  $x \neq 1$ , one has to solve the following quartic equation which has at most four real solutions with only a valid one in  $[a, a + b]$

$$x^4 + (-a - 2)x^3 + (2a + b)x^2 + (a + b - ab - b^2)x + (-a^2 - ab) = 0, \quad (11)$$

and then compute  $y$  as  $y = \frac{a+b-x}{1-x}$ .

Fortunately, the solutions can be easily calculated numerically by these computing systems, and even with Matlab™system<sup>10</sup> as soon as the numerical values are committed to  $a$  and to  $b$ , and this is what we do in our simulations in the sequel.

**Example 1:** Let consider  $\Theta = \{A, \bar{A}\}$  and  $m(A) = 0.6$ ,  $m(\bar{A}) = 0.3$  and  $m(A \cup \bar{A}) = 1 - m(A) - m(\bar{A}) = 0.1$ . Hence,  $a = 0.6$  and  $b = 0.3$ . The quartic equation (11) becomes

$$x^4 - 2.6x^3 + 1.5x^2 + 0.63x - 0.54 = 0. \quad (12)$$

The four solutions of this quartic equation provided by the computing system<sup>11</sup> are approximately

$$\begin{aligned} x_1 &\approx 0.7774780438, & x_2 &\approx 0.9297589637, \\ x_3 &\approx 1.4191515820, & x_4 &\approx -0.5263885898. \end{aligned}$$

Clearly  $x_3$  and  $x_4$  are not acceptable solutions because they don't belong to  $[0, 1]$ . If we take  $x_1 \approx 0.7774780438$ , then we will get  $y_1 = (a + b - x_1)/(1 - x_1) = (0.9 - x_1)/(1 - x_1) \approx 0.5506061437$ . The pair  $(x_1, y_1) \in [0, 1]^2$  is a solution of the decomposition problem of the BBA  $m(\cdot)$ . If we take  $x_2 \approx 0.9297589637$ , then we will get  $y_2 = (a + b - x_2)/(1 - x_2) = (0.9 - x_2)/(1 - x_2) \approx -0.4236692006$ . We see that  $y_2 \notin [0, 1]$ , and therefore the pair  $(x_2, y_2)$  cannot be a solution of the decomposition problem of the BBA  $m(\cdot)$ . Therefore the canonical masses  $m_p(\cdot)$  and  $m_c(\cdot)$  are given by

$$\begin{aligned} m_p(A) &\approx 0.7774780438, & m_p(A \cup \bar{A}) &\approx 0.2225219562, \\ m_c(\bar{A}) &\approx 0.5506061437, & m_c(A \cup \bar{A}) &\approx 0.4493938563. \end{aligned}$$

It can be verified that the PCR5 combination of BBAs  $m_p$  and  $m_c$ , denoted by  $PCR5(m_p, m_c)$ , is equal to the BBA  $m(\cdot)$ .

Of course there are necessarily numerical approximations involved by the proposed decomposition because this decomposition is obtained by numerical solvers. This may have some little impact in the PCR5 fusion result but because PCR5 rule is numerically robust to small input changes (contrariwise to Dempster's rule) the PCR5 result will not change substantially with small changes (due to small numerical imprecisions) in the values of BBAs to combine.

#### A. Particular cases

1) *Case  $(a, b) = (0, 0)$  (i.e.  $m$  is the vacuous BBA):* This is the most degenerate case where the BBA  $m(\cdot)$  corresponds to the vacuous BBA. For averaging rule, conjunctive rule, Yager's, Dubois-Prade's, Dempster's and PCR5 rules one has

$x = 0$  and  $y = 0$  (conflict between canonical masses is zero). In fact the vacuous BBA  $m(\cdot)$  can always be interpreted as the fusion of  $m_p$  and  $m_c$ , where  $m_p$  and  $m_c$  are also vacuous BBAs. This degenerate case has no particular interest in practice but to model the total ignorant state of knowledge.

2) *Case when  $a = 0$ , or  $b = 0$ :* In the case  $a = 0$  and  $0 < b \leq 1$ , then for conjunctive rule, Yager's, Dubois-Prade's, Dempster's and PCR5 rules one has  $x = 0$  and  $y = b$  (conflict between canonical masses is zero) and  $m(\cdot)$  corresponds to the fusion of vacuous pro-evidence  $m_p = m_v$  with the contra-evidence  $m_c = m$ . In the case  $0 < a \leq 1$  and  $b = 0$ , then for conjunctive rule, Yager's, Dubois-Prade's, Dempster's and PCR5 rules one has  $x = a$  and  $y = 0$  (conflict between canonical masses is zero) and  $m(\cdot)$  corresponds to the fusion of the pro-evidence  $m_p = m$  with the vacuous contra-evidence  $m_c = m_v$ . These cases have no particular interest because they can be seen just as the combination of pro (or contra) BBA with the vacuous BBA.

3) *Case when  $a = b \in (0, 0.5)$ :* In this case, the BBA  $m(A) = m(\bar{A}) = a$  and  $m(A \cup \bar{A}) = 1 - 2a$  can be canonically decomposed from PCR5 rule with the BBAs  $m_p(A) = 1 - \sqrt{1 - 2a}$ ,  $m_p(A \cup \bar{A}) = \sqrt{1 - 2a}$  and  $m_c(\bar{A}) = 1 - \sqrt{1 - 2a}$ ,  $m_c(A \cup \bar{A}) = \sqrt{1 - 2a}$  - see details and proof in [7].

#### B. Benefits of canonical decomposition

The canonical decomposition based on PCR5 offers several interests and advantages that are briefly listed.

- 1) This canonical decomposition of  $m(\cdot)$  into the pro-evidence  $m_p(\cdot)$  and the contra-evidence  $m_c(\cdot)$  allows to define the notion of internal conflict of a dichotomous source of evidence, denoted by  $K_{int}(m)$ , as

$$K_{int}(m) \triangleq m_p(A)m_c(\bar{A}), \quad (13)$$

where  $m_p(A) = x$  and  $m_c(\bar{A}) = y$  are the canonical factors of the BBA  $m(\cdot)$  based on PCR5 rule of combination.

- 2) The canonical decomposition also allows to adjust/revise easily a dichotomous source of evidence (if needed) according to the knowledge one has on it. For instance, if one knows that a source over (or under) estimate the hypothesis  $A$ , then one could apply an adjustment (based on some discounting or reinforcing factors) on the pro (or contra) evidence to de-bias this source of evidence.
- 3) This canonical decomposition can help to develop new fast rules of combination for the fusion of  $S \geq 2$  (dichotomous) distinct<sup>12</sup> BBAs  $m_s(\cdot) = (m_s(A), m_s(\bar{A}), m_s(A \cup \bar{A})) = (a_s, b_s, 1 - a_s - b_s)$ ,  $s = 1, 2, \dots, S$ . This is presented next.

#### IV. FAST FUSION OF DICHOTOMOUS BBAS

In this section, we show how to combine many dichotomous BBAs defined on the same FoD  $\Theta$  thanks to their canonical decompositions.

<sup>10</sup>thanks to the *fsolve* Matlab™ command.

<sup>11</sup>We did get same solutions with Maple™, and with Matlab™.

<sup>12</sup>i.e. cognitively independent.

### A. Principle of the fast fusion of dichotomous BBAs

The main idea for making the fast fusion of dichotomous BBAs is, at first, to decompose canonically each dichotomous BBA  $m_s(\cdot)$ , for  $s = 1, 2, \dots, S$  into their pro and contra evidences  $m_{p,s} = (m_{p,s}(A), m_{p,s}(\bar{A}), m_{p,s}(A \cup \bar{A})) = (x_s, 0, 1 - x_s)$  and  $m_{c,s} = (m_{c,s}(A), m_{c,s}(\bar{A}), m_{c,s}(A \cup \bar{A})) = (0, y_s, 1 - y_s)$ , and then to combine the pro-evidences  $m_{p,s}$  for  $s = 1, 2, \dots, S$  altogether on one hand to get a global pro-evidence  $m_p$ , and to combine the contra-evidences  $m_{c,s}$  for  $s = 1, 2, \dots, S$  altogether on the other hand to get a global contra-evidence  $m_c$ . The fusion step of pro and contra evidences is discussed in section IV-D. Once  $m_p$  and  $m_c$  are calculated, then one combines them with PCR5 fusion rule to get the final result. This general principle of the new fusion method is represented by the diagram of figure 1 for convenience.

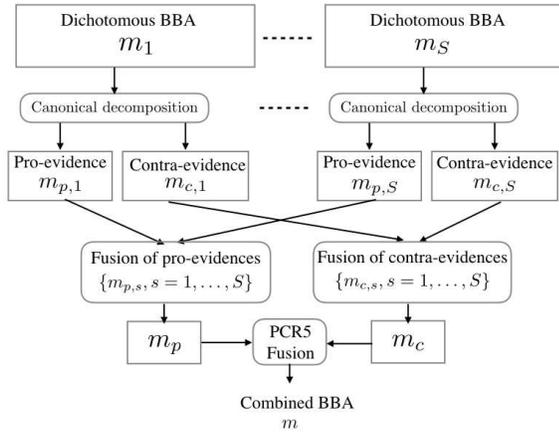

Figure 1. General principle of the fusion of dichotomous BBAs from their canonical decompositions.

This new fusion approach is interesting because the fusion of the pro-evidence  $m_{p,s}$  (resp. contra-evidences  $m_{c,s}$ ) is quite simple because there is no conflict between  $m_{p,s}$  (resp. between  $m_{c,s}$ ), so that their fusion can be done quite easily and a large number of sources can be combined without a high computational burden. In fact, with this fusion approach, only one PCR5 fusion step of simple (combined) canonical BBAs is needed at the very end of the fusion process. It is worth noting that in this work there is no link with the canonical decomposition proposed by Shafer and then extended by Smets because here we use another fusion rule based on the proportional conflict redistribution principle.

### B. Analysis of the effectiveness of this new fusion approach

Because the PCR5 rule<sup>13</sup> of combination is not associative, the fusion<sup>14</sup> of the canonical BBAs followed by their PCR5

<sup>13</sup>The same remark holds for PCR6 rule with more than two BBAs.

<sup>14</sup>We assume here that the fusion of all the pro-evidences (resp. contra-evidences) is done with PCR5 rule which coincides in this case with the conjunctive rule because there is no conflict between the pro-evidences (resp. the contra-evidences).

fusion will not provide in general the same result as the direct fusion of the dichotomous BBAs altogether but only an approximate result, which is normal.

The main question is to know how good is the approximation obtained by this new fusion method based on the fusion of pro-evidences and contra-evidences with respect to the direct fusion of the BBAs with PCR5 (or PCR6 when considering more than two sources to combine). To answer to this important question we make a statistical analysis of the quality of the combined result  $m$ , with respect to the direct PCR5, or PCR6 fusion of all BBAs altogether.

The measure of the goodness is obtained by the normalized (Euclidean) Belief Interval distance  $d_{BI}(m_{PCR5}, m)$  (for the case of two BBAs only), or by  $d_{BI}(m_{PCR6}, m)$  if more than two sources are considered in the fusion process, where  $m$  is the result of the fusion principle based on canonical decompositions, and  $m_{PCR5}$  (resp.  $m_{PCR6}$ ) is the result of the combination of original BBAs altogether with PCR5 (resp. PCR6) rule. The  $d_{BI}$  distance between two BBAs  $m_1(\cdot)$  and  $m_2(\cdot)$  defined on the powerset of a given FoD  $\Theta = \{\theta_1, \dots, \theta_n\}$  has been proposed and justified in [21], [22]. It is defined by

$$d_{BI}(m_1, m_2) \triangleq \sqrt{N_c \cdot \sum_{X \in 2^\Theta} d_W^2(BI_1(X), BI_2(X))}, \quad (14)$$

where  $N_c = 1/2^{n-1}$  is a normalization factor to make  $d_{BI}(m_1, m_2) \in [0, 1]$ , and  $d_W(BI_1(X), BI_2(X))$  is Wasserstein's distance [23] between belief intervals  $BI_1(X) \triangleq [Bel_1(X), Pl_1(X)] = [a_1, b_1]$  and  $BI_2(X) \triangleq [Bel_2(X), Pl_2(X)] = [a_2, b_2]$ . Here,  $d_W^2(BI_1(X), BI_2(X))$  entering in (14) is given by

$$d_W^2([a_1, b_1], [a_2, b_2]) \triangleq \left[ \frac{a_1 + b_1}{2} - \frac{a_2 + b_2}{2} \right]^2 + \frac{1}{3} \left[ \frac{b_1 - a_1}{2} - \frac{b_2 - a_2}{2} \right]^2. \quad (15)$$

Figure 2 shows the normalized histogram (i.e. the empirical probability distribution) of the distance values  $d_{BI}^E(m_{PCR5}, m)$  based on 20000 random<sup>15</sup> generations of dichotomous BBAs  $m_1$  and  $m_2$ . One observes that the new fusion approach based on the canonical decompositions of BBAs (with the conjunctive fusion of pro-evidences, and the conjunctive fusion of contra-evidences) provides a solution which is very close to what we obtain from the direct application of PCR5 rule, with a mean of 0.0287 and a standard deviation of 0.0289. In 98.20% of cases, the final decision (based on the min of  $d_{BI}^E$  decision-making strategy explained in [22]) based on  $m_{PCR5}$ , or on  $m$  are in agreement. This means that the decision agreement (DA) rate is 98.20%.

Figures 3 show the normalized histograms of the  $d_{BI}^E(m_{PCR6}, m)$  values based also on 20000 random runs for the fusion of 6 dichotomous BBAs respectively. We use

<sup>15</sup>For this, we generate three random numbers uniformly distributed in  $[0, 1]$  and we normalize them to generate randomly a dichotomous BBA.

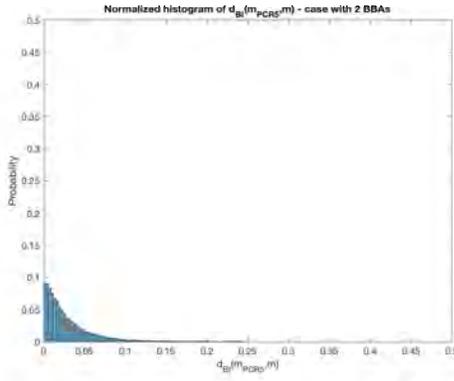

Figure 2. Normalized histogram of  $d_{BI}^E(m_{PCR5}, m)$  for 2 dichotomous BBAs case (20000 runs).

PCR6 rule instead of PCR5 rule to combine the 6 dichotomous BBAs altogether because PCR6 rule has been recognized to be more effective than PCR5 in applications [5] (Vol.2 - Chap. 2). As we can observe, the shape of the histograms is a bit different from the histogram of fig. 2, but what matters is that the mean value and the standard deviation of the  $d_{BI}^E$  distance are still low (0.1119 and 0.0392 respectively) indicating that the approximation obtained by this new fusion method is globally very good. Also the decision based on this new fusion approach is globally coherent with the decision taken by the direct PCR6 fusion of the BBAs (95.84% of decision coherence).

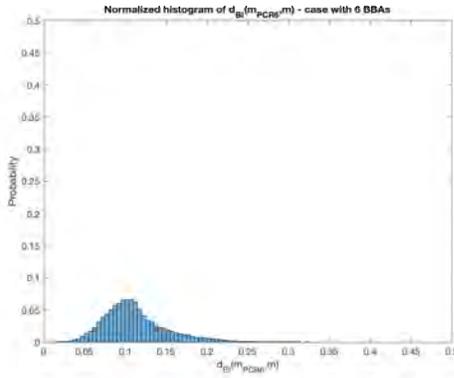

Figure 3. Normalized histogram of  $d_{BI}^E(m_{PCR6}, m)$  for 6 dichotomous BBAs case (20000 runs).

Several Monte Carlo simulations have been done with different numbers of dichotomous BBAs to combine. The results obtained based on 20000 runs Monte Carlo simulations are summarized in the Table I.

The second column of Table I indicates the mean value, denoted by  $\text{mean}(d_{BI}^E)$ , of the normalized Euclidean belief Interval distance between the direct fusion of the BBAs by the PCR5 (when combining 2 BBAs only), or PCR6 rule (when combining more than two BBAs) and the new fusion

# of BBAs	$\text{mean}(d_{BI}^E)$	$\text{std}(d_{BI}^E)$	Decision Agreement (%)
2	0.0287	0.0289	98.20
3	0.0578	0.0373	97.52
4	0.0838	0.0394	96.69
5	0.1008	0.0397	96.05
6	0.1119	0.0392	95.84
7	0.1169	0.0385	95.40
8	0.1200	0.0374	94.89
9	0.1211	0.0365	94.25
10	0.1204	0.0348	94.21

Table I  
COMPARATIVE EVALUATION OF CANONICAL DECOMPOSITION FUSION METHOD W.R.T. THE DIRECT PCR-BASED FUSION METHOD.

rule based on their canonical decomposition. The third column of the Table I shows the corresponding standard deviation values denoted by  $\text{std}(d_{BI}^E)$ . The last column indicates the decision agreement (DA) factor between the decision taken from the direct fusion method, and the indirect (canonical decomposition based) method. As we can see, the DA factors are very high which means that most of the time the decisions taken from the direct fusion method and from the indirect fusion method are the same.

After a deep analysis of our simulation results, one can attest that the decision-making disagreement occurs when the numerical values of the mass of  $A$  and the mass of  $\bar{A}$  are very close. This indicates a very high ambiguity in the decision to take in such situation which can be easily tracked in practice by evaluating the quality indicator of the decision-making - see [22] for details.

In this paper we did not investigate the quality of the approximation of the fusion result based on this canonical decomposition when replacing the PCR5 fusion step of  $m_p$  and  $m_c$  by other rules of combination because the core of the canonical decomposition is based on PCR5.

### C. Computational time of the new fusion method

Because of very high combinatorial complexity (and thus high computational time) required for applying the direct PCR6 fusion of many BBAs, we did only make the performance evaluation up to the fusion of ten BBAs only with PCR6. We conjecture that the performances of this new fusion method based on canonical decomposition will very slowly degrade with the increase of the number of BBAs involved in the fusion process. Of course the new fusion method based on this canonical decomposition does not suffer of combinatorial complexity limitation which is of great interest in some applications (like in multi-spectral imagery for detection and classification) because many (hundreds or even thousands) of dichotomous BBAs could be easily combined very quickly. Actually with this method what takes a bit time is only the canonical decomposition done by the numerical solver<sup>16</sup>.

Figure 4 shows the average (based on 50 random runs) computational time (in seconds) of the direct PCR6 fusion of the BBAs altogether (red plot), and the average computational time of the new fusion method based on canonical decomposition (blue plot). It is clear that the computational

<sup>16</sup>We did use Matlab™ *fsolve* function for this.

time of the direct PCR6 fusion method (the red curve) grows exponentially with the number of sources, whereas the computational time grows only slowly and quasi-linearly with the new method proposed in this work.

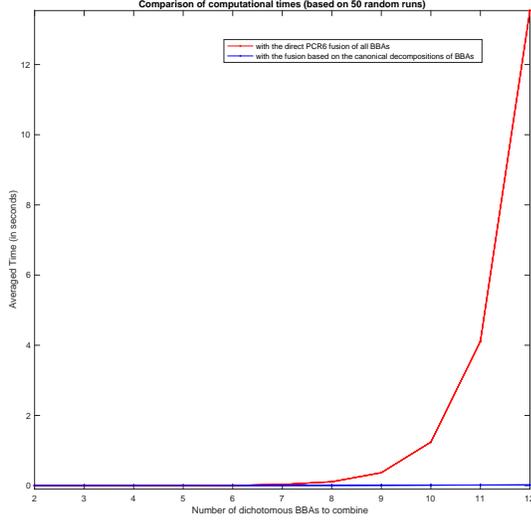

Figure 4. Computing time versus number of BBAs to combine.

Based on a set of 1000 random dichotomous BBAs, figure 5 shows that the computational time (in seconds) of the fusion based on the canonical decomposition is a quasi-linear<sup>17</sup> function of the number of BBAs to combine.

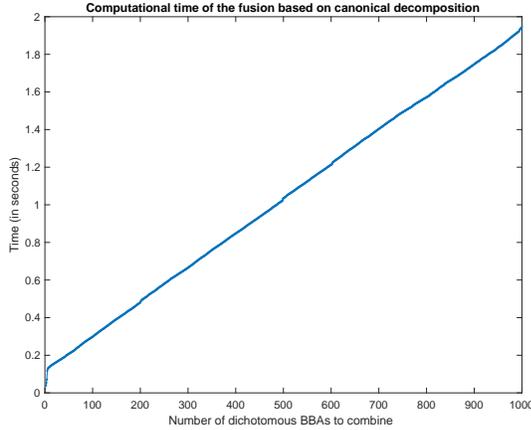

Figure 5. Computing time versus number of BBAs to combine.

Figures 4 and 5 show the computational times including the canonical decomposition itself done on the fly. Of course, the canonical decomposition could be done off-line once for all and stored in the computer memory (if necessary) - see for instance the  $(x, y)$  values given in [7] for convenience. If we have  $n$  dichotomous BBAs to combine, we have to make their canonical decomposition at first and because the  $n$

<sup>17</sup>It is not strictly linear because the time for the numerical *fsolve* search of pro-evidence and contra-evidence factors for making the canonical decomposition is not constant.

pro-evidence BBAs to combine (resp. contra evidence BBAs) have a very simple structure their conjunctive fusion  $m_p(A)$  is obtained very quickly by the direct product of  $n$  real numbers, that is  $m_p(A) = \prod_{i=1}^n m_{p,i}(A)$ , and we need also a subtraction because  $m_p(A \cup \bar{A}) = 1 - m_p(A)$ . The complexity of this fast suboptimal PCR fusion approach (once the canonical decomposition is available) is therefore  $2(n-1)$  multiplications and 2 subtractions for making the conjunctive fusion of  $m_{p,i}$  and the conjunctive fusion of  $m_{c,i}$ , and 7 additions and 5 multiplications for making the PCR5 fusion of  $m_p$  with  $m_c$ . There is no need to use the commonality function or the Smets canonical decomposition to make the fusion of these dichotomous BBAs. These figures show clearly the real advantage of the fusion of dichotomous BBAs based on their canonical decompositions in term of computational time, and that is why we can say that the new proposed method is really a fast fusion method with respect to the direct PCR5 or PCR6 rule of combination when working with a dichotomous frame of discernment.

#### D. On the fusion of pro and contra evidences

In the previous analysis, we did use the conjunctive rule for the intermediary fusion step of pro-evidences in one hand, and the intermediary fusion step of contra-evidences in the other hand. It is worth noting that the intermediary step of fusion of pro-evidences, and the intermediary step of fusion of contra-evidences can be done in parallel which offers a computational advantage with respect to the direct fusion method (if one has many sources to combine in a specific application). This parallelization cannot be achieved in general with the other existing rules of combination of evidences.

Because of the fusion principle depicted in Figure 1, this new fusion method offers also the possibility (if one prefers for some own specific reasons) of selecting other fusion rules for the intermediary fusion steps for combining the pro-evidences, and the contra-evidences. Of course the choice of the fusion rules used for the combination of pro-evidences and the combination of contra-evidences impacts the final result, but depending on the type of rules chosen we can obtain an associative rule, an idempotent rule, and even a new cautious rule. For example, let's consider the same type of fusion rule for combining the pro-evidences  $m_{p,s}$   $s = 1, \dots, S$ , and for combining contra-evidences  $m_{c,s}$   $s = 1, \dots, S$  and consider the following cases:

- 1) If we use the conjunctive rule [5] (Vol. 1), denoted by  $Conj(\dots)$  (as we did previously in our Monte Carlo simulations for histogram plots), then

$$m_p = Conj(m_{p,1}, \dots, m_{p,S}),$$

and one has  $m_p(A \cup \bar{A}) = \prod_{s=1}^S (1 - x_s)$  and  $m_p(A) = 1 - m_p(A \cup \bar{A})$ . Because the conjunctive rule is associative the fusion of pro-evidences can be done sequentially. Similarly, for the fusion of contra-evidences using the conjunctive rule one has  $m_c(A \cup \bar{A}) = \prod_{s=1}^S (1 - y_s)$  and  $m_p(\bar{A}) = 1 - m_c(A \cup \bar{A})$ . Because there is no conflict between the pro-evidences (resp. contra-evidences), the

fusion result of the pro-evidences (resp. the contra-evidences) by PCR5 (or PCR6) rules is equivalent to the conjunctive fusion result. The conjunctive rule however is not idempotent in general but in very specific cases where only one focal element gets all the mass of belief.

- 2) If we prefer to use the averaging rule, then we will have  $m_p(A) = \frac{1}{S} \sum_{s=1}^S x_s$  and  $m_p(A \cup \bar{A}) = 1 - m_p(A) = \frac{1}{S} \sum_{s=1}^S (1 - x_s)$ , and  $m_c(\bar{A}) = \frac{1}{S} \sum_{s=1}^S y_s$  and  $m_c(A \cup \bar{A}) = 1 - m_c(\bar{A}) = \frac{1}{S} \sum_{s=1}^S (1 - y_s)$ . Because the averaging rule is not associative, the sequential fusion of pro-evidences (and contra-evidences) is not recommended, however the averaging rule allows to get an idempotent fusion rule based on canonical decompositions if needed.
- 3) We could also prefer to use the min rule to build a new cautious rule of combination which will be associative and idempotent. For this, we just have to take  $m_p(A) = \min_{s=1, \dots, S}(x_s)$  and  $m_p(A \cup \bar{A}) = 1 - m_p(A)$ . Similarly,  $m_c(\bar{A}) = \min_{s=1, \dots, S}(y_s)$  and  $m_c(A \cup \bar{A}) = 1 - m_c(\bar{A})$ .

## V. CONCLUSIONS

In this research paper, we did propose a new fusion method to combine very quickly many BBAs defined on a dichotomous frame of discernment thanks to their unique canonical decompositions. This new interesting method can be parallelized and offers the advantage to have a quasi-linear computational time with the number of sources. For now, this method is limited to the fusion of many BBAs that are defined on a simple (dichotomous) frame of discernment. After some unsuccessful attempts, it appears that the development of a fast fusion method based on the canonical decomposition principle for working with non-dichotomous frames of discernment is actually a very difficult problem that we want to address to the scientific community working with belief functions as a future research challenge. This very new method brings already a significant benefit for real application involving inter-criteria analysis for the evaluation of multiple-objective ant colony optimization algorithm for wireless sensor networks deployment that should be reported in a forthcoming publication.

**Abstract**—In this paper, we present a fast Belief Function based Inter-Criteria Analysis (BF-ICrA) method based on the canonical decomposition of basic belief assignments defined on a dichotomous frame of discernment. This new method is then applied for evaluating the Multiple-Objective Ant Colony Optimization (MO-ACO) algorithm for Wireless Sensor Networks (WSN) deployment.

**Keywords:** Inter-Criteria Analysis, belief functions, information fusion, canonical decomposition, PCR5 rule.

## I. INTRODUCTION

In our previous work [1] we propose a new and improved version of classical Atanassov's InterCriteria Analysis (ICrA) [2]–[4] approach based on Belief Functions (BF-ICrA). This method proposes a better construction of Inter-Criteria Matrix that fully exploits all the information of the score matrix, and the closeness measure of agreement between criteria based on belief interval distance. In [5], we show how the fusion of many sources of evidences represented by Basic Belief Assignments (BBAs) defined on a same dichotomous frame of discernment can be fast and easily done thanks to the Proportional Conflict Redistribution rule no.5 (PCR5) and based on canonical decomposition of the BBAs, proposed recently in [6]. In the recent paper we consider BF-ICrA based on this promising technique. Then we show how to apply it for the evaluation of the Multiple-Objective Ant Colony Optimization (MO-ACO) algorithm for Wireless Sensor Networks (WSN) deployment. After a condensed presentation of basics of belief functions in Section II, including the short description of canonical decomposition of dichotomous BBAs approach, and the main steps of fast fusion method of dichotomous BBAs, in Section III the BF-ICrA method is described and analyzed. Section IV is devoted to the multi-objective ACO algorithm. In Section V the results of the fast BF-ICrA method with the MO-ACO algorithm for WSN layout deployment is presented and discussed. Conclusion is given in Section VI.

## II. BASICS OF BELIEF FUNCTIONS

### A. Basic definitions

Belief functions (BF) have been introduced by Shafer in [7] to model epistemic uncertainty and to combine distinct sources of evidence thanks to Dempster's rule of combination.

In Shafer's framework, we assume that the answer<sup>1</sup> of the problem under concern belongs to a known finite discrete frame of discernment (FoD)  $\Theta = \{\theta_1, \theta_2, \dots, \theta_n\}$ , with  $n > 1$ , and where all elements of  $\Theta$  are mutually exclusive and exhaustive. The set of all subsets of  $\Theta$  (including empty set  $\emptyset$  and  $\Theta$ ) is the power-set of  $\Theta$  denoted by  $2^\Theta$ . A proper Basic Belief Assignment (BBA) associated with a given source of evidence is defined [7] as a mapping  $m(\cdot) : 2^\Theta \rightarrow [0, 1]$  satisfying  $m(\emptyset) = 0$  and  $\sum_{A \in 2^\Theta} m(A) = 1$ . The quantity  $m(A)$  is called the mass of  $A$  committed by the source of evidence. Belief and plausibility functions are respectively defined from a proper BBA  $m(\cdot)$  by

$$Bel(A) = \sum_{B \in 2^\Theta | B \subseteq A} m(B), \quad (1)$$

and

$$Pl(A) = \sum_{B \in 2^\Theta | A \cap B \neq \emptyset} m(B) = 1 - Bel(\bar{A}), \quad (2)$$

where  $\bar{A}$  is the complement of  $A$  in  $\Theta$ .

$Bel(A)$  and  $Pl(A)$  are usually interpreted respectively as lower and upper bounds of an unknown (subjective) probability measure  $P(A)$ . The quantities  $m(\cdot)$  and  $Bel(\cdot)$  are one-to-one and linked by the Möbius inverse formula (see [7], p. 39).  $A$  is called a Focal Element (FE) of  $m(\cdot)$  if  $m(A) > 0$ . When all focal elements are singletons,  $m(\cdot)$  is called a *Bayesian BBA* [7] and its corresponding  $Bel(\cdot)$  function is equal to  $Pl(\cdot)$  and they are homogeneous to a (subjective) probability measure  $P(\cdot)$ . The vacuous BBA, representing a totally ignorant source, is defined as  $m_v(\Theta) = 1$ . A dichotomous BBA is a BBA defined on a FoD which has only two proper subsets, for instance  $\Theta = \{A, \bar{A}\}$  with  $A \neq \Theta$  and  $A \neq \emptyset$ . A dogmatic BBA is a BBA such that  $m(\Theta) = 0$ . If  $m(\Theta) > 0$  the BBA  $m(\cdot)$  is nondogmatic. A simple BBA is a BBA that has at most two focal sets and one of them is  $\Theta$ . A dichotomous non dogmatic mass of belief is a BBA having three focal elements  $A$ ,  $\bar{A}$  and  $A \cup \bar{A}$  with  $A$  and  $\bar{A}$  subsets of  $\Theta$ .

In his Mathematical Theory of Evidence [7], Shafer proposed to combine  $s \geq 2$  distinct sources of evidence represented by BBAs with Dempster's rule (i.e. the normalized conjunctive rule), which unfortunately behaves counterintuitively

<sup>1</sup>i.e. the solution, or the decision to take.

both in high and low conflicting situations as reported in [8]–[11]. In our previous works (see [12], Vol. 2 and Vol. 3 for full justification and examples) we did propose new rules of combination based on different Proportional Conflict Redistribution (PCR) principles, and we have shown the interest of the PCR rule No 5 (PCR5) for combining two BBAs, and PCR rule No 6 (PCR6) for combining more than two BBAs altogether [12], Vol. 2. PCR6 coincides with PCR5 when one combines two sources. The difference between PCR5 and PCR6 lies in the way the proportional conflict redistribution is done as soon as three (or more) sources are involved in the fusion. PCR5 transfers the conflicting mass only to the elements involved in the conflict and proportionally to their individual masses, so that the specificity of the information is entirely preserved in this fusion process.

The general (complicate) formulas for PCR5 and PCR6 rules are given in [12], Vol. 2. The fusion of two BBAs based on PCR5 (or PCR6) rule which will be use for canonical decomposition of a dichotomous BBA is obtained by the formula

$$m_{PCR5}(X) = \sum_{\substack{X_1, X_2 \in 2^\Theta \\ X_1 \cap X_2 = X}} m_1(X_1)m_2(X_2) + \sum_{\substack{X_2 \in 2^\Theta \\ X_2 \cap X = \emptyset}} \left[ \frac{m_1(X)^2 m_2(X_2)}{m_1(X) + m_2(X_2)} + \frac{m_2(X)^2 m_1(X_2)}{m_2(X) + m_1(X_2)} \right], \quad (3)$$

where all denominators in (3) are different from zero. If a denominator is zero, that fraction is discarded.

From the implementation point of view, PCR6 is simpler to implement than PCR5. For convenience, very basic (not optimized) Matlab™ codes of PCR5 and PCR6 fusion rules can be found in [12], [13] and from the toolboxes repository on the web [14]. The main drawback of PCR5 and PCR6 rules is their very high combinatorial complexity when the number of source is big, as well as the cardinality of the FoD. In this case, PCR5 or PCR6 rules cannot be used directly because of memory overflow. Even for combining BBAs defined on a simple dichotomous FoD as those involved in the Inter-Criteria Analysis (ICrA), the computational time for combining more than 10 sources can take several hours<sup>2</sup>. That is why a fast fusion method to combine dichotomous BBAs is necessary, and we present it in the next subsections.

### B. Canonical decomposition of dichotomous BBA

A FoD  $\Theta = \{A, \bar{A}\}$  is called dichotomous if it consists of only two proper subsets  $A$  and  $\bar{A}$  with  $A \cup \bar{A} = \Theta$  and  $A \cap \bar{A} = \emptyset$ , where  $\bar{A}$  is the complement of  $A$  in  $\Theta$  and  $A$  is different from  $\Theta$  and from Empty-Set. We consider a given proper BBA  $m(\cdot) : 2^\Theta \rightarrow [0, 1]$  of the general form

$$m(A) = a, \quad m(\bar{A}) = b, \quad m(A \cup \bar{A}) = 1 - a - b. \quad (4)$$

<sup>2</sup>with a MacBook Pro 2.8 GHz Intel Core i7 with 16 Go 1600 MHz DDR3 memory running Matlab™ R2018a.

The canonical decomposition problem consists in finding the two following simple proper BBAs  $m_p$  and  $m_c$  of the form

$$m_p(A) = x, \quad m_p(A \cup \bar{A}) = 1 - x, \quad (5)$$

$$m_c(\bar{A}) = y, \quad m_c(A \cup \bar{A}) = 1 - y, \quad (6)$$

with  $(x, y) \in [0, 1] \times [0, 1]$ , such that  $m = Fusion(m_p, m_c)$ , for a chosen rule of combination denoted by  $Fusion(\cdot, \cdot)$ . The simple BBA  $m_p(\cdot)$  is called the *pro-BBA* (or pro-evidence) of  $A$ , and the simple BBA  $m_c(\cdot)$  the *contra-BBA* (or contra-evidence) of  $A$ . The BBA  $m_p(\cdot)$  is interpreted as a source of evidence providing an uncertain evidence in favor of  $A$ , whereas  $m_c(\cdot)$  is interpreted as a source of evidence providing an uncertain contrary evidence about  $A$ .

In [6], we have shown that this decomposition is possible with Dempster's rule only if  $0 < a < 1$ ,  $0 < b < 1$  and  $a + b < 1$ , and we have  $x = \frac{a}{1-b}$  and  $y = \frac{b}{1-a}$ . However, any dogmatic BBA  $m(A) = a$ ,  $m(\bar{A}) = b$  with  $a + b = 1$  is not decomposable from Dempster's rule for the case when  $(a, b) \neq (1, 0)$  and  $(a, b) \neq (0, 1)$ , and the dogmatic BBAs  $m(A) = 1$ ,  $m(\bar{A}) = 0$ , or  $m(A) = 0$ ,  $m(\bar{A}) = 1$  have infinitely many decompositions based on Dempster's rule of combination. We have also proved that this canonical decomposition cannot be done from conjunctive, disjunctive, Yager's [15] or Dubois-Prade [16] rules of combination, neither from the averaging rule. The main result of [6] is that this canonical decomposition is unique and is always possible in all cases using the PCR5 rule of combination. This is very useful to implement a fast efficient approximating fusion method of dichotomous BBAs as presented in details in [5]. We recall the following two important theorems proved in [6].

**Theorem 1:** Consider a dichotomous FoD  $\Theta = \{A, \bar{A}\}$  with  $A \neq \emptyset$  and  $A \neq \Theta$  and a nondogmatic BBA  $m(\cdot) : 2^\Theta \rightarrow [0, 1]$  defined on  $\Theta$  by  $m(A) = a$ ,  $m(\bar{A}) = b$ , and  $m(A \cup \bar{A}) = 1 - a - b$ , where  $a, b \in [0, 1]$  and  $a + b < 1$ . Then the BBA  $m(\cdot)$  has a unique canonical decomposition using PCR5 rule of combination of the form  $m = PCR5(m_p, m_c)$  with pro-evidence  $m_p(A) = x$ ,  $m_p(A \cup \bar{A}) = 1 - x$  and contra-evidence  $m_c(\bar{A}) = y$ ,  $m_c(A \cup \bar{A}) = 1 - y$  where  $x, y \in [0, 1]$ .

**Theorem 2:** Any dogmatic BBA defined by  $m(A) = a$  and  $m(\bar{A}) = b$ , where  $a, b \in [0, 1]$  and  $a + b = 1$ , has a canonical decomposition using PCR5 rule of combination of the form  $m = PCR5(m_p, m_c)$  with  $m_p(A) = x$ ,  $m_p(A \cup \bar{A}) = 1 - x$  and  $m_c(\bar{A}) = y$ ,  $m_c(A \cup \bar{A}) = 1 - y$  where  $x, y \in [0, 1]$ .

Theorems 1 & 2 prove that the decomposition based on PCR5 always exists and it is unique for any dichotomous (nondogmatic, or dogmatic) BBA.

For the case of dichotomous nondogmatic BBA considered in Theorem 1, one has to find  $x$  and  $y$  solutions of the system

$$a = x(1 - y) + \frac{x^2 y}{x + y} = \frac{x^2 + xy - xy^2}{x + y}, \quad (7)$$

$$b = (1 - x)y + \frac{xy^2}{x + y} = \frac{y^2 + xy - x^2 y}{x + y}, \quad (8)$$

under the constraints  $(a, b) \in [0, 1]^2$ , and  $0 < a + b < 1$ . The explicit expression of  $x$  and  $y$  are difficult to obtain analytically (even with modern symbolic computing systems like Mathematica™, or Maple™) because one has a quartic equation to solve whose general analytical expression of its solutions is very complicate. Fortunately, the solutions can be easily calculated numerically by these computing systems, and even with Matlab™ system (thanks to the *fsolve* function) as soon as the numerical values are committed to  $a$  and to  $b$ , and this is what we use in our simulations.

### C. Fast Fusion of dichotomous BBAs

The main idea for making the fast fusion of dichotomous BBAs  $m_s(\cdot)$ , for  $s = 1, 2, \dots, S$  defined on the same FoD  $\Theta$  is based on the three following main steps:

- 1) In the first step, one decomposes canonically each dichotomous BBA  $m_s(\cdot)$  into its pro and contra evidences  $m_{p,s} = (m_{p,s}(A), m_{p,s}(\bar{A}), m_{p,s}(A \cup \bar{A})) = (x_s, 0, 1 - x_s)$  and  $m_{c,s} = (m_{c,s}(A), m_{c,s}(\bar{A}), m_{c,s}(A \cup \bar{A})) = (0, y_s, 1 - y_s)$ ;
- 2) In the second step, one combines the pro-evidences  $m_{p,s}$  for  $s = 1, 2, \dots, S$  altogether to get a global pro-evidence  $m_p$ , and in parallel one combines all the contra-evidences  $m_{c,s}$  for  $s = 1, 2, \dots, S$  altogether to get a global contra-evidence  $m_c$ . The fusion step of pro and contra evidences is based on conjunctive rule of combination;
- 3) Once  $m_p$  and  $m_c$  are calculated, then one combines them with PCR5 fusion rule to get the final result.

Because the PCR5 rule of combination is not associative, the fusion of the canonical BBAs followed by their PCR5 fusion will not provide in general the same result as the direct fusion of the dichotomous BBAs altogether but only an approximate result, which is normal. However, this new fusion approach is interesting because the fusion of the pro-evidence  $m_{p,s}$  (resp. contra-evidences  $m_{c,s}$ ) is very simple because there is no conflict between  $m_{p,s}$  (resp. between  $m_{c,s}$ ), so that their fusion can be done quite easily and a large number of sources can be combined without a high computational burden. In fact, with this fusion approach, only one PCR5 fusion step of simple (combined) canonical BBAs is needed at the very end of the fusion process. In [5], we have proved with a Monte-Carlo simulation analysis that the approximation obtained by this new fusion method based on the fusion of pro-evidences and contra-evidences with respect to the direct fusion of the BBAs with PCR5 (or PCR6 when considering more than two sources to combine) is effective because the agreement between the decision taken from the direct fusion method, and the indirect (canonical decomposition based) method is very good. This new fusion method based on this canonical decomposition does not suffer of combinatorial complexity limitation which is of great interest in some applications because many (hundreds or even thousands) of dichotomous BBAs could be easily combined very quickly. Actually with this method what takes a bit time is only the canonical decomposition done by the

numerical solver. Our analysis [5] has shown that complexity of this fast approach is quasi-linear with the number of sources to combine.

### III. THE BF-ICRA METHOD

In [1], we did present an improved version of Atanassov's Inter-Criteria Analysis (ICrA) method [2]–[4] based on belief functions. This new method has been named BF-ICrA (Belief Function based Inter-Criteria Analysis) for short. It has already been applied to GPS surveying problems in [17]. We present briefly in this section the principles of BF-ICrA.

BF-ICrA starts with the construction of an  $M \times N$  BBA matrix  $\mathbf{M} = [m_{ij}(\cdot)]$  from the score matrix  $\mathbf{S} = [S_{ij}]$ . The BBA matrix  $\mathbf{M}$  is obtained as follows - see [18] for details and justification.

$$m_{ij}(A_i) = Bel_{ij}(A_i), \quad (9)$$

$$m_{ij}(\bar{A}_i) = Bel_{ij}(\bar{A}_i) = 1 - Pl_{ij}(A_i), \quad (10)$$

$$m_{ij}(A_i \cup \bar{A}_i) = Pl_{ij}(A_i) - Bel_{ij}(A_i), \quad (11)$$

where<sup>3</sup>

$$Bel_{ij}(A_i) \triangleq Sup_j(A_i)/A_{\max}^j, \quad (12)$$

$$Bel_{ij}(\bar{A}_i) \triangleq Inf_j(A_i)/A_{\min}^j, \quad (13)$$

with

$$Sup_j(A_i) \triangleq \sum_{k \in \{1, \dots, M\} | S_{kj} \leq S_{ij}} |S_{ij} - S_{kj}|, \quad (14)$$

$$Inf_j(A_i) \triangleq - \sum_{k \in \{1, \dots, M\} | S_{kj} \geq S_{ij}} |S_{ij} - S_{kj}|, \quad (15)$$

and

$$A_{\max}^j \triangleq \max_i Sup_j(A_i), \quad (16)$$

$$A_{\min}^j \triangleq \min_i Inf_j(A_i). \quad (17)$$

For another criterion  $C_{j'}$  and the  $j'$ -th column of the score matrix we will obtain another set of BBA values  $m_{ij'}(\cdot)$ . Applying this method for each column of the score matrix we are able to compute the BBA matrix  $\mathbf{M} = [m_{ij}(\cdot)]$  whose each component is in fact a triplet  $(m_{ij}(A_i), m_{ij}(\bar{A}_i), m_{ij}(A_i \cup \bar{A}_i))$  of BBA values in  $[0, 1]$  such that  $m_{ij}(A_i) + m_{ij}(\bar{A}_i) + m_{ij}(A_i \cup \bar{A}_i) = 1$  for all  $i = 1, \dots, M$  and  $j = 1, \dots, N$ .

The next step of BF-ICrA approach is the construction of the  $N \times N$  Inter-Criteria Matrix  $\mathbf{K} = [K_{jj'}]$  from  $M \times N$  BBA matrix  $\mathbf{M} = [m_{ij}(\cdot)]$  where elements  $K_{jj'}$  corresponds to the BBA  $(m_{jj'}(\theta), m_{jj'}(\bar{\theta}), m_{jj'}(\theta \cup \bar{\theta}))$  about positive consonance  $\theta$ , negative consonance  $\bar{\theta}$  and uncertainty between criteria  $C_j$  and  $C_{j'}$  respectively. The construction of the triplet  $K_{jj'} = (m_{jj'}(\theta), m_{jj'}(\bar{\theta}), m_{jj'}(\theta \cup \bar{\theta}))$  is based on two steps:

- **Step 1 (BBA construction):** Getting  $m_{jj'}^i(\cdot)$ .

For each alternative  $A_i$  for  $i = 1, \dots, M$ , we first compute the BBA  $(m_{jj'}^i(\theta), m_{jj'}^i(\bar{\theta}), m_{jj'}^i(\theta \cup \bar{\theta}))$  for

<sup>3</sup>assuming that  $A_{\max}^j \neq 0$  and  $A_{\min}^j \neq 0$ . If  $A_{\max}^j = 0$  then  $Bel_{ij}(A_i) = 0$ , and if  $A_{\min}^j = 0$  then  $Pl_{ij}(A_i) = 1$ .

any two criteria  $j, j' \in \{1, 2, \dots, N\}$ . For this, we consider two sources of evidences (SoE) indexed by  $j$  and  $j'$  providing the BBA  $m_{ij}$  and  $m_{ij'}$  defined on the simple FoD  $\{A_i, \bar{A}_i\}$  and denoted  $m_{ij} = [m_{ij}(A_i), m_{ij}(\bar{A}_i), m_{ij}(A_i \cup \bar{A}_i)]$  and  $m_{ij'} = [m_{ij'}(A_i), m_{ij'}(\bar{A}_i), m_{ij'}(A_i \cup \bar{A}_i)]$ . We also denote  $\Theta = \{\theta, \bar{\theta}\}$  the FoD about the relative state of the two SoE, where  $\theta$  means that the two SoE agree,  $\bar{\theta}$  means that they disagree and  $\theta \cup \bar{\theta}$  means that we don't know. Hence, two SoE are in total agreement if both commit their maximum belief mass to the same element  $A_i$  or to the same element  $\bar{A}_i$ . Similarly, two SoE are in total disagreement if each one commits its maximum mass of belief to one element and the other to its opposite, that is if one has  $m_{ij}(A_i) = 1$  and  $m_{ij'}(\bar{A}_i) = 1$ , or if  $m_{ij}(\bar{A}_i) = 1$  and  $m_{ij'}(A_i) = 1$ . Based on this very simple and natural principle, one can now compute the belief masses as follows:

$$m_{jj'}^i(\theta) = m_{ij}(A_i)m_{ij'}(A_i) + m_{ij}(\bar{A}_i)m_{ij'}(\bar{A}_i), \quad (18)$$

$$m_{jj'}^i(\bar{\theta}) = m_{ij}(A_i)m_{ij'}(\bar{A}_i) + m_{ij}(\bar{A}_i)m_{ij'}(A_i), \quad (19)$$

$$m_{jj'}^i(\theta \cup \bar{\theta}) = 1 - m_{jj'}^i(\theta) - m_{jj'}^i(\bar{\theta}). \quad (20)$$

$m_{jj'}^i(\theta)$  represents the degree of agreement between the BBA  $m_{ij}(\cdot)$  and  $m_{ij'}(\cdot)$  for the alternative  $A_i$ ,  $m_{jj'}^i(\bar{\theta})$  represents the degree of disagreement of the two BBAs and  $m_{jj'}^i(\theta \cup \bar{\theta})$  the level of uncertainty (i.e. how much we don't know if they agree or disagree). By construction  $m_{jj'}^i(\cdot) = m_{jj'}^i(\cdot), m_{jj'}^i(\theta), m_{jj'}^i(\bar{\theta}), m_{jj'}^i(\theta \cup \bar{\theta}) \in [0, 1]$  and  $m_{jj'}^i(\theta) + m_{jj'}^i(\bar{\theta}) + m_{jj'}^i(\theta \cup \bar{\theta}) = 1$ . This BBA modeling permits to build a set of  $M$  symmetrical Inter-Criteria Belief Matrices (ICBM)  $\mathbf{K}^i = [K_{jj'}^i]$  of dimension  $N \times N$  relative to each alternative  $A_i$  whose components  $K_{jj'}^i$  correspond to the triplet of BBA values  $m_{jj'}^i = (m_{jj'}^i(\theta), m_{jj'}^i(\bar{\theta}), m_{jj'}^i(\theta \cup \bar{\theta}))$  modeling the belief of agreement and of disagreement between  $C_j$  and  $C_{j'}$  based on  $A_i$ .

- **Step 2 (fusion):** Getting  $\mathbf{m}_{jj'}^i(\cdot)$ .

In this step, one needs to combine the BBAs  $\mathbf{m}_{jj'}^i(\cdot)$  for  $i = 1, \dots, M$  altogether to get the component  $K_{jj'} = (m_{jj'}(\theta), m_{jj'}(\bar{\theta}), m_{jj'}(\theta \cup \bar{\theta}))$  of the Inter-Criteria Belief matrix<sup>4</sup> (ICBM)  $\mathbf{K} = [K_{jj'}]$ . For this and from the theoretical standpoint, we recommend to use the PCR6 fusion rule [12] (Vol. 3) because of known deficiencies of Dempster's rule.

Once the global Inter-Criteria Belief Matrix (ICBM)  $\mathbf{K} = [K_{jj'} = (m_{jj'}(\theta), m_{jj'}(\bar{\theta}), m_{jj'}(\theta \cup \bar{\theta}))]$  is calculated, we can identify the criteria that are in strong agreement, in strong disagreement, and those on which we are uncertain. For identifying the criteria that are in strong agreement, we evaluate the distance of each component of  $K_{jj'}$  with the BBA

<sup>4</sup>For the presentation convenience, the ICBM  $\mathbf{K}$ , with  $\mathbf{K} = [K_{jj'} = (m_{jj'}(\theta), m_{jj'}(\bar{\theta}), m_{jj'}(\theta \cup \bar{\theta}))]$ , is decomposed into three matrices  $\mathbf{K}(\theta) = [K_{jj'}^\theta = m_{jj'}(\theta)]$ ,  $\mathbf{K}(\bar{\theta}) = [K_{jj'}^{\bar{\theta}} = m_{jj'}(\bar{\theta})]$  and  $\mathbf{K}(\theta \cup \bar{\theta}) = [K_{jj'}^{\theta \cup \bar{\theta}} = 1 - m_{jj'}(\theta) - m_{jj'}(\bar{\theta})]$ .

representing the best agreement state and characterized by the specific BBA<sup>5</sup>  $m_T(\theta) = 1$ . From a similar approach we can also identify, if we want, the criteria that are in very strong disagreement using the distance of  $m_{jj'}(\cdot)$  with respect to the BBA representing the best disagreement state characterized by the specific BBA  $m_F(\bar{\theta}) = 1$ . We use the belief interval distance  $d_{BI}(m_1, m_2)$  presented in [19] for measuring the distance between the two BBAs.

#### A. Fast BF-ICrA method

The computational complexity of BF-ICrA is of course higher than the complexity of ICrA because it makes a more precise evaluation of local and global inter-criteria belief matrices with respect to inter-criteria matrices calculated by Atanassov's ICrA. The overall reduction of the computational burden of the original MCDM problem thanks to BF-ICrA depends highly on the problem under concern, the complexity and cost to evaluate each criteria involved in it, as well as the number of redundant criteria identified by BF-ICrA method.

The main drawback of BF-ICrA method is the PCR6 combination required in its step 2 for combining altogether the dichotomous BBAs  $m_{jj'}^i(\cdot)$ . Because of combinatorial complexity of PCR6 rule, it cannot work in reasonable computational time as soon as the number of sources to combine altogether is greater than 10, which prevents its use for solving ICrA problems involving more than 10 alternatives (as in the examples 2 and 3 presented in section V). That is why it is necessary to adapt the original BF-ICrA method for working with a large number of alternatives and criteria. For this, we can in step 2 of BF-ICrA exploit the method for the fast fusion of dichotomous BBAs presented in section II-C. More precisely, each dichotomous BBA  $m_{jj'}^i(\cdot)$  will be canonically decomposed in its pro-evidence  $m_{jj',p}^i(\cdot)$  and its contra-evidence  $m_{jj',c}^i(\cdot)$  that will be combined separately to get the global pro-evidence  $m_{jj',p}(\cdot)$  and the global contra-evidence  $m_{jj',c}(\cdot)$ . Then, the BBAs  $m_{jj',p}(\cdot)$  and  $m_{jj',c}(\cdot)$  are combined with PCR5 rule to get the BBAs  $m_{jj'}(\cdot)$  and, finally, the global Inter-Criteria Belief Matrix  $\mathbf{K} = [K_{jj'} = (m_{jj'}(\theta), m_{jj'}(\bar{\theta}), m_{jj'}(\theta \cup \bar{\theta}))]$ . The principle of this modified step 2 of BF-ICrA is summarized in the Figure 1 for convenience.

Another simpler fusion method to combine the dichotomous BBAs  $m_{jj'}^i(\cdot)$  would just consist to average them. In section V, we will show how these two methods behave in the examples chosen for the evaluation of MO-ACO Algorithm for optimal WSN deployment.

## IV. MULTI-OBJECTIVE ACO ALGORITHM

Recently Wireless Sensor Networks (WSNs) have attracted the attention of the research scientists community, conditioned by a set of challenges: theoretical and practical. WSNs consists of distributed sensor nodes and their main purpose is to monitor the real-time environmental status, based on gathering available sensor information, processing and transmitting the

<sup>5</sup>We use the index  $T$  in the notation  $m_T(\cdot)$  to refer that the agreement is true, and  $F$  in  $m_F(\cdot)$  to specify that the agreement is false.

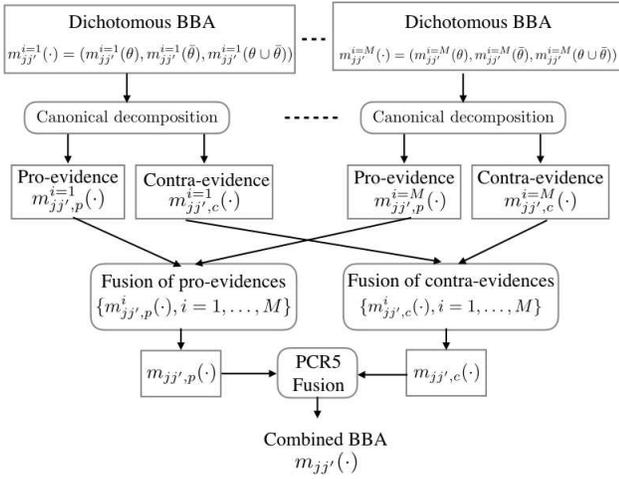

Figure 1. Principle of fast fusion of  $m_{jj'}^i(\cdot)$  of Step 2 of BF-ICrA.

collected data to the specified remote base station. It is a promising technology that is used in a coverage of application requiring minimum human contribution, ranging from civil and military to healthcare and environmental monitoring. One of the key mission of WSN is the full surveillance of the monitoring region with a minimal number of sensors and minimized energy consumption of the network. The lifetime of the sensors is strongly related to the amount of the power loaded in the battery, that is why the control of the energy consumption of sensors is an important active research problem. The small energy storage capacity of sensor nodes intrudes the possibility to gather the information directly to the main base. Because of this they transfer their data to the so called High Energy Communication Node (HECN), which is able to collect the information from across the network and to transmit it to the base computer for processing. The sensors transmit their data to the HECN, either directly or via hops, using closest sensors as communication relays. The WSN can have large numbers of nodes and the problem can be very complex.

In order to solve successfully the key mission of WSNs, in [20], we did apply multi-objective Ant Colony Optimization (ACO) to solve this hard, from the computational point of view, telecommunication problem. The number of ants is one of the key algorithm parameters in the ACO and it is important to find the optimal number of ants needed to achieve good solutions with minimal computational resources. In [20], the optimal solution was obtained by applying the classical Atanassov's ICRA method. In the next section we will present the results obtained by the fast BF-ICrA approach and compare their results.

The problem of designing a WSN is multi-objective, with two objective functions: 1) one wants to minimize the energy consumption of the nodes in the network, and 2) one wants to minimize the number of nodes. The full coverage of the network and connectivity are considered as constraints. For solving this problem, we have proposed to use a Multi-

Objective Ant Colony Optimization (MO-ACO) algorithm in [20] and we have studied the influence of the number of ants on the algorithm performance and quality of the achieved solutions. The computational resources, which the algorithm needs, are not negligible. The computational resources depends on the size of the solved problem and on the number of ants. The aim is to find a minimal number of ants which allow the algorithm to find good solution for WSN deployment.

The ACO algorithm uses a colony of artificial ants that behave as cooperating agents. With the help of the pheromone and the heuristic information they try to construct better solutions and to find the optimal ones. The pheromone corresponds to the global memory of the ants and the heuristic information is a some preliminary knowledge of the problem. The problem is represented by a graph and the solution is represented by a path in the graph or by tree in the graph. Ants start from random nodes and construct feasible solutions. When all ants construct their solution the pheromone is updated. The new, added, pheromone depends to the quality of the solution. The elements of the graph, which belong to better solutions will receive more pheromone and will be more desirable in the next iteration. In our implementation, we use the MAX-MIN Ant System (MMAS) which is one of the most successful ant approaches originally presented in [21]. In our case, the graph of the problem is represented by a square grid. The nodes of the graph are enumerated. The ants will deposit their pheromone on the nodes of the grid. We will deposit the sensors on the nodes of the grid too. The solution is represented by tree. An ant starts to create a solution starting from random node, which communicates with the HECN. Construction of the heuristic information is a crucial point in the ant algorithms. Our heuristic information represented by (21) is a product of three values.

$$\eta_{ij}(t) = s_{ij} l_{ij} (1 - b_{ij}) \quad (21)$$

where  $s_{ij}$  is the number of the new points (nodes of the graph) which the new sensor will cover, and which are not covered by other sensors, and

$$l_{ij} = \begin{cases} 1 & \text{if communication exists;} \\ 0 & \text{if there is no communication.} \end{cases} \quad (22)$$

and where  $b_{ij}$  is the solution matrix. The matrix element  $b_{ij}$  equals 1 when there is sensor on this position, otherwise  $b_{ij} = 0$ . With  $s_{ij}$ , we try to increase the number of points covered by one sensor and thus to decrease the number of sensors we need. With  $l_{ij}$ , we guarantee that all sensors will be connected. With  $b_{ij}$  we guarantee that maximum one sensor will be mapped on the same point. The search stops when transition probability  $p_{ij} = 0$  for all values of  $i$  and  $j$ . It means that there are no more free positions, or that all area is fully covered. At the end of every iteration the quantity of the pheromone is updated according to the rule:  $\tau_{ij} \leftarrow \rho \tau_{ij} + \Delta \tau_{ij}$ , with the increment  $\Delta \tau_{ij} = 1/F(k)$  if  $(i, j)$  belongs to the non-dominated solution constructed by ant  $k$ , or  $\Delta \tau_{ij} = 0$  otherwise. The parameter  $\rho$  is a pheromone

decreasing parameter chosen in  $[0, 1]$ . This parameter  $\rho$  models evaporation in the nature and decreases the influence of old information on the search process. After that, we add the new pheromone, which is proportional to the value of the fitness function constructed as  $F(k) = \frac{f_1(k)}{\max_i(f_1(i))} + \frac{f_2(k)}{\max_i(f_2(i))}$ , where  $f_1(k)$  is the number of sensors proposed by the  $k$ -th ant, and  $f_2(k)$  is the energy of the solution of the  $k$ -th ant. These are also the objective functions of the WSN layout problem. We normalize the values of two objective functions with their maximal achieved values from the first iteration.

V. APPLICATION OF THE FAST BF-ICRA METHOD

In this section we present the results of the fast BF-ICrA method with the MO-ACO algorithm for WSN layout deployment. Fidanova and Roeva have developed a software, which realizes the MO-ACO algorithm. This software can solve the problem at any rectangular area, the communication and the coverage radius can be different and can have any positive value. We can have regions in the area. The program was written in C language, and the tests were run on computer with an Intel Pentium 2.8GHz processor. In their tests, they use an example where the area is square. The coverage and communication radii cover 30 points. The HECN is fixed in the centre of the area. In the sequel we consider three examples of areas with three sizes:  $350 \times 350$  points,  $500 \times 500$  points, and  $700 \times 700$  points. The MO-ACO algorithm is based on 30 runs for each number of ants. We extract the Pareto front from the solutions of these 30 runs, and we show the achieved non dominated solutions (approximate Pareto fronts) for each case on which the BF-ICrA will be applied. The score matrices for each case is given in Tables I, II and III [20].

THE 19 × 10 SCORE MATRIX S FOR 700 × 700 CASE (EXAMPLE 3).

to ACO<sub>j</sub> algorithm used with  $j$  ants ( $j = 1, 2, \dots, 10$ ). Each element  $S_{ij}$  of S corresponds to the energy corresponding to this number of sensors and with the number of ants used for Multiple Objective ACO algorithm.

Application of BF-ICrA in example 1 (350 × 350 points)

In this example, one sees from the score matrix of the Table I that ACO<sub>1</sub>, ACO<sub>3</sub> and ACO<sub>9</sub> algorithms perform equally for all alternatives (i.e. all rows) and they define a first group/cluster of methods providing exactly the same performances. Similarly, ACO<sub>4</sub>, ACO<sub>5</sub> and ACO<sub>6</sub> constitute a second group of algorithms. The third group is made of ACO<sub>7</sub>, ACO<sub>8</sub> and ACO<sub>10</sub> algorithms. It is worth noting that these three groups {ACO<sub>1</sub>, ACO<sub>3</sub>, ACO<sub>9</sub>}, {ACO<sub>4</sub>, ACO<sub>5</sub>, ACO<sub>6</sub>}, and {ACO<sub>7</sub>, ACO<sub>8</sub>, ACO<sub>10</sub>} differ only very slightly, whereas the ACO<sub>2</sub> algorithm (i.e the 2nd column of the score matrix S) differs a bit more from all the three aforementioned groups.

**Example 1 with fast PCR6:** If we apply the fast BF-ICrA method using approximate PCR6 fusion rule based on the canonical decomposition of the  $M = 6$  dichotomous BBAs ( $m_{jj}^i(\theta), m_{jj'}^i(\theta), m_{jj'}^i(\theta \cup \theta')$ ), we get the matrix of mass of belief of agreement between criteria given in Table<sup>6</sup> IV.

Table IV

MATRIX  $K_{\approx PCR6}(\theta)$  FOR EXAMPLE 1.

The matrix of distances to full agreement based on fast BF-ICrA method, denoted by  $D_{\approx PCR6}(\theta)$ , is given in Table V.

In examining the table V, one sees that ACO<sub>1</sub>, ACO<sub>3</sub> and ACO<sub>9</sub> are at a small distance 0.134, with respect to other algorithms, so that they belong to the same group and behave similarly. Same remarks holds for the group {ACO<sub>4</sub>, ACO<sub>5</sub>, ACO<sub>6</sub>} because its inter-distance is zero,

<sup>6</sup>All the numerical values presented in the matrices have been truncated at their 3rd digit for typesetting convenience.

Table V

 MATRIX  $\mathbf{D}_{\approx PCR6}(\theta)$  WITH FAST BF-ICRA FOR EXAMPLE 1.

and for the group  $\{\text{ACO}_7, \text{ACO}_8, \text{ACO}_{10}\}$  because its inter-distance is 0.156. In a relative manner  $\text{ACO}_2$  appears closer to  $\{\text{ACO}_4, \text{ACO}_5, \text{ACO}_6\}$ , than  $\{\text{ACO}_1, \text{ACO}_3, \text{ACO}_9\}$  or  $\{\text{ACO}_7, \text{ACO}_8, \text{ACO}_{10}\}$ , which intuitively makes sense when comparing directly the columns of the matrix of Table I.

**Example 1 with averaging fusion:** The matrix of distances to full agreement based on BF-ICrA method using average fusion rule, denoted by  $\mathbf{D}_{\text{Aver.}}(\theta)$ , is given in Table VI.

0.084	0.082	0.084	0.081	0.081	0.081	0.156	0.156	0.084	0.156

Table VI

 MATRIX  $\mathbf{D}_{\text{Aver.}}(\theta)$  WITH BF-ICrA USING AVERAGING RULE FOR EXAMPLE 1.

One sees that only the group  $\{\text{ACO}_4, \text{ACO}_5, \text{ACO}_6\}$  can be clearly identified based on the averaging fusion rule. The other groups  $\text{ACO}_2$  appears also close to  $\{\text{ACO}_4, \text{ACO}_5, \text{ACO}_6\}$ . But  $\text{ACO}_1, \text{ACO}_3$  and  $\text{ACO}_9$  are closer to  $\{\text{ACO}_4, \text{ACO}_5, \text{ACO}_6\}$  also than in-between. Same remarks holds for  $\text{ACO}_7, \text{ACO}_8$ , and  $\text{ACO}_{10}$ . So one sees that the averaging fusion rule is not recommended for making the BF-ICrA in this example.

*Application of BF-ICrA in example 2 (500 × 500 points)*

**Example 2 with fast PCR6:** If we apply the fast BF-ICrA method using approximate PCR6 fusion rule based on the canonical decomposition of the  $M = 22$  dichotomous BBAs  $(m_{jj'}^i(\theta), m_{jj'}^i(\bar{\theta}), m_{jj'}^i(\theta \cup \bar{\theta}))$ , we get the following matrix of distances to full agreement, denoted by  $\mathbf{D}_{\approx PCR6}(\theta)$ , given in Table VII.

0.158	0.376	0.338	0.300	0.286	0.279	0.247	0.251	<b>0.225</b>	0.280

Table VII

 MATRIX  $\mathbf{D}_{\approx PCR6}(\theta)$  WITH FAST BF-ICrA FOR EXAMPLE 2.

Based on these results, one sees that no clear group can be identified but we emphasize in boldface in Table VII the minimal value for each row of the distance matrix  $\mathbf{D}_{\approx PCR6}(\theta)$

(diagonal elements excluded). We see that  $\text{ACO}_2$  is at the farthest distance of  $\text{ACO}_1$  because  $D_{12}(\theta) = 0.376$ , but in the mean time  $\text{ACO}_2$  is at closest distance to  $\text{ACO}_1$  because  $D_{2j}(\theta) > 0.376$  (for  $j > 2$ ) as shown in second line of Table VII. So we can conclude that  $\text{ACO}_2$  is not close to any other algorithm in fact. If we choose a ad-hoc distance threshold, say for instance 0.28, then we can identify the group  $\{\text{ACO}_1, \text{ACO}_7, \text{ACO}_8, \text{ACO}_9\}$ .

**Example 2 with averaging fusion:** The matrix of distances to full agreement based on BF-ICrA method using average fusion rule, denoted by  $\mathbf{D}_{\text{Aver.}}(\theta)$ , is given in Table VIII.

Table IX

 MATRIX  $\mathbf{D}_{\approx PCR6}(\theta)$  WITH FAST BF-ICrA FOR EXAMPLE 3.

We observe that the average distance between ACO algorithms is much higher than in Tables V and VII of examples 1 and 2. This shows clearly the difficulty to precisely identify the clusters of similar algorithms because only few ACO algorithms perform actually very well for this third example. Eventually, and based on shortest inter-distance we could make the first pairwise group  $\{\text{ACO}_7, \text{ACO}_8\}$  because  $D_{78}(\theta) = 0.185$  is the minimal inter-distance we have between the ACO algorithms. Once the rows and columns of Table IX corresponding to  $\text{ACO}_7$  and  $\text{ACO}_8$  are eliminated, then the second best group will be  $\{\text{ACO}_5, \text{ACO}_9\}$  because  $D_{59}(\theta) = 0.300$ .

Similarly, we will get the group  $\{ACO_4, ACO_{10}\}$  because  $D_{4,10}(\theta) = 0.303$ , and then the group  $\{ACO_1, ACO_2\}$  because  $D_{12}(\theta) = 0.388$ . Finally we could also cluster  $ACO_3$  with  $ACO_6$  because  $D_{36}(\theta) = 0.500$ , although this distance of agreement is quite large to be considered as a trustable cluster.

**Example 3 with averaging fusion:** The matrix of distances to full agreement based on BF-ICrA method using average fusion rule, denoted by  $\mathbf{D}_{Aver.}(\theta)$ , is given in Table X.

0.170	0.154	0.142	0.221	0.351	0.350	0.392	0.345	0.332	0.298
0.154	0.120	0.092	0.167	0.321	0.295	0.369	0.313	0.290	0.261
0.142	0.092	0.042	0.114	0.289	0.237	0.342	0.279	0.242	0.224
0.221	0.167	0.114	0.054	0.255	0.139	0.327	0.260	0.184	0.177
0.351	0.321	0.289	0.255	0.339	0.245	0.391	0.355	0.287	0.324
0.350	0.295	0.237	0.139	0.245	0	0.304	0.242	0.115	0.247
0.392	0.369	0.342	0.327	0.391	0.304	0.390	0.368	0.336	0.387
0.345	0.313	0.279	0.260	0.355	0.242	0.368	0.328	0.288	0.341
0.332	0.290	0.242	0.184	0.287	0.115	0.336	0.288	0.190	0.279
0.298	0.261	0.224	0.177	0.324	0.247	0.387	0.341	0.279	0.261

Table X

MATRIX  $\mathbf{D}_{Aver.}(\theta)$  WITH BF-ICrA USING AVERAGING RULE FOR EXAMPLE 3.

Surprisingly, the use of averaging rule provides in this example lower distance values on average with respect to values given in Table IX. However no clear clustering of algorithms can be made because only few ACO algorithms perform actually very well for this third example. If we adopt the pairwise strategy to cluster algorithms, we will obtain now as first group  $\{ACO_2, ACO_3\}$  because  $D_{23}(\theta) = 0.092$ , as second group  $\{ACO_6, ACO_9\}$  because  $D_{69}(\theta) = 0.115$ , as third group  $\{ACO_4, ACO_{10}\}$  because  $D_{4,10}(\theta) = 0.177$ , as fourth group  $\{ACO_1, ACO_8\}$  because  $D_{18}(\theta) = 0.345$ , and finally we could also cluster  $ACO_5$  with  $ACO_7$  because  $D_{57}(\theta) = 0.391$ . one sees that there is no strong correlation between results obtained from BF-ICrA based on fast PCR6 and those based on averaging rule, which is not surprising because the rules are totally different. Nevertheless the group  $\{ACO_4, ACO_{10}\}$  is agreed by both methods here.

## VI. CONCLUSIONS

The fast Belief Function based Inter-Criteria Analysis method, using the canonical decomposition of basic belief assignments defined on a dichotomous frame of discernment was applied, tested and analysed in this paper. This new method was applied for evaluating the Multiple-Objective Ant Colony Optimization (MO-ACO) algorithm for Wireless Sensor Networks (WSN) deployment. Based on the BF-ICrA outcomes it was shown a very high correlation with fast PCR6 rule for the  $ACO_1, ACO_3$  and  $ACO_9$  group, for the  $ACO_4, ACO_5$  and  $ACO_6$  group, and for the  $ACO_7, ACO_8$  and  $ACO_{10}$  group of algorithms in example 1 (case of size  $350 \times 350$ ) as intuitively expected. This is because the considered ACO algorithms can solve the problem with good solution quality in example 1. These high correlations were not observed in the other two cases for example 2 (case of size  $500 \times 500$ ) and 3 (case of size  $700 \times 700$ ) because only few ACO algorithms perform actually very well for these examples. So, if we considered results in case of larger

problem sizes, the BF-ICrA results show that the number of ants has the significant influence on the obtained results, as already pointed out in [20].

**Abstract**—This paper discusses and analyzes the behaviors of the proportional conflict redistribution rules no. 5 (PCR5) and no. 6 (PCR6) to combine several distinct sources of evidence characterized by their basic belief assignments defined over the same frame of discernment. After a brief review of these rules, the paper shows through simple examples why their behaviors can sometimes increase the uncertainty more than necessary which is detrimental to decision-making support drawn from the result of the combination. We present a theoretical improvement of these rules, and establish new PCR5<sup>+</sup> and PCR6<sup>+</sup> rules of combination. These new rules overcome the weakness of PCR5 and PCR6 rules by computing binary keeping-indexes that allow to keep only focal elements that play an effective role in the partial conflict redistribution. PCR5<sup>+</sup> and PCR6<sup>+</sup> rules are not associative but they preserve the neutrality of the vacuous belief assignment contrary to the PCR5 and PCR6 rules, and they make a more precise redistribution which does not increase improperly the mass of partial uncertainties.

**Keywords:** information fusion, belief functions, PCR5<sup>+</sup>, PCR6<sup>+</sup>, PCR5, PCR6 fusion rules..

## I. INTRODUCTION

There exist different theories based on distinct representations and modelings of uncertainty to deal with uncertain information to conduct information fusion [1]. The theory of probability [2], [3], the theory of fuzzy sets [4], [5], the possibility theory [6], [7], and the theory of belief functions [8]–[10] are the most well-known ones. This paper addresses the problem of information fusion in the mathematical framework of the belief functions introduced by Shafer from Dempster's works [11], [12]. The belief functions are often used in decision-making support applications because the experts are generally able to express only a belief in a hypothesis (or a set of hypotheses) from their partial knowledge, experience and from their own perception of the reality. To conduct information fusion, we need some efficient rules of combination that are able to manage the conflicting sources of evidence (if any), or expert opinions expressed in terms of belief functions. Readers interested in belief functions can found classical related papers in [13] and in the special issue [14] which includes also a list of good selected papers. It is worth to mention that the recent book of Cuzzolin [15] includes 2137 references, with many of them related to belief functions.

In this paper, we adopt the notion of conflict introduced by Shafer in [8] (p. 65). This notion of conflict is often adopted by researchers working with belief functions, as in [16] p. 17 for instance, because this notion is quite simple to understand. Different definitions and interpretations of conflict can be also found in [17]–[27] for readers interested in this topic. In this paper, two (or more) sources are said conflicting if they support incompatible (disjoint, or contradictory) hypotheses. We also work with distinct sources of evidences that are considered as (cognitively) independent and reliable. We do not consider, nor apply discounting techniques of belief assessments listed in [14] before combining them to keep the presentation and notations as simple as possible<sup>1</sup>.

While the conjunctive rule makes it possible to combine information between different sources of information by estimating the level of existing conflict, Dempster-Shafer (DS) rule [8], [16] proposes a distribution of this conflict on the hypotheses characterized by the sources of information. The normalization carried out by the DS rule may however be considered counter-intuitive especially when the level of conflict between the sources of information is high [28], [29], but also in some situations where the level of conflict between sources is low as shown in [30] showing a dictatorial behavior of DS rule. The Proportional Conflict Redistribution rules (PCR5 [31] and PCR6 [32], [33]) have been proposed to circumvent the problem of the DS rule to make a more judicious management of the conflict.

In this paper, we put forward a flawed behavior of these combination rules in some cases attributed to the non-neutrality of the vacuous BBA (Basic Belief Assignment), and we propose an improvement of these two combination rules (denoted by PCR5<sup>+</sup> and PCR6<sup>+</sup>) in order to ensure the neutrality property of the vacuous BBA. This is achieved by discarding specific elements implied in the partial conflict and which are not useful for making the conflict redistribution.

In the PCR rules [32]–[34] one redistributes the product of masses of belief of incompatible (i.e. conflicting) elements whose intersection is empty only to elements involved in

<sup>1</sup>Of course discounted belief assignments can also be combined by the rules presented in this paper.

this product and proportionally to their mass of belief. For instance, let's consider two elements  $A, B$  of a frame of discernment (FoD) with  $A \cap B = \emptyset$ , and three basic belief assignments  $m_1(\cdot), m_2(\cdot), m_3(\cdot)$  defined on this FoD with  $m_1(A) > 0, m_2(B) > 0$ , and  $m_3(A \cup B) > 0$ . The product  $m_1(A)m_2(B)m_3(A \cup B) > 0$  is called a *conflicting product hereafter because*  $A \cap B \cap (A \cup B) = \emptyset$ . Based on PCR5 (and PCR6) rule, we will redistribute the value of this product back to the focal<sup>2</sup> elements  $A, B$  and  $A \cup B$ , and proportionally to  $m_1(A), m_2(B)$  and  $m_3(A \cup B)$ . In the improved PCR rules developed in this paper we will redistribute this conflicting product only to the focal elements  $A$  and  $B$  since the focal element  $A \cup B$  is neither in conflict with  $A$ , nor with  $B$ . Such an improvement in the proportional conflict redistribution is made possible by defining a binary keeping-index for each focal element involved in the conflicting product. This index will allow the identification of elements of the conflicting product that will have an effective role in the proportional redistribution of conflicting product. All elements (if any) having a binary keeping-index equal to zero are discarded of the conflict redistribution process. This main idea is developed in this paper and illustrated with several examples. It allows to preserve the neutrality of the total ignorant source of evidence in the improved versions of PCR5 and PCR6 rules, which is often considered as a desirable property for a rule of combination of distinct and reliable sources of evidence.

For the reader not immersed in the belief mathematics notion, the comparative numerical examples of Example 1 of section III-B as compared with Example 1 revisited of section VII, provide a quick verification of the improvements.

This paper is organized as follows. We give the basics of belief functions in Section II. We present the PCR5 and PCR6 rules of combination in Section III with new general formulas in subsection III-C, and associated examples in Section IV. The flawed behavior of PCR5 and PCR6 rules are highlighted in Section V through specific examples. Then, Section VI proposes the mathematical expression of the new improved PCR5<sup>+</sup> and PCR6<sup>+</sup> rules of combination, as well as the very detailed procedure to select the focal elements for these new proportional redistributions. Finally, comparative results for relevant examples are shown in Section VII in order to compare the PCR5 and PCR6 results with the PCR5<sup>+</sup> and PCR6<sup>+</sup> results. Concluding remarks are given in section VIII. For convenience, two Matlab<sup>TM</sup> routines are also given in the appendix 3 of this paper for PCR5<sup>+</sup> and PCR6<sup>+</sup> rules of combination.

## II. BASICS OF BELIEF FUNCTIONS

We consider a given finite set  $\Theta$  of  $n > 1$  distinct elements  $\Theta = \{\theta_1, \theta_2, \dots, \theta_n\}$  corresponding to the frame of discernment (FoD) of the fusion problem, or the decision-making problem, under concern. All elements of  $\Theta$  are mutually

<sup>2</sup>A focal element is an element (i.e. a subset) having a strictly positive mass of belief committed to it - see section II elements

exclusive<sup>3</sup> and each element is an elementary choice of the potential decision to take. The power set of  $\Theta$  is the set of all subsets of  $\Theta$  (including empty set  $\emptyset$  and  $\Theta$ ) and it is usually denoted  $2^\Theta$  because its cardinality equals  $2^{|\Theta|}$ . We adopt Shafer's formalism whereby propositions are represented by subsets [8] (Chap.2, pp. 35–37). Hence, the propositions under concern are in one-to-one correspondance with subsets of  $\Theta$ . We also use classical notations of set theory [35], i.e.  $\emptyset$  for the empty set,  $A \cup B$  for the union<sup>4</sup> of sets  $A$  and  $B$  (which is the set of all objects that are a member of the set  $A$ , or the set  $B$ , or both),  $A \cap B$  for their intersection (which is the set of all objects that are members of both  $A$  and  $B$ ), etc. A Basic Belief Assignment (BBA) given by a source of evidence is defined by Shafer [8] in his Mathematical Theory of Evidence (known also as Dempster-Shafer Theory, or DST) as  $m(\cdot) : 2^\Theta \rightarrow [0, 1]$  satisfying

$$\begin{cases} m(\emptyset) = 0, \\ \sum_{A \in 2^\Theta} m(A) = 1, \end{cases} \quad (1)$$

where  $m(A)$  is the mass of belief exactly committed to  $A$ , what we usually call the mass of  $A$ . A BBA is said proper (or normal) if it satisfies Shafer's definition (1). The subset  $A \subseteq \Theta$  is called a Focal Element (FE) of the BBA  $m(\cdot)$  if and only if  $m(A) > 0$ . The empty set is not a focal element of a BBA because  $m(\emptyset) = 0$  according to definition (1). The set of all focal elements of a BBA  $m(\cdot)$  is denoted  $\mathcal{F}(m)$ . Its mathematical definition is  $\mathcal{F}(m) = \{X \in 2^\Theta | m(X) > 0\}$ . The cardinality  $|\mathcal{F}(m)|$  of the set  $\mathcal{F}(m)$  is denoted  $\mathcal{F}_m$ . The order of focal elements of  $\mathcal{F}(m)$  does not matter and all the focal elements are different. The set  $\mathcal{F}(m)$  of focal elements of  $m(\cdot)$  has at least one focal element, and at most  $2^{|\Theta|} - 1$  focal elements.

Belief and plausibility functions are respectively defined from  $m(\cdot)$  by [8]

$$Bel(A) = \sum_{X \in 2^\Theta | X \subseteq A} m(X), \quad (2)$$

and

$$Pl(A) = \sum_{X \in 2^\Theta | A \cap X \neq \emptyset} m(X) = 1 - Bel(\bar{A}). \quad (3)$$

where  $\bar{A}$  represents the complement of  $A$  in  $\Theta$ .

$Bel(A)$  and  $Pl(A)$  are usually interpreted respectively as lower and upper bounds of an unknown (subjective) probability measure  $P(A)$  [11], [12]. The functions  $m(\cdot), Bel(\cdot)$  and  $Pl(\cdot)$  are one-to-one. A belief function  $Bel(\cdot)$  is *Bayesian* if all Bel's focal elements are singletons [8] (Theorem 2.8 p. 45). In this case,  $m(X) = Bel(X)$  for any (singleton) focal element  $X$ , and  $m(\cdot)$  is called a *Bayesian BBA*. Corresponding  $Bel(\cdot)$  function is equal to  $Pl(\cdot)$  and these functions can be

<sup>3</sup>This standard assumption is called *Shafer's model of FoD* in DSmt (Dezert-Smarandache Theory) framework [34].

<sup>4</sup>We prefer the notation  $A \cup B$  for denoting the union of sets  $A$  and  $B$ , which is a formal mathematical notation for the union of two sets, instead of the notations  $AB$  or  $\{A, B\}$  used by some authors.

interpreted as a same (possibly subjective) probability measure  $P(\cdot)$ . The vacuous BBA (VBBA for short) representing a totally ignorant source is defined as  $m_v(\Theta) = 1$ .

### III. COMBINATION OF BBAS

This Section presents at first the conjunctive rule of combination which is one of the main rules to combine reliable sources of evidence and which allows to identify the conflicting information among the sources. Then we present the proportional conflict redistribution rules no. 5 (PCR5) [31] and no. 6 (PCR6) [32], [33] as alternatives of Dempster's rule of combination [8]. The development of these rules has been motivated by the counter-intuitive behavior of Dempster's rule [8] when combining high conflicting sources of evidences, but also when combining low conflicting sources of evidences as well<sup>5</sup>. The reader interested in this topic can refer to [13], [28]–[30] to see theoretical justifications and examples. In the following, and for simplicity, we restrain our presentation to the classical framework of belief functions, and we work with BBAs defined only on the power set  $2^\Theta$  of a FoD  $\Theta$ . PCR rules have been defined originally for working with Dedekind's lattice as well, see Chapter 1 of [34] (Volume 2). In this paper, we present simple general expressions of PCR5 and PCR6 fusion rules because they are more easy to understand than the original general formulas, and they afford expressions of the improved PCR5<sup>+</sup> and PCR6<sup>+</sup> rules in a direct and useful manner.

After a brief presentation of the main notations used in this paper, we will recall both PCR5 and PCR6 rules for historical and technical reasons. PCR5 has been developed at first, and then PCR6 has been proposed based on a modified redistribution principle inspired by PCR5. In this paper, we follow the logical and historical development of these PCR5 and PCR6 rules to make the presentation of their improved versions PCR5<sup>+</sup> and PCR6<sup>+</sup>. It seems easier to understand PCR6<sup>+</sup> fusion formula once the PCR5<sup>+</sup> formula will have been established. By presenting both rules, we offer to the readers a global deeper view on how these new rules work and their fundamental and mathematical differences in their conflict redistribution principles. In the sequel, all the introduced examples assume the model of Shafer's frame of discernment as in the classical DST framework.

#### A. Notations

When we make the combination of  $S \geq 2$  BBAs by the conjunctive rule, or by the PCR5 and PCR6 fusion rules, we have to compute the product of the masses of the focal elements composing any possible  $S$ -tuple of focal elements. Each possible  $S$ -tuple is noted by<sup>6</sup>

$$\mathbf{X}_j \triangleq (X_{j_1}, X_{j_2}, \dots, X_{j_S}) \in \mathcal{F}(m_1) \times \mathcal{F}(m_2) \times \dots \times \mathcal{F}(m_S),$$

where  $j_1 \in \{1, 2, \dots, \mathcal{F}_{m_1}\}$ ,  $j_2 \in \{1, 2, \dots, \mathcal{F}_{m_2}\}$ ,  $\dots$ ,  $j_S \in \{1, 2, \dots, \mathcal{F}_{m_S}\}$ . The element  $X_{j_i}$  is the focal element

of  $m_i(\cdot)$  that makes the  $i$ -th component of the  $j$ -th  $S$ -tuple  $\mathbf{X}_j$ .

For notation convenience also, the cartesian product  $\mathcal{F}(m_1) \times \mathcal{F}(m_2) \times \dots \times \mathcal{F}(m_S)$  is denoted by  $\mathcal{F}(m_1, \dots, m_S)$  in the sequel.

We have  $\mathcal{F} \triangleq |\mathcal{F}(m_1, \dots, m_S)| = \prod_{i=1}^S |\mathcal{F}(m_i)| = \prod_{i=1}^S \mathcal{F}_{m_i}$  products of masses of focal elements to consider and to calculate because we have  $\mathcal{F}_{m_1}$  focal elements in  $\mathcal{F}(m_1)$ ,  $\mathcal{F}_{m_2}$  focal elements in  $\mathcal{F}(m_2)$ ,  $\dots$ , and  $\mathcal{F}_{m_S}$  focal elements in  $\mathcal{F}(m_S)$ . Each product for  $j = 1$  to  $\mathcal{F}$  is of the form

$$\pi_j(X_{j_1} \cap X_{j_2} \cap \dots \cap X_{j_S}) \triangleq \prod_{i=1}^S m_i(X_{j_i}). \quad (4)$$

There are two types of products:

- $\pi_j(X_{j_1} \cap X_{j_2} \cap \dots \cap X_{j_S})$  is called a *non-conflicting (mass) product* if

$$X_{j_1} \cap X_{j_2} \cap \dots \cap X_{j_S} = X \neq \emptyset.$$

In this case,  $\pi_j(X_{j_1} \cap X_{j_2} \cap \dots \cap X_{j_S})$  is also noted by  $\pi_j(X)$  for short.

- $\pi_j(X_{j_1} \cap X_{j_2} \cap \dots \cap X_{j_S})$  is called a *conflicting (mass) product* if

$$X_{j_1} \cap X_{j_2} \cap \dots \cap X_{j_S} = \emptyset.$$

In this case,  $\pi_j(X_{j_1} \cap X_{j_2} \cap \dots \cap X_{j_S})$  is also noted by  $\pi_j(\emptyset)$  for short.

It is worth noting that an element  $X \in 2^\Theta \setminus \{\emptyset\}$  may belong to sets of focal elements of the different BBAs to combine, and therefore a  $S$ -tuple  $\mathbf{X}_j$  can have duplicate components. Because all the BBAs are normalized, we always have

$$\sum_{j=1}^{\mathcal{F}} \pi_j(X_{j_1} \cap X_{j_2} \cap \dots \cap X_{j_S}) = 1. \quad (5)$$

As a simple example to illustrate our notations, let's consider two BBAs  $m_1(\cdot)$  and  $m_2(\cdot)$  defined over the FoD  $\Theta = \{A, B, C\}$  with respectively two and three focal elements, say  $\mathcal{F}(m_1) = \{A, B \cup C\}$  and  $\mathcal{F}(m_2) = \{B, C, A \cup C\}$ . Here  $\mathcal{F}_{m_1} = |\mathcal{F}(m_1)| = 2$  and  $\mathcal{F}_{m_2} = |\mathcal{F}(m_2)| = 3$ . For  $j_1 = 1$  (the first focal element of  $m_1(\cdot)$ ) one has  $X_{j_1} = A$ , and for  $j_1 = 2$  (the second focal element of  $m_1(\cdot)$ ) one has  $X_{j_1} = B \cup C$ . Similarly, for  $j_2 = 1$  (the first focal element of  $m_2(\cdot)$ ) one has  $X_{j_2} = B$ , for  $j_2 = 2$  (the 2nd focal element of  $m_2(\cdot)$ ) one has  $X_{j_2} = C$ , and  $j_2 = 3$  (the 3rd focal element of  $m_2(\cdot)$ ) one has  $X_{j_2} = A \cup C$ . In this case we have  $\mathcal{F} = \mathcal{F}_{m_1} \cdot \mathcal{F}_{m_2} = 6$  products of masses to consider in the conjunctive fusion rule (see next sub-section) which are

$$\pi_1(A \cap B) = m_1(A)m_2(B),$$

$$\pi_2(A \cap C) = m_1(A)m_2(C),$$

$$\pi_3(A \cap (A \cup C)) = m_1(A)m_2(A \cup C),$$

$$\pi_4((B \cup C) \cap B) = m_1(B \cup C)m_2(B),$$

$$\pi_5((B \cup C) \cap C) = m_1(B \cup C)m_2(C),$$

$$\pi_6((B \cup C) \cap (A \cup C)) = m_1(B \cup C)m_2(A \cup C).$$

<sup>5</sup>Which is known as the dictatorial behavior of Dempster's rule [30].

<sup>6</sup>The symbol  $\triangleq$  means "equals by definition".

The products  $\pi_1$  and  $\pi_2$  are called *conflicting products* because

- for  $\pi_1$ , the focal elements  $A$  and  $B$  involved in  $\pi_1$  are incompatible (i.e. disjoint) because  $A \cap B = \emptyset$ .  $\pi_1(A \cap B)$  is of course equivalent to  $\pi_j(X_{j_1} \cap X_{j_2})$  with  $j = 1$  by taking  $X_{j_1} = A$  and  $X_{j_2} = B$ ;
- for  $\pi_2$ , one has  $A \cap C = \emptyset$ .  $\pi_2(A \cap C)$  is equivalent to  $\pi_j(X_{j_1} \cap X_{j_2})$  with  $j = 2$  by taking  $X_{j_1} = A$  and  $X_{j_2} = C$ , etc.

The products  $\pi_3, \dots$ , and  $\pi_6$  are not conflicting products because the focal elements involved in each product have non-empty intersection. Because  $m_1(A) + m_1(B \cup C) = 1$  and  $m_2(B) + m_2(C) + m_2(A \cup C) = 1$ , one has  $(m_1(A) + m_1(B \cup C))(m_2(B) + m_2(C) + m_2(A \cup C)) = 1$ , and therefore  $\sum_{j=1}^6 \pi_j = 1$ . This illustrates the formula (5).

In this paper,  $i \in \{1, \dots, S\}$  represents the index of the  $i$ -th source of evidence characterized by the BBA  $m_i(\cdot)$ , and  $j \in \{1, \dots, \mathcal{F}\}$  represents the index of the  $j$ -th product  $\pi_j(X_{j_1} \cap X_{j_2} \cap \dots \cap X_{j_S})$ .

### B. The conjunctive rule of combination

Let's consider  $S \geq 2$  distinct reliable sources of evidence characterized by their BBA  $m_s(\cdot)$  ( $s = 1, \dots, S$ ) defined on  $2^\Theta$ . Their conjunctive fusion<sup>7</sup> is defined for all  $A \in 2^\Theta$  by

$$\begin{aligned} m_{1,2,\dots,S}^{\text{Conj}}(A) &= \sum_{\substack{X_j \in \mathcal{F}(m_1, \dots, m_S) \\ X_{j_1} \cap \dots \cap X_{j_S} = A}} \pi_j(X_{j_1} \cap X_{j_2} \cap \dots \cap X_{j_S}) \\ &= \sum_{\substack{X_j \in \mathcal{F}(m_1, \dots, m_S) \\ X_{j_1} \cap \dots \cap X_{j_S} = A}} \prod_{i=1}^S m_i(X_{j_i}). \end{aligned} \quad (6)$$

The symbol  $\odot$  is also used in the literature, for instance in [36], to note the conjunctive fusion operator, i.e.  $m_{1,2,\dots,S}^{\text{Conj}}(A) = [m_1 \odot m_2 \odot \dots \odot m_S](A)$ .

The total conflicting mass between the  $S$  sources of evidence, denoted  $m_{1,2,\dots,S}^{\text{Conj}}(\emptyset)$ , is nothing but the sum of all existing conflicting mass products, that is

$$\begin{aligned} m_{1,2,\dots,S}^{\text{Conj}}(\emptyset) &= \sum_{\substack{X_j \in \mathcal{F}(m_1, \dots, m_S) \\ X_{j_1} \cap \dots \cap X_{j_S} = \emptyset}} \pi_j(X_{j_1} \cap X_{j_2} \cap \dots \cap X_{j_S}) \\ &= 1 - \sum_{A \in 2^\Theta \setminus \{\emptyset\}} m_{1,2,\dots,S}^{\text{Conj}}(A). \end{aligned} \quad (7)$$

Note that the combined BBA  $m_{1,2,\dots,S}^{\text{Conj}}(\cdot)$  given in (6) is not a proper BBA because it does not satisfy Shafer's definition (1). In general the  $S$  sources of evidence to combine do not fully agree, and we have consequently  $m_{1,2,\dots,S}^{\text{Conj}}(\emptyset) > 0$ .

Dempster's rule of combination (called also *orthogonal sum* by Shafer [8], p. 6) coincides with the normalized version of the conjunctive rule. It is defined by  $m_{1,2,\dots,S}^{\text{DS}}(A) =$

<sup>7</sup>The conjunctive fusion rule is also called Smets' rule of combination by some authors because it has been widely used by Philippe Smets in his works related to belief functions. But Smets himself call it conjunctive rule, see his last paper [20], p. 388.

$m_{1,2,\dots,S}^{\text{Conj}}(A)/(1 - m_{1,2,\dots,S}^{\text{Conj}}(\emptyset))$ , assuming  $m_{1,2,\dots,S}^{\text{Conj}}(\emptyset) \neq 1$ . The DS upper notation refers to initials of Dempster and Shafer names because Dempster's rule has gained its popularity through Shafer's works on belief functions. Shafer uses the symbol  $\oplus$  to note Dempster's fusion operator, i.e.  $m_{1,2,\dots,S}^{\text{DS}}(A) = [m_1 \oplus m_2 \oplus \dots \oplus m_S](A)$  for  $A \neq \emptyset$ , and  $m_{1,2,\dots,S}^{\text{DS}}(\emptyset) = 0$ . A probabilistic analysis of Dempster's rule of combination can be found in [37], and the geometry of Dempster's rule is analyzed in [38].

**Example 1:** Consider  $\Theta = \{A, B\}$  and two following BBAs

$$\begin{aligned} m_1(A) &= 0.1, & m_1(B) &= 0.2, & m_1(A \cup B) &= 0.7, \\ m_2(A) &= 0.4, & m_2(B) &= 0.3, & m_2(A \cup B) &= 0.3. \end{aligned}$$

We have  $m_{1,2}^{\text{Conj}}(\emptyset) = 0.11$ , and

$$m_{1,2}^{\text{Conj}}(A) = 0.35, \quad m_{1,2}^{\text{Conj}}(B) = 0.33, \quad m_{1,2}^{\text{Conj}}(\Theta) = 0.21.$$

Symbolically we denote the conjunctive fusion of  $S$  sources as  $m_{1,2,\dots,S}^{\text{Conj}} = \text{Conj}(m_1, m_2, \dots, m_S)$ . This conjunctive rule is commutative and associative. This means that the sources can be combined altogether in one step, or sequentially in any order and it does not matter. Also, the total ignorant source represented by the vacuous (non-informative) BBA has no impact in the fusion result - see Lemma 1 below.

**Lemma 1:** The vacuous BBA  $m_v$  has a neutral impact in the conjunctive rule of combination, that is

$$\text{Conj}(m_1, m_2, \dots, m_S, m_v) = \text{Conj}(m_1, m_2, \dots, m_S). \quad (8)$$

**Proof:** see appendix 1.

The main drawback of this fusion rule is that it does not generate a proper BBA because  $m_{1,2,\dots,S}^{\text{Conj}}(\emptyset) > 0$  in general, and also it can provide a fusion result  $m_{1,2,\dots,S}^{\text{Conj}}(\emptyset)$  that quickly tends to one after only few steps of a sequential fusion processing of the sources which is not very useful for decision-making support. This is because the empty set  $\emptyset$  is the absorbing element for the conjunctive operation since  $\emptyset \cap A = \emptyset$  for all  $A \in 2^\Theta$  so that the mass committed to the empty set always increases through the repeated conjunctive fusion rule. The main interest of this rule is its ability to identify the partial conflicts and to provide a measure of the total level of conflict  $m_{1,2,\dots,S}^{\text{Conj}}(\emptyset)$  between the sources which can be used to manage (select or discard) the sources in the fusion process if one prefers, see [39] for an application in geophysics for instance.

### C. PCR5 and PCR6 rules of combination

The Proportional Conflict Redistribution Rules (PCR) have been developed originally in the framework of DSMT (Dezert-Smarandache Theory) [31], [32], [34] but they can work also in the classical framework of Shafer's belief functions as well. Six rules have been proposed and they are referred as PCR1, ..., PCR6 rules of combination having different complexities, PCR1 being the most simplest (but less effective) one. All these rules share the same general principle which consists of three steps:

- apply the conjunctive rule (6);
- calculate the conflicting mass products  $\pi_j(\emptyset)$ ;
- redistribute the conflicting mass products  $\pi_j(\emptyset)$  proportionally on all non-empty sets involved in the conflict.

The way the conflicting mass product  $\pi_j(\emptyset)$  is redistributed yields to different versions of PCR combination rules that work for any degree of conflict. The sophistication/complexity and preciseness of PCR rules increases from the first PCR1 rule up to the last rule PCR6. The main disadvantage of these rules, aside their complexity, is their non-associativity properties which impose to combine all the BBAs altogether with PCR rules rather than sequentially to expect the best fusion result.

In this paper, we focus on the presentation of PCR5 and PCR6 only because they are the most well-known advanced fusion rules used so far in the belief functions community. A detailed presentation of other rules of combination encountered in the literature can be found in [40]. Symbolically, the PCR5 fusion and the PCR6 fusion of  $S \geq 2$  BBAs are respectively denoted  $m_{1,2,\dots,S}^{\text{PCR5}} = \text{PCR5}(m_1, m_2, \dots, m_S)$ , and  $m_{1,2,\dots,S}^{\text{PCR6}} = \text{PCR6}(m_1, m_2, \dots, m_S)$ .

Readers familiar with PCR rules could quickly read the example 1 given in section III-B, and the results obtained with classical and improved PCR5 and PCR6 rules in section VII to appreciate the discussion throughout the paper.

**The PCR5 rule of combination** [31]: This rule transfers the conflicting mass  $\pi_j(\emptyset)$  to all the elements involved in this conflict and proportionally to their individual masses, so that a more sophisticate and specific distribution is done with the PCR5 fusion process with respect to other existing rules (including Dempster's rule). The PCR5 rule is presented in details (with justification and examples) in [34], Vol. 2 and Vol. 3.

- The PCR5 fusion of two BBAs is obtained by  $m_{1,2}^{\text{PCR5}}(\emptyset) = 0$ , and for all  $A \in 2^\Theta \setminus \{\emptyset\}$  by

$$m_{1,2}^{\text{PCR5}}(A) = m_{1,2}^{\text{Conj}}(A) + \sum_{\substack{X \in 2^\Theta \\ X \cap A = \emptyset}} \left[ \frac{m_1(A)^2 m_2(X)}{m_1(A) + m_2(X)} + \frac{m_2(A)^2 m_1(X)}{m_2(A) + m_1(X)} \right], \quad (9)$$

where  $m_{1,2}^{\text{Conj}}(A)$  is the conjunctive rule formula (6) with  $S = 2$ , and where all denominators in (9) are different from zero. If a denominator is zero, that fraction is discarded. All propositions/sets are in a canonical form. We take the disjunctive normal form, which is a disjunction of conjunctions, and it is unique in Boolean algebra and simplest. For example,  $X = A \cap B \cap (A \cup B \cup C)$  it is not in a canonical form, but we simplify the formula and  $X = A \cap B$  is in a canonical form.

The PCR5 formula (9) for two BBAs can also be expressed by considering only the focal elements of  $m_1(\cdot)$  and  $m_2(\cdot)$  as follows

$$\begin{aligned} m_{1,2}^{\text{PCR5}}(A) &= m_{1,2}^{\text{Conj}}(A) \\ &+ \sum_{\substack{(X_{j_1}, X_{j_2}) \in \mathcal{F}(m_1) \times \mathcal{F}(m_2) \\ X_{j_1} \cap X_{j_2} = \emptyset \\ X_{j_1} = A}} m_1(X_{j_1}) \cdot \frac{m_1(X_{j_1}) m_2(X_{j_2})}{m_1(X_{j_1}) + m_2(X_{j_2})} \\ &+ \sum_{\substack{(X_{j_1}, X_{j_2}) \in \mathcal{F}(m_1) \times \mathcal{F}(m_2) \\ X_{j_1} \cap X_{j_2} = \emptyset \\ X_{j_2} = A}} m_2(X_{j_2}) \cdot \frac{m_1(X_{j_1}) m_2(X_{j_2})}{m_1(X_{j_1}) + m_2(X_{j_2})}, \end{aligned} \quad (10)$$

or equivalently, with shorthand  $\pi_j$  notations, as

$$\begin{aligned} m_{1,2}^{\text{PCR5}}(A) &= m_{1,2}^{\text{Conj}}(A) \\ &+ \sum_{\substack{j \in \{1, \dots, \mathcal{F}\} | \mathbf{X}_j \in \mathcal{F}(m_1, m_2) \\ X_{j_1} \cap X_{j_2} = \emptyset \\ A \in \mathbf{X}_j}} \left[ m_{i \in \{1,2\} | X_{j_i} = A} (X_{j_i}) \right. \\ &\quad \left. \cdot \frac{\pi_j(X_{j_1} \cap X_{j_2})}{m_1(X_{j_1}) + m_2(X_{j_2})} \right], \end{aligned} \quad (11)$$

where  $\mathcal{F} = |\mathcal{F}(m_1)| \cdot |\mathcal{F}(m_2)|$  is the total number of products  $\pi_j(X_{j_1} \cap X_{j_2}) = m_1(X_{j_1}) m_2(X_{j_2})$ , and  $A \in \mathbf{X}_j$  means that at least one component of  $\mathbf{X}_j$  equals  $A$ .

- The explicit formula of the PCR5 fusion of three BBAs is given in [41].
- A simple formulation of the general expression of the PCR5 fusion of  $S > 2$  basic belief assignments is obtained by redistributing each conflicting product  $\pi_j(\emptyset) = \pi_j(X_{j_1} \cap \dots \cap X_{j_S} = \emptyset) = \prod_{i=1}^S m_i(X_{j_i})$  to some elements of the power set of the FoD that are involved in the conflict. Each  $\pi_j(\emptyset)$  is redistributed proportionally to elements involved in this conflict based on the PCR5 redistribution principle. When an element  $A \in 2^\Theta$  is not involved in a conflicting product  $\pi_j(\emptyset)$ , i.e.  $A \notin \mathbf{X}_j$ , the conflicting product  $\pi_j(\emptyset)$  is not redistributed to  $A$ . If an element  $A$  is involved in the conflict  $X_{j_1} \cap \dots \cap X_{j_S} = \emptyset$ , i.e.  $A \in \mathbf{X}_j$  and  $\pi_j(\emptyset)$  occur, then the proportional redistribution of  $\pi_j(\emptyset)$  to  $A$  is given by

$$\begin{aligned} x_j(A) &\triangleq \left( \prod_{i \in \{1, \dots, S\} | X_{j_i} = A} m_i(X_{j_i}) \right) \\ &\cdot \frac{\pi_j(\emptyset)}{\sum_{X \in \mathbf{X}_j} \left( \prod_{i \in \{1, \dots, S\} | X_{j_i} = X} m_i(X_{j_i}) \right)}, \end{aligned} \quad (12)$$

where  $A \in \mathbf{X}_j$  means that at least one component of the  $S$ -tuple  $\mathbf{X}_j = (X_{j_1}, \dots, X_{j_S}) \in \mathcal{F}(m_1, \dots, m_S)$  equals  $A$ .

Finally the mass value of  $A$  obtained by the PCR5 rule is calculated by

$$m_{1,2,\dots,S}^{\text{PCR5}}(A) = m_{1,2,\dots,S}^{\text{Conj}}(A) + \sum_{j \in \{1, \dots, \mathcal{F}\} | A \in \mathbf{X}_j \wedge \pi_j(\emptyset)} x_j(A), \quad (13)$$

where  $A \in \mathbf{X}_j \wedge \pi_j(\emptyset)$  is a shorthand notation meaning that at least one component of the  $S$ -tuple  $\mathbf{X}_j$  equals  $A$  and the components of  $\mathbf{X}_j$  are conflicting, i.e.  $X_{j_1} \cap \dots \cap X_{j_S} = \emptyset$ .

Therefore the general PCR5 formula can be expressed as  $m_{1,2,\dots,S}^{\text{PCR5}}(\emptyset) = 0$ , and for  $A \in 2^\Theta \setminus \{\emptyset\}$  by

$$m_{1,2,\dots,S}^{\text{PCR5}}(A) = m_{1,2,\dots,S}^{\text{Conj}}(A) + \sum_{j \in \{1,\dots,\mathcal{F}\} | A \in \mathbf{X}_j \wedge \pi_j(\emptyset)} \left[ \left( \prod_{i \in \{1,\dots,S\} | X_{j_i} = A} m_i(X_{j_i}) \right) \cdot \frac{\pi_j(\emptyset)}{\sum_{X \in \mathbf{X}_j} \left( \prod_{i \in \{1,\dots,S\} | X_{j_i} = X} m_i(X_{j_i}) \right)} \right]. \quad (14)$$

It is worth noting that the formula (14) is a generalization of the formula (11), i.e. (14) coincides with (11) when  $S = 2$ .

This general PCR5 formula is equivalent to the original PCR5 formula given in [31] but it involves only the focal elements of the BBAs to combine which makes the derivation more efficient (less computationally demanding) than the original general PCR5 formula, specially when each BBA has only few focal elements. We use this new general PCR5 formula because it is relatively simple and easy to improve it into PCR5<sup>+</sup> formula - see section VI-B. The extension of PCR5 for combining qualitative<sup>8</sup> BBAs can be found in [34], Vol. 2 & 3, and in [33]. PCR5 rule is not associative and the best fusion result is obtained by combining the sources altogether at the same time when possible. A suboptimal fast fusion method using PCR5-based canonical decomposition [42] can be found in [43].

**The PCR6 rule of combination** [32]: A variant of PCR5 rule, called PCR6 rule, has been proposed by Martin and Osswald in [32], [33] for combining  $S > 2$  sources. Because PCR6 coincides with PCR5 when one combines two sources, we do not provide the PCR6 formula for two sources which is the same as (9). The difference between PCR5 and PCR6 lies in the way the proportional conflict redistribution is done as soon as three (or more) sources are involved in the fusion as it will be shown in the example 2 introduced in the next section. The explicit formula of the PCR6 fusion of three BBAs is given in [41] for convenience.

The PCR6 fusion of  $S > 2$  BBAs is obtained by  $m_{1,2,\dots,S}^{\text{PCR6}}(\emptyset) = 0$ , and for all  $A \in 2^\Theta \setminus \{\emptyset\}$  by<sup>9</sup>

$$m_{1,2,\dots,S}^{\text{PCR6}}(A) = m_{1,2,\dots,S}^{\text{Conj}}(A) + \sum_{j \in \{1,\dots,\mathcal{F}\} | A \in \mathbf{X}_j \wedge \pi_j(\emptyset)} \left[ \left( \sum_{i \in \{1,\dots,S\} | X_{j_i} = A} m_i(X_{j_i}) \right) \cdot \frac{\pi_j(\emptyset)}{\sum_{X \in \mathbf{X}_j} \left( \sum_{i \in \{1,\dots,S\} | X_{j_i} = X} m_i(X_{j_i}) \right)} \right]. \quad (15)$$

The difference between the general PCR5 and PCR6 formulas is that the PCR5 proportional redistribution involves the products  $\prod_{i \in \{1,\dots,S\} | X_{j_i} = A} m_i(X_{j_i})$  of multiple same

<sup>8</sup>A qualitative BBA is a BBA whose values are labels (e.g. low, medium, high, etc) instead of real numbers.

<sup>9</sup>We wrote this PCR6 general formula in the style of PCR5 formula (14).

focal elements  $A$  (if any) in the conflict, whereas the PCR6 conflict redistribution principle works with their sum  $\sum_{i \in \{1,\dots,S\} | X_{j_i} = A} m_i(X_{j_i})$  instead. The next section presents some examples for PCR5 and PCR6 rules of combinations.

We use this general PCR6 formula instead of the original Martin-Osswald's PCR6 formula [32] because it is more easy to improve it into PCR6<sup>+</sup> formula - see section VI-B. From the implementation point of view, PCR6 is simpler to implement than PCR5. From the Decision-Making (DM) standpoint, PCR6 is better than PCR5 when  $S > 2$  as reported by Martin and Osswald in [32] (see also the Example 3 in the next section) in their applications. For convenience, some Matlab<sup>TM</sup> codes of PCR5 and PCR6 fusion rules can be found in the appendix of [44], also in Chap. 7 of [34] (Vol. 3), or from Arnaud Martin's web page [45]. PCR6 code (in R programming language) can be found also in iBelief package developed by Kuang Zhou and Arnaud Martin from the BFAS<sup>10</sup> repository [46], or directly from [47] as well. When we have only two BBAs to combine, PCR5 and PCR6 rules provide the same result because formulas (14) and (15) coincide for  $S = 2$ .

In this paper, we have voluntarily chosen to present the two rules PCR5, PCR6 and their improved versions mainly for historical reasons and because these two rules have strong theoretical links as we have shown. By doing this, we offer the possibility to readers (and potential users) to test each of these advanced fusion methods and evaluate their performances on their own applications. Even though PCR6 is posterior to PCR5, since some researchers have implemented and are using PCR5 fusion rule, it appears important to introduce the improved version of this rule. Furthermore, PCR5 goes back exactly on the tracks of the conjunctive rule, while PCR6 does not.

#### IV. EXAMPLES FOR PCR5 AND PCR6 FUSION RULES

Here we provide two simple examples showing the difference of the results between PCR5 and PCR6 rules. For convenience, all numerical values given in the examples of this paper have been rounded to six decimal places when necessary.

**Example 2:** We consider the simplest FoD  $\Theta = \{A, B\}$ , and the three following BBAs

$$\begin{aligned} m_1(A) &= 0.6, m_1(B) = 0.1, m_1(A \cup B) = 0.3, \\ m_2(A) &= 0.5, m_2(B) = 0.3, m_2(A \cup B) = 0.2, \\ m_3(A) &= 0.4, m_3(B) = 0.1, m_3(A \cup B) = 0.5. \end{aligned}$$

Because  $\mathcal{F}_{m_1} = |\mathcal{F}(m_1)| = 3$ ,  $\mathcal{F}_{m_2} = |\mathcal{F}(m_2)| = 3$  and  $\mathcal{F}_{m_3} = |\mathcal{F}(m_3)| = 3$ , we have  $\mathcal{F} = \mathcal{F}_{m_1} \cdot \mathcal{F}_{m_2} \cdot \mathcal{F}_{m_3} = 27$  products to consider. Fifteen products are non-conflicting and will enter in the calculation of  $m_{1,2,3}^{\text{Conj}}(A)$ ,  $m_{1,2,3}^{\text{Conj}}(B)$  and  $m_{1,2,3}^{\text{Conj}}(A \cup B)$ , and twelve products are conflicting products

<sup>10</sup>Belief Functions and Applications Society.

that will need to be proportionally redistributed. The conjunctive combination of these three BBAs is

$$\begin{aligned}
 m_{1,2,3}^{\text{Conj}}(A) &= m_1(A)m_2(A)m_3(A) \\
 &+ m_1(A)m_2(A)m_3(A \cup B) \\
 &+ m_1(A)m_2(A \cup B)m_3(A) \\
 &+ m_1(A \cup B)m_2(A)m_3(A) \\
 &+ m_1(A)m_2(A \cup B)m_3(A \cup B) \\
 &+ m_1(A \cup B)m_2(A)m_3(A \cup B) \\
 &+ m_1(A \cup B)m_2(A \cup B)m_3(A) \\
 &= 0.5370,
 \end{aligned}$$

$$\begin{aligned}
 m_{1,2,3}^{\text{Conj}}(B) &= m_1(B)m_2(B)m_3(B) \\
 &+ m_1(B)m_2(B)m_3(A \cup B) \\
 &+ m_1(B)m_2(A \cup B)m_3(B) \\
 &+ m_1(A \cup B)m_2(B)m_3(B) \\
 &+ m_1(B)m_2(A \cup B)m_3(A \cup B) \\
 &+ m_1(A \cup B)m_2(B)m_3(A \cup B) \\
 &+ m_1(A \cup B)m_2(A \cup B)m_3(B) \\
 &= 0.0900,
 \end{aligned}$$

$$\begin{aligned}
 m_{1,2,3}^{\text{Conj}}(A \cup B) &= m_1(A \cup B)m_2(A \cup B)m_3(A \cup B) \\
 &= 0.3 \cdot 0.2 \cdot 0.5 = 0.0300,
 \end{aligned}$$

and

$$\begin{aligned}
 m_{1,2,3}^{\text{Conj}}(\emptyset) &= 1 - m_{1,2,3}^{\text{Conj}}(A) - m_{1,2,3}^{\text{Conj}}(B) - m_{1,2,3}^{\text{Conj}}(A \cup B) \\
 &= 0.3430.
 \end{aligned}$$

In this example we have twelve partial conflicts, noted  $\pi_j(\emptyset)$  ( $j = 1, \dots, 12$ ), which are given by the following products

$$\begin{aligned}
 \pi_1(\emptyset) &= m_1(A)m_2(A)m_3(B) = 0.0300, \\
 \pi_2(\emptyset) &= m_1(A)m_2(B)m_3(A) = 0.0720, \\
 \pi_3(\emptyset) &= m_1(B)m_2(A)m_3(A) = 0.0200, \\
 \pi_4(\emptyset) &= m_1(B)m_2(B)m_3(A) = 0.0120, \\
 \pi_5(\emptyset) &= m_1(B)m_2(A)m_3(B) = 0.0050, \\
 \pi_6(\emptyset) &= m_1(A)m_2(B)m_3(B) = 0.0180, \\
 \pi_7(\emptyset) &= m_1(A \cup B)m_2(A)m_3(B) = 0.0150, \\
 \pi_8(\emptyset) &= m_1(A \cup B)m_2(B)m_3(A) = 0.0360, \\
 \pi_9(\emptyset) &= m_1(B)m_2(A)m_3(A \cup B) = 0.0250, \\
 \pi_{10}(\emptyset) &= m_1(A)m_2(B)m_3(A \cup B) = 0.0900, \\
 \pi_{11}(\emptyset) &= m_1(A)m_2(A \cup B)m_3(B) = 0.0120, \\
 \pi_{12}(\emptyset) &= m_1(B)m_2(A \cup B)m_3(A) = 0.0080.
 \end{aligned}$$

In applying the PCR5 formula (14), and the PCR6 formula (15) we obtain finally  $m_{1,2,3}^{\text{PCR5}}(\emptyset) = m_{1,2,3}^{\text{PCR6}}(\emptyset) = 0$ , and<sup>11</sup>

$$\begin{aligned}
 m_{1,2,3}^{\text{PCR5}}(A) &\approx 0.723281, \\
 m_{1,2,3}^{\text{PCR5}}(B) &\approx 0.182460, \\
 m_{1,2,3}^{\text{PCR5}}(A \cup B) &\approx 0.094259,
 \end{aligned}$$

$$\begin{aligned}
 m_{1,2,3}^{\text{PCR6}}(A) &\approx 0.743496, \\
 m_{1,2,3}^{\text{PCR6}}(B) &\approx 0.162245, \\
 m_{1,2,3}^{\text{PCR6}}(A \cup B) &\approx 0.094259.
 \end{aligned}$$

We see a difference between the BBAs  $m_{1,2,3}^{\text{PCR5}}$  and  $m_{1,2,3}^{\text{PCR6}}$  which is normal because the PCR principles are quite different. Using the PCR5 fusion rule the first partial conflicting mass  $\pi_1(\emptyset) = m_1(A)m_2(A)m_3(B) = 0.03$  will be redistributed back to  $A$  and  $B$  proportionally to  $m_1(A)m_2(A)$  and to  $m_3(B)$  as follows

$$\frac{x_1(A)}{m_1(A)m_2(A)} = \frac{x_1(B)}{m_3(B)} = \frac{\pi_1(\emptyset)}{m_1(A)m_2(A) + m_3(B)},$$

whence

$$x_1(A) = \frac{m_1(A)m_2(A)\pi_1(\emptyset)}{m_1(A)m_2(A) + m_3(B)} = 0.0225,$$

$$x_1(B) = \frac{m_3(B)\pi_1(\emptyset)}{m_1(A)m_2(A) + m_3(B)} = 0.0075.$$

We can verify  $\pi_1(\emptyset) = x_1(A) + x_1(B) = 0.03$ .

Using the PCR6 fusion rule the first partial conflicting mass  $\pi_1(\emptyset) = 0.03$  will be redistributed back to  $A$  and  $B$  proportionally to  $(m_1(A) + m_2(A))$  and to  $m_3(B)$ . So we will get the following redistributions  $x_1(A) = 0.0275$  for  $A$  and  $x_1(B) = 0.0025$  for  $B$  because

$$\frac{x_1(A)}{m_1(A) + m_2(A)} = \frac{x_1(B)}{m_3(B)} = \frac{\pi_1(\emptyset)}{m_1(A) + m_2(A) + m_3(B)},$$

whence

$$x_1(A) = \frac{(m_1(A) + m_2(A))\pi_1(\emptyset)}{m_1(A) + m_2(A) + m_3(B)} = 0.0275$$

$$x_1(B) = \frac{m_3(B)\pi_1(\emptyset)}{m_1(A) + m_2(A) + m_3(B)} = 0.0025$$

We can verify  $\pi_1(\emptyset) = x_1(A) + x_1(B) = 0.03$ .

Note that for all the partial conflicts having no duplicate element involved in the conflicting product  $\pi_j(\emptyset)$  we make the same redistribution with PCR5 rule and with PCR6 rule. For instance, for  $\pi_7(\emptyset) = m_1(A \cup B)m_2(A)m_3(B) = 0.0150$  we get

$$\begin{aligned}
 \frac{x_7(A \cup B)}{m_1(A \cup B)} &= \frac{x_7(A)}{m_2(A)} = \frac{x_7(B)}{m_3(B)} \\
 &= \frac{\pi_7(\emptyset)}{m_1(A \cup B) + m_2(A) + m_3(B)},
 \end{aligned}$$

whence  $\pi_7(\emptyset) = x_7(A \cup B) + x_7(A) + x_7(B) = 0.0150$  with

$$x_7(A \cup B) = \frac{m_1(A \cup B)\pi_7(\emptyset)}{m_1(A \cup B) + m_2(A) + m_3(B)} = 0.0050,$$

$$x_7(A) = \frac{m_2(A)\pi_7(\emptyset)}{m_1(A \cup B) + m_2(A) + m_3(B)} \approx 0.0083,$$

$$x_7(B) = \frac{m_3(B)\pi_7(\emptyset)}{m_1(A \cup B) + m_2(A) + m_3(B)} \approx 0.0017.$$

The next example shows also the difference between PCR5 and PCR6 rules, and it justifies why PCR6 rule is usually preferred to PCR5 rule in applications.

<sup>11</sup>The symbol  $\approx$  means ‘‘approximately equal to’’.

**Example 3:** we consider the FoD  $\Theta = \{A, B, C\}$ , and the four very simple BBAs defined by

$$m_1(A \cup B) = 1, m_2(B) = 1, m_3(A \cup B) = 1, \text{ and } m_4(C) = 1.$$

These BBAs are in conflict because the intersection of their focal elements is  $(A \cup B) \cap A \cap (A \cup B) \cap C = \emptyset$ . In this example, one has only one product of masses to calculate, which is  $\pi_1((A \cup B) \cap A \cap (A \cup B) \cap C) = m_1(A \cup B)m_2(A)m_3(A \cup B)m_4(C) = 1$ . In fact this product is a conflicting product denoted  $\pi_1(\emptyset)$ . We can also denote it  $\pi(\emptyset)$  because the index  $j = 1$  is useless in this case. Moreover, these BBAs are also in total conflict because  $\pi(\emptyset) = m_1(A \cup B)m_2(A)m_3(A \cup B)m_4(C) = 1$ .

If one applies the PCR5 rule principle we get

$$\begin{aligned} \frac{x(A \cup B)}{m_1(A \cup B)m_3(A \cup B)} &= \frac{x(B)}{m_2(B)} = \frac{x(C)}{m_4(C)} \\ &= \frac{\pi(\emptyset)}{m_1(A \cup B)m_3(A \cup B) + m_2(B) + m_4(C)} \end{aligned}$$

whence  $x(A \cup B) = 1/3$ ,  $x(B) = 1/3$  and  $x(C) = 1/3$  so that

$$\begin{aligned} m_{1,2,3,4}^{\text{PCR5}}(A \cup B) &= x(A \cup B) = 1/3 \\ m_{1,2,3,4}^{\text{PCR5}}(B) &= x(B) = 1/3 \\ m_{1,2,3,4}^{\text{PCR5}}(C) &= x(C) = 1/3 \end{aligned}$$

This PCR5 result appears counter-intuitive because three sources among the four sources exclude definitely the hypothesis  $C$  because one has  $Pl_1(C) = Pl_2(C) = Pl_3(C) = 0$ , so it is intuitively expected that after the combination of all the four BBAs the mass committed to  $C$  should not be greater than  $1/4 = 0.25$ .

If one applies the PCR6 rule principle we get

$$\begin{aligned} \frac{x(A \cup B)}{m_1(A \cup B) + m_3(A \cup B)} &= \frac{x(B)}{m_2(B)} = \frac{x(C)}{m_4(C)} \\ &= \frac{\pi(\emptyset)}{m_1(A \cup B) + m_3(A \cup B) + m_2(B) + m_4(C)}, \end{aligned}$$

whence  $x(A \cup B) = 2/4$ ,  $x(B) = 1/4$  and  $x(C) = 1/4$  so that

$$\begin{aligned} m_{1,2,3,4}^{\text{PCR6}}(A \cup B) &= x(A \cup B) = 0.5, \\ m_{1,2,3,4}^{\text{PCR6}}(B) &= x(B) = 0.25, \\ m_{1,2,3,4}^{\text{PCR6}}(C) &= x(C) = 0.25, \end{aligned}$$

which is in better agreement with what we intuitively expect because  $m_{1,2,3,4}^{\text{PCR6}}(C)$  is not greater than than  $1/4$ . Of course in this example, Dempster's rule of combination cannot be simply applied because the conflict is total yielding a division by zero in Dempster's rule formula [8], but by using eventually some discounting methods to modify the BBAs to combine.

## V. FLAWED BEHAVIOR OF PCR5 AND PCR6 RULES

Formula (17) shows that in general PCR6 is not associative, and by combining two sources in a row each time and we continue doing that the results is different from the global combination of all sources using PCR6. The formula is true. Formula (18) says that in general PCR5 is different from PCR6, of course except the case when we combine only 2 sources. Formula (19) shows that in general PCR5 does not have the ignorance source as a neutral element.

The PCR5 and PCR6 rules of combination are not associative which means that the fusion of the BBAs must be done using general formulas (14) or (15) if one has more than two BBAs to combine, which is not very convenient. Therefore, the sequential PCR5 or PCR6 combination of  $S > 2$  BBAs are not in general equal to the global PCR5 or PCR6 fusion of the  $S$  BBAs altogether because the order of the combination of the sources does matter in the sequential combination. In general (i.e. when conflicts exist between the sources of evidence to combine) one has for  $S > 2$

$$\begin{aligned} \text{PCR5}(m_1, m_2, \dots, m_S) &\neq \\ \text{PCR5}(\text{PCR5}(\text{PCR5}(m_1, m_2), m_3), \dots, m_S), \end{aligned} \quad (16)$$

and

$$\begin{aligned} \text{PCR6}(m_1, m_2, \dots, m_S) &\neq \\ \text{PCR6}(\text{PCR6}(\text{PCR6}(m_1, m_2), m_3), \dots, m_S), \end{aligned} \quad (17)$$

and also for  $S > 2$  PCR5 fusion result is generally different of PCR6 fusion result that is

$$\text{PCR5}(m_1, m_2, \dots, m_S) \neq \text{PCR6}(m_1, m_2, \dots, m_S). \quad (18)$$

PCR5 and PCR6 rules can become computationally intractable for combining a large number of sources and for working with large FoD. This is a well-known limitation of these rules, but this is the price to pay to get better results than with classical rules.

Aside the complexity of these rules, it is worth to mention that the neutral impact property of the vacuous BBA  $m_v$  is lost in general when considering the PCR5 or PCR6 combination of  $S > 2$  BBAs altogether, that is

$$\text{PCR5}(m_1, \dots, m_{S-1}, m_v) \neq \text{PCR5}(m_1, \dots, m_{S-1}), \quad (19)$$

and

$$\text{PCR6}(m_1, \dots, m_{S-1}, m_v) \neq \text{PCR6}(m_1, \dots, m_{S-1}). \quad (20)$$

This is due to the redistribution principles used in PCR5 and in PCR6 rules. Example 4 shows the non-neutral impact of the vacuous BBA in PCR5 and PCR6 rules for convenience. Note that the vacuous BBA has a neutral impact in the fusion result if and only if one has only two BBAs to combine with PCR5, or PCR6, and one of them is the vacuous BBA because in this case there is no possible (partial) conflict to redistribute between any BBA  $m(\cdot)$  defined over the FoD  $\Theta$

and the vacuous BBA  $m_v(\cdot)$ . That is, for any BBA  $m_1(\cdot)$  one always has

$$\text{PCR5}(m_1, m_v) = \text{PCR6}(m_1, m_v) = m_1. \quad (21)$$

**Example 4:** we consider the FoD  $\Theta = \{A, B\}$  having only two elements, and the following four BBAs as follows:

$$\begin{aligned} m_1(A) &= 0.6, m_1(B) = 0.1, m_1(A \cup B) = 0.3, \\ m_2(A) &= 0.5, m_2(B) = 0.3, m_2(A \cup B) = 0.2, \\ m_3(A) &= 0.4, m_3(B) = 0.1, m_3(A \cup B) = 0.5, \\ m_4(A \cup B) &= 1 \end{aligned}$$

BBAs  $m_1$ ,  $m_2$  and  $m_3$  are as in example 2, and the BBA  $m_4$  is nothing but the vacuous BBA  $m_v$  defined over this FoD  $\Theta$ .

In example 2, we did obtain with  $\text{PCR5}(m_1, m_2, m_3)$  and with  $\text{PCR5}(m_1, m_2, m_3, m_4)$  the following resulting BBAs

$$\begin{aligned} m_{1,2,3}^{\text{PCR5}}(A) &\approx 0.723281, \\ m_{1,2,3}^{\text{PCR5}}(B) &\approx 0.182460, \\ m_{1,2,3}^{\text{PCR5}}(A \cup B) &\approx 0.094259, \end{aligned}$$

and

$$\begin{aligned} m_{1,2,3,4}^{\text{PCR5}}(A) &\approx 0.654604, \\ m_{1,2,3,4}^{\text{PCR5}}(B) &\approx 0.144825, \\ m_{1,2,3,4}^{\text{PCR5}}(A \cup B) &\approx 0.200571. \end{aligned}$$

Clearly,  $\text{PCR5}(m_1, m_2, m_3) \neq \text{PCR5}(m_1, m_2, m_3, m_4)$  even if  $m_4$  is the vacuous BBA.

Analogously, we did obtain with  $\text{PCR6}(m_1, m_2, m_3)$  and with  $\text{PCR6}(m_1, m_2, m_3, m_4)$

$$\begin{aligned} m_{1,2,3}^{\text{PCR6}}(A) &\approx 0.743496, \\ m_{1,2,3}^{\text{PCR6}}(B) &\approx 0.162245, \\ m_{1,2,3}^{\text{PCR6}}(A \cup B) &\approx 0.094259, \end{aligned}$$

and

$$\begin{aligned} m_{1,2,3,4}^{\text{PCR6}}(A) &\approx 0.647113, \\ m_{1,2,3,4}^{\text{PCR6}}(B) &\approx 0.128342, \\ m_{1,2,3,4}^{\text{PCR6}}(A \cup B) &\approx 0.224545. \end{aligned}$$

Therefore,  $\text{PCR6}(m_1, m_2, m_3) \neq \text{PCR6}(m_1, m_2, m_3, m_4)$ , even if  $m_4$  is the vacuous BBA.

This example 4 shows clearly that the vacuous BBA does not have a neutral impact in the PCR5 and PCR6 rules of combination. In fact, adding more vacuous BBAs  $m_v$  in the PCR5 or PCR6 fusion will increase more and more the mass of  $A \cup B$  while decreasing more and more the masses of  $A$  and of  $B$  with PCR5, and PCR6. When the number of vacuous BBAs  $m_v$  increases, we will have<sup>12</sup>  $m_{1,2,3,m_v,\dots,m_v}^{\text{PCR5/6}}(A \cup B) \rightarrow 1$ ,  $m_{1,2,3,m_v,\dots,m_v}^{\text{PCR5/6}}(A) \rightarrow 0$ , and  $m_{1,2,3,m_v,\dots,m_v}^{\text{PCR5/6}}(B) \rightarrow 0$ .

This is unsatisfactory because the vacuous BBA brings no useful information to exploit, and it is naturally expected that it

must not impact the fusion result in the combination of BBAs. This can be seen as a flaw of the behavior of PCR5 and PCR6 rules of combination.

To emphasize this flaw, we give in the example 5 a case where the mass committed to some partial uncertainties can increase more than necessary with PCR5 and with PCR6 rules of combination. This is detrimental for the quality of the fusion result and for decision-making because the result is more uncertain than it should be, and consequently the decision is more difficult to make.

**Example 5:** we consider the FoD  $\Theta = \{A, B, C, D, E\}$ , and the following three BBAs

$$\begin{cases} m_1(A \cup B) = 0.70, \\ m_1(C \cup D) = 0.06, \\ m_1(A \cup B \cup C \cup D) = 0.15, \\ m_1(E) = 0.09, \end{cases}$$

and

$$\begin{cases} m_2(A \cup B) = 0.06, \\ m_2(C \cup D) = 0.50, \\ m_2(A \cup B \cup C \cup D) = 0.04, \\ m_2(E) = 0.40, \end{cases}$$

and

$$\begin{cases} m_3(B) = 0.01 \\ m_3(A \cup B \cup C \cup D \cup E) = 0.99. \end{cases}$$

Note that the BBA  $m_3$  is not equal to the vacuous BBA but it is very close to the vacuous BBA because  $m_3(\Theta)$  is close to one.

If we make the  $\text{PCR6}(m_1, m_2)$  fusion of only the two BBAs  $m_1$  and  $m_2$  altogether, which is also equal to  $\text{PCR5}(m_1, m_2)$ , we obtain

$$\begin{cases} m_{1,2}^{\text{PCR6}}(A \cup B) \approx 0.465309, \\ m_{1,2}^{\text{PCR6}}(C \cup D) \approx 0.296299, \\ m_{1,2}^{\text{PCR6}}(A \cup B \cup C \cup D) \approx 0.023471, \\ m_{1,2}^{\text{PCR6}}(E) \approx 0.214921. \end{cases}$$

If we make the  $\text{PCR6}(m_1, m_2, m_3)$  fusion of all these three BBAs altogether we obtain

$$\begin{cases} m_{1,2,3}^{\text{PCR6}}(B) \approx 0.000962, \\ m_{1,2,3}^{\text{PCR6}}(A \cup B) \approx 0.286107, \\ m_{1,2,3}^{\text{PCR6}}(C \cup D) \approx 0.203454, \\ m_{1,2,3}^{\text{PCR6}}(A \cup B \cup C \cup D) \approx 0.012203, \\ m_{1,2,3}^{\text{PCR6}}(E) \approx 0.116038, \\ m_{1,2,3}^{\text{PCR6}}(A \cup B \cup C \cup D \cup E) \approx 0.381236. \end{cases}$$

One sees that combining the BBAs  $m_1$ ,  $m_2$  with the BBA  $m_3$  (where  $m_3$  is close to vacuous BBA, and therefore  $m_3$  is almost non-informative) generates a big increase of the belief of the uncertainty in the resulting BBA. This behaviour is clearly counter-intuitive because if the source is almost vacuous, only a small degradation of the uncertainty is expected and in the limit case when  $m_3$  is the vacuous BBA no impact of  $m_3$  on the fusion result should occur. Note that this behavior

<sup>12</sup>The notation  $m^{\text{PCR5/6}}$  indicates “ $m^{\text{PCR5}}$  or  $m^{\text{PCR6}}$ ” for convenience.

also occurs with PCR5( $m_1, m_2, m_3$ ) because one has for this example

$$\left\{ \begin{array}{l} m_{1,2,3}^{\text{PCR5}}(B) \approx 0.001103, \\ m_{1,2,3}^{\text{PCR5}}(A \cup B) \approx 0.286107, \\ m_{1,2,3}^{\text{PCR5}}(C \cup D) \approx 0.203384, \\ m_{1,2,3}^{\text{PCR5}}(A \cup B \cup C \cup D) \approx 0.012203, \\ m_{1,2,3}^{\text{PCR5}}(E) \approx 0.115967, \\ m_{1,2,3}^{\text{PCR5}}(A \cup B \cup C \cup D \cup E) \approx 0.381236. \end{array} \right.$$

The deep analysis of the partial conflict redistributions done in this interesting example reveals clearly the flaw of the principles of PCR5 and PCR6 rules of combination. Indeed, for this example one has  $\mathcal{F}_{m_1} \cdot \mathcal{F}_{m_2} \cdot \mathcal{F}_{m_3} = 4 \cdot 4 \cdot 2 = 32$  products  $\pi_j(X_{j_1} \cap X_{j_2} \cap X_{j_3}) = m_1(X_{j_1})m_2(X_{j_2})m_3(X_{j_3})$  to calculate, where  $X_{j_1} \in \mathcal{F}(m_1) = \{A \cup B, C \cup D, A \cup B \cup C \cup D, E\}$ ,  $X_{j_2} \in \mathcal{F}(m_2) = \{A \cup B, C \cup D, A \cup B \cup C \cup D, E\}$ , and  $X_{j_3} \in \mathcal{F}(m_3) = \{B, A \cup B \cup C \cup D \cup E\}$ . Among these 32 possible conjunctions of focal elements, twenty products corresponds to partial conflicts when  $X_{j_1} \cap X_{j_2} \cap X_{j_3} = \emptyset$ , which need to be redistributed properly to some elements of  $2^\Theta \setminus \{\emptyset\}$  according to the PCR5, or the PCR6 redistribution principles.

More precisely, we have to consider all the following products  $\pi_j$  for calculating the result

$$\begin{aligned} \pi_1(B) &= m_1(A \cup B)m_2(A \cup B)m_3(B) = 0.00042, \\ \pi_2(A \cup B) &= m_1(A \cup B)m_2(A \cup B)m_3(\Theta) = 0.04158, \\ \pi_3(\emptyset) &= m_1(A \cup B)m_2(C \cup D)m_3(B) = 0.0035, \\ \pi_4(\emptyset) &= m_1(A \cup B)m_2(C \cup D)m_3(\Theta) = 0.3465, \\ \pi_5(B) &= m_1(A \cup B)m_2(A \cup B \cup C \cup D)m_3(B) = 0.00028, \\ \pi_6(A \cup B) &= m_1(A \cup B)m_2(A \cup B \cup C \cup D)m_3(\Theta) = 0.02772, \\ \pi_7(\emptyset) &= m_1(A \cup B)m_2(E)m_3(B) = 0.0028, \\ \pi_8(\emptyset) &= m_1(A \cup B)m_2(E)m_3(\Theta) = 0.2772, \\ \pi_9(\emptyset) &= m_1(C \cup D)m_2(A \cup B)m_3(B) = 0.000036, \\ \pi_{10}(\emptyset) &= m_1(C \cup D)m_2(A \cup B)m_3(\Theta) = 0.003564, \\ \pi_{11}(\emptyset) &= m_1(C \cup D)m_2(C \cup D)m_3(B) = 0.0003, \\ \pi_{12}(C \cup D) &= m_1(C \cup D)m_2(C \cup D)m_3(\Theta) = 0.0297, \\ \pi_{13}(\emptyset) &= m_1(C \cup D)m_2(A \cup B \cup C \cup D)m_3(B) = 0.000024, \\ \pi_{14}(C \cup D) &= m_1(C \cup D)m_2(A \cup B \cup C \cup D)m_3(\Theta) \\ &= 0.002376, \\ \pi_{15}(\emptyset) &= m_1(C \cup D)m_2(E)m_3(B) = 0.00024, \\ \pi_{16}(\emptyset) &= m_1(C \cup D)m_2(E)m_3(\Theta) = 0.02376, \\ \pi_{17}(B) &= m_1(A \cup B \cup C \cup D)m_2(A \cup B)m_3(B) = 0.00009, \\ \pi_{18}(A \cup B) &= m_1(A \cup B \cup C \cup D)m_2(A \cup B)m_3(\Theta) = 0.00891, \\ \pi_{19}(\emptyset) &= m_1(A \cup B \cup C \cup D)m_2(C \cup D)m_3(B) = 0.00075, \\ \pi_{20}(C \cup D) &= m_1(A \cup B \cup C \cup D)m_2(C \cup D)m_3(\Theta) \\ &= 0.07425, \\ \pi_{21}(B) &= m_1(A \cup B \cup C \cup D)m_2(A \cup B \cup C \cup D)m_3(B) \\ &= 0.00006, \\ \pi_{22}(A \cup B \cup C \cup D) &= m_1(A \cup B \cup C \cup D)m_2(A \cup B \cup C \cup D) \\ &\quad \cdot m_3(\Theta) = 0.00594, \\ \pi_{23}(\emptyset) &= m_1(A \cup B \cup C \cup D)m_2(E)m_3(B) = 0.0006, \\ \pi_{24}(\emptyset) &= m_1(A \cup B \cup C \cup D)m_2(E)m_3(\Theta) = 0.0594, \\ \pi_{25}(\emptyset) &= m_1(E)m_2(A \cup B)m_3(B) = 0.000054, \end{aligned}$$

$$\begin{aligned} \pi_{26}(\emptyset) &= m_1(E)m_2(A \cup B)m_3(\Theta) = 0.005346, \\ \pi_{27}(\emptyset) &= m_1(E)m_2(C \cup D)m_3(B) = 0.00045, \\ \pi_{28}(\emptyset) &= m_1(E)m_2(C \cup D)m_3(\Theta) = 0.04455, \\ \pi_{29}(\emptyset) &= m_1(E)m_2(A \cup B \cup C \cup D)m_3(B) = 0.000036, \\ \pi_{30}(\emptyset) &= m_1(E)m_2(A \cup B \cup C \cup D)m_3(\Theta) = 0.003564, \\ \pi_{31}(\emptyset) &= m_1(E)m_2(E)m_3(B) = 0.00036, \\ \pi_{32}(E) &= m_1(E)m_2(E)m_3(\Theta) = 0.03564. \end{aligned}$$

The conjunctive rule gives

$$\begin{aligned} m_{1,2,3}^{\text{Conj}}(B) &= \pi_1(B) + \pi_5(B) + \pi_{17}(B) + \pi_{21}(B) = 0.00085, \\ m_{1,2,3}^{\text{Conj}}(A \cup B) &= \pi_2(A \cup B) + \pi_6(A \cup B) + \pi_{18}(A \cup B) \\ &= 0.07821, \\ m_{1,2,3}^{\text{Conj}}(C \cup D) &= \pi_{12}(C \cup D) + \pi_{14}(C \cup D) + \pi_{20}(C \cup D) \\ &= 0.106326, \\ m_{1,2,3}^{\text{Conj}}(A \cup B \cup C \cup D) &= \pi_{22}(A \cup B \cup C \cup D) = 0.00594, \\ m_{1,2,3}^{\text{Conj}}(E) &= \pi_{32}(E) = 0.03564. \end{aligned}$$

The total conflicting mass between these three BBAs is

$$\begin{aligned} m_{1,2,3}^{\text{Conj}}(\emptyset) &= \sum_{j=3,4,7,\dots,11,13,15,16,19,23,\dots,31} \pi_j(\emptyset) \\ &= 1 - m_{1,2,3}^{\text{Conj}}(B) - m_{1,2,3}^{\text{Conj}}(A \cup B) - m_{1,2,3}^{\text{Conj}}(C \cup D) \\ &\quad - m_{1,2,3}^{\text{Conj}}(A \cup B \cup C \cup D) - m_{1,2,3}^{\text{Conj}}(E) = 0.773034. \end{aligned}$$

Let's examine how the  $m_{1,2,3}^{\text{PCR5}}(\Theta) \approx 0.381236$  value is obtained based on the PCR5 redistribution principle. Based on the structures of  $\pi_j(\emptyset)$  products, we have to consider only products involving a proportional redistribution to  $\Theta$ . So we get a proportional redistribution to  $\Theta$  only from the following products

$$\begin{aligned} \pi_4(\emptyset) &= m_1(A \cup B)m_2(C \cup D)m_3(\Theta) = 0.3465, \\ \pi_8(\emptyset) &= m_1(A \cup B)m_2(E)m_3(\Theta) = 0.2772, \\ \pi_{10}(\emptyset) &= m_1(C \cup D)m_2(A \cup B)m_3(\Theta) = 0.003564, \\ \pi_{16}(\emptyset) &= m_1(C \cup D)m_2(E)m_3(\Theta) = 0.02376, \\ \pi_{24}(\emptyset) &= m_1(A \cup B \cup C \cup D)m_2(E)m_3(\Theta) = 0.0594, \\ \pi_{26}(\emptyset) &= m_1(E)m_2(A \cup B)m_3(\Theta) = 0.005346, \\ \pi_{28}(\emptyset) &= m_1(E)m_2(C \cup D)m_3(\Theta) = 0.04455, \\ \pi_{30}(\emptyset) &= m_1(E)m_2(A \cup B \cup C \cup D)m_3(\Theta) = 0.003564. \end{aligned}$$

Because there is no duplicate focal elements in each of these products, the PCR5 and PCR6 redistributions to  $\Theta$  will be the same in this example.

The proportional redistribution of  $\pi_4(\emptyset)$  to  $\Theta$  is

$$x_4(\Theta) = \frac{m_3(\Theta)\pi_4(\emptyset)}{m_1(A \cup B) + m_2(C \cup D) + m_3(\Theta)} \approx 0.156637.$$

The proportional redistribution of  $\pi_8(\emptyset)$  to  $\Theta$  is

$$x_8(\Theta) = \frac{m_3(\Theta)\pi_8(\emptyset)}{m_1(A \cup B) + m_2(E) + m_3(\Theta)} \approx 0.131305.$$

The proportional redistribution of  $\pi_{10}(\emptyset)$  to  $\Theta$  is

$$x_{10}(\Theta) = \frac{m_3(\Theta)\pi_{10}(\emptyset)}{m_1(C \cup D) + m_2(A \cup B) + m_3(\Theta)} \approx 0.003179.$$

The proportional redistribution of  $\pi_{16}(\emptyset)$  to  $\Theta$  is

$$x_{16}(\Theta) = \frac{m_3(\Theta)\pi_{16}(\emptyset)}{m_1(C \cup D) + m_2(E) + m_3(\Theta)} \approx 0.016222.$$

The proportional redistribution of  $\pi_{24}(\emptyset)$  to  $\Theta$  is

$$x_{24}(\Theta) = \frac{m_3(\Theta)\pi_{24}(\emptyset)}{m_1(A \cup B \cup C \cup D) + m_2(E) + m_3(\Theta)} \approx 0.038186.$$

The proportional redistribution of  $\pi_{26}(\emptyset)$  to  $\Theta$  is

$$x_{26}(\Theta) = \frac{m_3(\Theta)\pi_{26}(\emptyset)}{m_1(E) + m_2(A \cup B) + m_3(\Theta)} \approx 0.004643.$$

The proportional redistribution of  $\pi_{28}(\emptyset)$  to  $\Theta$  is

$$x_{28}(\Theta) = \frac{m_3(\Theta)\pi_{28}(\emptyset)}{m_1(E) + m_2(C \cup D) + m_3(\Theta)} \approx 0.027914.$$

The proportional redistribution of  $\pi_{30}(\emptyset)$  to  $\Theta$  is

$$x_{30}(\Theta) = \frac{m_3(\Theta)\pi_{30}(\emptyset)}{m_1(E) + m_2(A \cup B \cup C \cup D) + m_3(\Theta)} \approx 0.003150.$$

Therefore we finally obtain the quite big value for the mass committed to  $\Theta$

$$\begin{aligned} m_{1,2,3}^{\text{PCR5}}(\Theta) &= x_4(\Theta) + x_8(\Theta) + x_{10}(\Theta) + x_{16}(\Theta) + x_{24}(\Theta) \\ &\quad + x_{26}(\Theta) + x_{28}(\Theta) + x_{30}(\Theta) \\ &\approx 0.381236. \end{aligned}$$

We see clearly why PCR5 (and PCR6) redistributes some mass to uncertainty  $\Theta$  although the focal element  $\Theta$  is not in conflict with other focal elements involved in each product  $\pi_4(\emptyset)$ ,  $\pi_8(\emptyset)$ ,  $\pi_{10}(\emptyset)$ ,  $\pi_{16}(\emptyset)$ ,  $\pi_{24}(\emptyset)$ ,  $\pi_{26}(\emptyset)$ ,  $\pi_{28}(\emptyset)$  and  $\pi_{30}(\emptyset)$ , which is an undesirable behavior that we want to avoid. That is why we propose in the next section some improvement of PCR5 and PCR6 rules of combination.

## VI. IMPROVEMENT OF PCR5 AND PCR6 RULES

To circumvent the weakness of the original PCR5 and PCR6 redistribution principles, we propose an improvement of these rules that will be denoted as PCR5<sup>+</sup> and PCR6<sup>+</sup> in the sequel. These new rules are not redundant with PCR5 nor with PCR6 when combining more than two BBAs altogether.

The very simple and basic idea to improve PCR5 and PCR6 redistribution principles is to discard the elements that contain all the other elements implied in the partial conflict  $\pi_j(\emptyset)$  calculation. Indeed, the elements discarded are regarded as non-informative and not useful for making the conflict redistribution.

For instance, if we consider the previous Example 5, the conflicting mass with PCR5<sup>+</sup> and PCR6<sup>+</sup> for the conflicting product  $\pi_4(\emptyset) = m_1(A \cup B)m_2(C \cup D)m_3(\Theta)$  will be proportionally redistributed back only to  $A \cup B$  and to  $C \cup D$  but not to  $\Theta$  because  $A \cup B \subseteq \Theta$  and  $C \cup D \subseteq \Theta$ . Thus

with PCR5<sup>+</sup> and PCR6<sup>+</sup> rules we will make the following redistribution:

$$\frac{x_4(A \cup B)}{m_1(A \cup B)} = \frac{x_4(C \cup D)}{m_2(C \cup D)} = \frac{\pi_4(\emptyset)}{m_1(A \cup B) + m_2(C \cup D)}.$$

Here,  $x_4(\Theta)$  is set to 0 with PCR5<sup>+</sup> and PCR6<sup>+</sup> principles because no proportion of  $\pi_4(\emptyset)$  must be redistributed to  $\Theta$ .

However, with PCR5 and PCR6 rule we make the redistributions according to

$$\begin{aligned} \frac{x_4(A \cup B)}{m_1(A \cup B)} &= \frac{x_4(C \cup D)}{m_2(C \cup D)} = \frac{x_4(\Theta)}{m_3(\Theta)} \\ &= \frac{\pi_4(\emptyset)}{m_1(A \cup B) + m_2(C \cup D) + m_3(\Theta)}. \end{aligned}$$

### A. Selection of focal elements for proportional redistribution

The main issue to improve PCR5 and PCR6 rules of combination is how to identify in each conflicting product  $\pi_j(\emptyset)$  the set of elements to keep for making the improved proportional redistribution.

In this section we propose a solution of this problem that can be easily implemented. For convenience, we give also the basic Matlab™ codes of PCR5<sup>+</sup> and PCR6<sup>+</sup> in appendix 3.

Let's consider  $\pi_j(\emptyset) = m_1(X_{j_1})m_2(X_{j_2}) \dots m_S(X_{j_S})$  a conflicting product<sup>13</sup> where  $X_{j_1} \cap X_{j_2} \cap \dots \cap X_{j_S} = \emptyset$ . We denote by  $\mathcal{X}_j = \{X_1, \dots, X_{s_j}, s_j \leq S\}$  the set of all distinct components of the  $S$ -tuple  $\mathbf{X}_j$  related with the conflicting product  $\pi_j(\emptyset)$ . The order of the elements in  $\mathcal{X}_j$  does not matter. The number  $s_j$  of elements in  $\mathcal{X}_j$  can be less than  $S$  because it is possible to have duplicate focal elements in  $\pi_j(\emptyset)$ . We consider in  $\mathcal{X}_j$  only the distinct focal elements involved in  $\pi_j(\emptyset)$  (see the next example) and we will define their binary *keeping-index indicator* which will allow to know if each element of  $\mathcal{X}_j$  needs to be kept in the proportional conflict redistribution, or not, in the improved PCR5 and PCR6 rules of combination.

For each element  $X_l \in \mathcal{X}_j$  we first define its binary *containing indicator*  $\delta_j(X_{l'}, X_l)$  with respect to  $X_{l'} \in \mathcal{X}_j$  to characterize if  $X_l$  contains (includes)  $X_{l'}$  in wide sense, or not. Therefore, we take  $\delta_j(X_{l'}, X_l) = 1$  if  $X_{l'} \cap X_l = X_{l'}$ , or equivalently if  $X_{l'} \subseteq X_l$ , and  $\delta_j(X_{l'}, X_l) = 0$  otherwise. The definition of this binary *containing indicator* is summarized by the formula

$$\delta_j(X_{l'}, X_l) \triangleq \begin{cases} 1 & \text{if } X_{l'} \subseteq X_l, \\ 0 & \text{if } X_{l'} \not\subseteq X_l. \end{cases} \quad (22)$$

Of course  $\delta_j(X_l, X_l) = 1$  because  $X_l \cap X_l = X_l$ , and we have  $\delta_j(X_{l'}, X_l) = 0$  as soon as  $|X_{l'}| > |X_l|$ , where  $|X_{l'}|$  and  $|X_l|$  are the cardinalities of  $X_{l'}$  and  $X_l$  respectively. We have

<sup>13</sup>We consider  $S > 2$  BBAs because for  $S = 2$  BBAs no improper increasing of uncertainty occurs with PCR5 or PCR6.

also  $\delta_j(X_{l'}, X_l) = 0$  when  $X_{l'} \cap X_l \neq X_{l'}$ . For  $X_l = \Theta$ , we have  $\delta_j(X_{l'}, X_l) = \delta_j(X_{l'}, \Theta) = 1$  for any  $X_{l'} \in \mathcal{X}_j$ .

To know if a focal element  $X_{j_i} \in \mathbf{X}_j$  must be kept, or not, in the proportional redistribution of the  $j$ -th conflicting mass  $\pi_j(\emptyset)$  with PCR5<sup>+</sup> and PCR6<sup>+</sup> rules, we have to determinate its binary *keeping-index*  $\kappa_j(X_{j_i})$ . For this, we define  $\kappa_j(X_{j_i}) \in \{0, 1\}$  as follows

$$\kappa_j(X_{j_i}) \triangleq 1 - \prod_{\substack{X_{l'}, X_l \in \mathcal{X}_j \\ X_{l'} \neq X_l \\ |X_{j_i}| \leq |X_l| \\ |X_{l'}| \leq |X_l|}} \delta_j(X_{l'}, X_l). \quad (23)$$

The value  $\kappa_j(X_{j_i}) = 1$  stipulates that the focal element  $X_{j_i} \in \mathbf{X}_j$  must receive some proportional redistribution from the conflicting mass  $\pi_j(\emptyset)$ . The value  $\kappa_j(X_{j_i}) = 0$  indicates that the focal element  $X_{j_i}$  will not be involved in the proportional redistribution of the conflicting mass  $\pi_j(\emptyset)$ .

The binary keeping-index can also be defined equivalently as

$$\kappa_j(X_{j_i}) = \begin{cases} 1 & \text{if } c(X_{j_i}) \text{ is true,} \\ 1 - \prod_{\substack{X_{l'} \in \mathcal{X}_j \\ X_{l'} \neq X_{j_i} \\ |X_{l'}| \leq |X_{j_i}|}} \delta_j(X_{l'}, X_{j_i}) & \text{if } c(X_{j_i}) \text{ is false,} \end{cases} \quad (24)$$

where the condition  $c(X_{j_i})$  is defined as

$$c(X_{j_i}) \triangleq \exists X_l \in \mathcal{X}_j \text{ such } |X_l| > |X_{j_i}| \text{ and } \kappa_j(X_l) = 1.$$

Because this second definition of  $\kappa_j(X_{j_i})$  is self-referencing, we need to calculate the binary keeping-indexes iteratively starting by the element of  $\mathcal{X}_j$  of highest cardinality (say  $X$ ), then for elements of  $\mathcal{X}_j$  of cardinality  $|X| - 1$  (if any), then for elements of  $\mathcal{X}_j$  of cardinality  $|X| - 2$  (if any), etc. From the implementation standpoint the definition (24) is more efficient than the direct definition (23).

**Remark 1:** We always have  $\kappa_j(\Theta) = 0$  if  $\Theta \in \mathcal{X}_j$  because  $\Theta$  always includes all other focal elements of  $\mathcal{X}_j$  and  $\Theta$  has the highest cardinality, so  $\delta_j(X_{l'}, \Theta) = 1$  for all  $X_{l'} \in \mathcal{X}_j$ . Therefore the binary keeping-index formula (23) reduces to

$$\kappa_j(\Theta) = 1 - \prod_{X_{l'} \in \mathcal{X}_j} \delta_j(X_{l'}, \Theta) = 1 - \underbrace{1 \cdot 1 \cdot \dots \cdot 1}_{|\mathcal{X}_j| \text{ terms}} = 0.$$

**Remark 2:** For a given FoD and a given number of BBAs to combine, it is always possible to calculate off-line the values of the binary keeping-indexes of focal elements of all possible combinations of focal elements involved in conflicting products  $\pi_j(\emptyset) > 0$  because the binary keeping-index depends only on the structure of the focal elements, and not on the numerical mass values of the focal elements. This remark is important, especially in applications where we have thousands or millions of fusion steps to make because we will not have to recalculate in each fusion step the binary keeping-indexes for each  $\pi_j(\emptyset)$  even if the input BBAs values to combine change.

**Remark 3:** It is worth to recall that PCR5<sup>+</sup> and PCR6<sup>+</sup> have interest if and only if we have more than two ( $S > 2$ ) BBAs to combine. If we have only two BBAs to combine ( $S = 2$ ) we always get  $m_{\text{PCR5}} = m_{\text{PCR5}^+} = m_{\text{PCR6}} = m_{\text{PCR6}^+}$  because in this case the PCR5, PCR5<sup>+</sup>, PCR6, PCR6<sup>+</sup> rules coincide.

For convenience, we illustrate the calculation of these binary keeping-indexes based on the direct calculation (23) for different examples.

**Example 6:** We consider the FoD  $\Theta = \{A, B, C, D\}$ , six BBAs, and the  $j$ -th conflicting (assumed strictly positive) product whose structure is as follows

$$\pi_j(\emptyset) = m_1(A)m_2(B \cup C)m_3(A \cup C)m_4(B \cup C) \\ \cdot m_5(A \cup B \cup C)m_6(A \cup B \cup C \cup D)$$

In this product  $\pi_j(\emptyset)$  we have the duplicate focal element  $B \cup C$  because it appears both in  $m_2(B \cup C)$  and in  $m_4(B \cup C)$ . The focal elements entering in each BBA of  $\pi_j(\emptyset)$  are respectively  $X_{j_1} = A$ ,  $X_{j_2} = B \cup C$ ,  $X_{j_3} = A \cup C$ ,  $X_{j_4} = B \cup C$ ,  $X_{j_5} = A \cup B \cup C$ , and  $X_{j_6} = A \cup B \cup C \cup D = \Theta$ . So we have to consider only the following set of distinct focal elements for this  $\pi_j(\emptyset)$  product

$$\mathcal{X}_j = \{X_1 = A, X_2 = B \cup C, X_3 = A \cup C, \\ X_4 = A \cup B \cup C, X_5 = A \cup B \cup C \cup D\}$$

Therefore, considering only  $X_{l'} \neq X_l$  and  $|X_{l'}| \leq |X_l|$  that are conditions entering in formula (23), we have the following binary containing indicator  $\delta_j(X_{l'}, X_l)$  values:

$$\begin{aligned} \delta_j(X_1, X_2) &= 0 \text{ because } (X_1 = A) \not\subseteq (X_2 = B \cup C), \\ \delta_j(X_1, X_3) &= 1 \text{ because } (X_1 = A) \subseteq (X_3 = A \cup C), \\ \delta_j(X_1, X_4) &= 1 \text{ because } (X_1 = A) \subseteq (X_4 = A \cup B \cup C), \\ \delta_j(X_1, X_5) &= 1 \text{ because } (X_1 = A) \subseteq (X_5 = \Theta), \\ \delta_j(X_2, X_3) &= 0 \text{ because } (X_2 = B \cup C) \not\subseteq (X_3 = A \cup C), \\ \delta_j(X_2, X_4) &= 1 \text{ because } (X_2 = B \cup C) \subseteq (X_4 = A \cup B \cup C), \\ \delta_j(X_2, X_5) &= 1 \text{ because } (X_2 = B \cup C) \subseteq (X_5 = \Theta), \\ \delta_j(X_3, X_2) &= 0 \text{ because } (X_3 = A \cup C) \not\subseteq (X_2 = B \cup C), \\ \delta_j(X_3, X_4) &= 1 \text{ because } (X_3 = A \cup C) \subseteq (X_4 = A \cup B \cup C), \\ \delta_j(X_3, X_5) &= 1 \text{ because } (X_3 = A \cup C) \subseteq (X_5 = \Theta), \\ \delta_j(X_4, X_5) &= 1 \text{ because } (X_4 = A \cup B \cup C) \subseteq (X_5 = \Theta). \end{aligned}$$

The binary keeping-indexes  $\kappa_j(X_{j_i})$  for  $i = 1, 2, \dots, 6$  are calculated based on the formula (23) as follows:

- For the focal element  $X_{j_1} = A = X_1$  of  $\mathcal{X}_j$  having  $|X_{j_1}| = 1$ , we get

$$\begin{aligned} \kappa_j(A) &= 1 - \prod_{\substack{X_{l'}, X_l \in \mathcal{X}_j \\ X_{l'} \neq X_l \\ |X_{j_1}| \leq |X_l| \\ |X_{l'}| \leq |X_l|}} \delta_j(X_{l'}, X_l) \\ &= 1 - [\delta_j(X_1, X_2)\delta_j(X_1, X_3)\delta_j(X_1, X_4)\delta_j(X_1, X_5) \\ &\quad \cdot \delta_j(X_2, X_3)\delta_j(X_2, X_4)\delta_j(X_2, X_5)\delta_j(X_3, X_2) \\ &\quad \cdot \delta_j(X_3, X_4)\delta_j(X_3, X_5)\delta_j(X_4, X_5)] \\ &= 1 - 0 \cdot 1 \cdot 1 \cdot 1 \cdot 0 \cdot 1 \cdot 1 \cdot 0 \cdot 1 \cdot 1 \cdot 1 = 1. \end{aligned}$$

Hence the focal element  $X_{j_1} = A$  will be kept in the proportional redistribution of the conflicting mass  $\pi_j(\emptyset)$ .

- For the focal element  $X_{j_2} = B \cup C = X_2$  of  $\mathcal{X}_j$  having  $|X_{j_2}| = 2$ , we get

$$\begin{aligned} \kappa_j(B \cup C) &= 1 - \prod_{\substack{X_{l'}, X_l \in \mathcal{X}_j \\ X_{l'} \neq X_l \\ |X_{j_2}| \leq |X_l| \\ |X_{l'}| \leq |X_l|}} \delta_j(X_{l'}, X_l) \\ &= 1 - [\delta_j(X_1, X_2)\delta_j(X_1, X_3)\delta_j(X_1, X_4) \\ &\quad \cdot \delta_j(X_1, X_5)\delta_j(X_2, X_3)\delta_j(X_2, X_4) \\ &\quad \cdot \delta_j(X_2, X_5)\delta_j(X_3, X_2)\delta_j(X_3, X_4) \\ &\quad \cdot \delta_j(X_3, X_5)\delta_j(X_4, X_5)] \\ &= 1 - 0 \cdot 1 \cdot 1 \cdot 1 \cdot 0 \cdot 1 \cdot 1 \cdot 0 \cdot 1 \cdot 1 \cdot 1 = 1. \end{aligned}$$

Hence the focal element  $X_{j_2} = B \cup C$  will be kept in the proportional redistribution of the conflicting mass  $\pi_j(\emptyset)$ .

- For the focal element  $X_{j_3} = A \cup C = X_3$  of  $\mathcal{X}_j$  having  $|X_{j_3}| = 2$ , we get

$$\begin{aligned} \kappa_j(A \cup C) &= 1 - \prod_{\substack{X_{l'}, X_l \in \mathcal{X}_j \\ X_{l'} \neq X_l \\ |X_{j_3}| \leq |X_l| \\ |X_{l'}| \leq |X_l|}} \delta_j(X_{l'}, X_l) \\ &= 1 - [\delta_j(X_1, X_2)\delta_j(X_1, X_3)\delta_j(X_1, X_4) \\ &\quad \cdot \delta_j(X_1, X_5)\delta_j(X_2, X_3)\delta_j(X_2, X_4) \\ &\quad \cdot \delta_j(X_2, X_5)\delta_j(X_3, X_2)\delta_j(X_3, X_4) \\ &\quad \cdot \delta_j(X_3, X_5)\delta_j(X_4, X_5)] \\ &= 1 - 0 \cdot 1 \cdot 1 \cdot 1 \cdot 0 \cdot 1 \cdot 1 \cdot 0 \cdot 1 \cdot 1 \cdot 1 = 1. \end{aligned}$$

Hence the focal element  $X_{j_3} = A \cup C$  will be kept in the proportional redistribution of the conflicting mass  $\pi_j(\emptyset)$ .

- For the duplicate focal element  $X_{j_4} = B \cup C$  of  $\mathcal{X}_j$  having  $|X_{j_4}| = 2$ , we have  $\kappa_j(X_{j_4}) = 1$  because  $X_{j_4} = X_{j_2}$  and  $\kappa_j(X_{j_2}) = 1$ .
- For the focal element  $X_{j_5} = A \cup B \cup C = X_4$  of  $\mathcal{X}_j$  having  $|X_{j_5}| = 3$ , we get

$$\begin{aligned} \kappa_j(A \cup B \cup C) &= 1 - \prod_{\substack{X_{l'}, X_l \in \mathcal{X}_j \\ X_{l'} \neq X_l \\ |X_{j_5}| \leq |X_l| \\ |X_{l'}| \leq |X_l|}} \delta_j(X_{l'}, X_l) \\ &= 1 - [\delta_j(X_1, X_4)\delta_j(X_1, X_5) \\ &\quad \cdot \delta_j(X_2, X_4)\delta_j(X_2, X_5)\delta_j(X_3, X_4) \\ &\quad \cdot \delta_j(X_3, X_5)\delta_j(X_4, X_5)] \\ &= 1 - 1 \cdot 1 = 0. \end{aligned}$$

Hence the focal element  $X_{j_5} = A \cup B \cup C$  will be discarded in the proportional redistribution of the conflicting mass  $\pi_j(\emptyset)$ .

- For the focal element  $X_{j_6} = A \cup B \cup C \cup D = \Theta = X_5$  of  $\mathcal{X}_j$  having  $|X_{j_6}| = 4$ , we get

$$\begin{aligned} \kappa_j(\Theta) &= 1 - \prod_{\substack{X_{l'}, X_l \in \mathcal{X}_j \\ X_{l'} \neq X_l \\ |X_{j_6}| \leq |X_l| \\ |X_{l'}| \leq |X_l|}} \delta_j(X_{l'}, X_l) \\ &= 1 - \delta_j(X_1, X_5)\delta_j(X_2, X_5)\delta_j(X_3, X_5)\delta_j(X_4, X_5) \\ &= 1 - 1 \cdot 1 \cdot 1 \cdot 1 = 0. \end{aligned}$$

This result illustrates the validity of the aforementioned remark 1. Hence the focal element  $X_{j_5} = A \cup B \cup C \cup D = \Theta$  will be discarded in the proportional redistribution of the conflicting mass  $\pi_j(\emptyset)$ .

In summary, the conflicting product  $\pi_j(\emptyset) = m_1(A)m_2(B \cup C)m_3(A \cup C)m_4(B \cup C)m_5(A \cup B \cup C)m_6(\Theta)$  will be redistributed only to the three focal elements  $A$ ,  $B \cup C$  and  $A \cup C$  with the improved rules PCR5<sup>+</sup> and PCR6<sup>+</sup>, whereas it would have been redistributed to all five focal elements  $A$ ,  $B \cup C$ ,  $A \cup C$ ,  $A \cup B \cup C$  and  $\Theta$  with the classical PCR5 and PCR6 rules. Thus, two focal elements were discarded.

**Example 7:** This example is somehow an extension of example 6 by including a new element  $E$  in the FoD. So, the FoD is  $\Theta = \{A, B, C, D, E\}$ , seven BBAs, and the  $j$ -th conflicting (assumed strictly positive) product whose structure is as follows

$$\begin{aligned} \pi_j(\emptyset) &= m_1(A \cup E)m_2(B \cup C \cup E)m_3(A \cup C \cup E)m_4(B \cup C \cup E) \\ &\quad \cdot m_5(A \cup B \cup C \cup E)m_6(A \cup B \cup C \cup D \cup E)m_7(A). \end{aligned}$$

In this product  $\pi_j(\emptyset)$  we have the duplicate focal element  $B \cup C \cup E$  because it appears both in  $m_2(B \cup C \cup E)$  and in  $m_4(B \cup C \cup E)$ . The focal elements entering in each BBA of  $\pi_j(\emptyset)$  are respectively  $X_{j_1} = A \cup E$ ,  $X_{j_2} = B \cup C \cup E$ ,  $X_{j_3} = A \cup C \cup E$ ,  $X_{j_4} = B \cup C \cup E$ ,  $X_{j_5} = A \cup B \cup C \cup E$ ,  $X_{j_6} = A \cup B \cup C \cup D \cup E = \Theta$  and  $X_{j_7} = A$ . So we have to consider only the following set of distinct focal elements for this  $\pi_j(\emptyset)$  product

$$\mathcal{X}_j = \{X_1 = A \cup E, X_2 = B \cup C \cup E, X_3 = A \cup C \cup E, X_4 = A \cup B \cup C \cup E, X_5 = A \cup B \cup C \cup D \cup E, X_6 = A\}.$$

Therefore, considering only  $X_{l'} \neq X_l$  and  $|X_{l'}| \leq |X_l|$  that are conditions entering in formula (23), we have the following binary containing indicator  $\delta_j(X_{l'}, X_l)$  values:

$$\begin{aligned} \delta_j(X_6, X_1) &= 1 \text{ because } (X_6 = A) \subseteq (X_1 = A \cup E), \\ \delta_j(X_6, X_2) &= 0 \text{ because } (X_6 = A) \not\subseteq (X_2 = B \cup C \cup E), \\ \delta_j(X_6, X_3) &= 1 \text{ because } (X_6 = A) \subseteq (X_3 = A \cup C \cup E), \\ \delta_j(X_6, X_4) &= 1 \text{ because } (X_6 = A) \subseteq (X_4 = A \cup B \cup C \cup E), \\ \delta_j(X_6, X_5) &= 1 \text{ because } (X_6 = A) \subseteq (X_5 = \Theta), \\ \delta_j(X_1, X_2) &= 0 \text{ because } (X_1 = A \cup E) \not\subseteq (X_2 = B \cup C \cup E), \\ \delta_j(X_1, X_3) &= 1 \text{ because } (X_1 = A \cup E) \subseteq (X_3 = A \cup C \cup E), \\ \delta_j(X_1, X_4) &= 1 \text{ because } (X_1 = A \cup E) \subseteq (X_4 = A \cup B \cup C \cup E), \\ \delta_j(X_1, X_5) &= 1 \text{ because } (X_1 = A \cup E) \subseteq (X_5 = \Theta), \\ \delta_j(X_2, X_3) &= 0 \text{ because } (X_2 = B \cup C \cup E) \not\subseteq (X_3 = A \cup C \cup E), \\ \delta_j(X_2, X_4) &= 1 \text{ because } (X_2 = B \cup C \cup E) \subseteq (X_4 = A \cup B \cup C \cup E), \end{aligned}$$

$$\begin{aligned}
 \delta_j(X_2, X_5) &= 1 \text{ because } (X_2 = B \cup C \cup E) \subseteq (X_5 = \Theta), \\
 \delta_j(X_3, X_2) &= 0 \text{ because } (X_3 = A \cup C \cup E) \not\subseteq (X_2 = B \cup C \cup E), \\
 \delta_j(X_3, X_4) &= 1 \text{ because } (X_3 = A \cup C \cup E) \subseteq (X_4 = A \cup B \cup C \cup E), \\
 \delta_j(X_3, X_5) &= 1 \text{ because } (X_3 = A \cup C \cup E) \subseteq (X_5 = \Theta), \\
 \delta_j(X_4, X_5) &= 1 \text{ because } (X_4 = A \cup B \cup C \cup E) \subseteq (X_5 = \Theta).
 \end{aligned}$$

The binary keeping-indexes  $\kappa_j(X_{j_i})$  for  $i = 1, 2, \dots, 7$  are calculated based on the formula (23) as follows

- For the focal element  $X_{j_1} = A \cup E = X_1$  of  $\mathcal{X}_j$  having  $|X_{j_1}| = 2$ , we get

$$\begin{aligned}
 \kappa_j(X_{j_1}) &= 1 - \prod_{\substack{X_{l'}, X_l \in \mathcal{X}_j \\ X_{l'} \neq X_l \\ |X_{j_1}| \leq |X_l| \\ |X_{l'}| \leq |X_l|}} \delta_i(X_{l'}, X_l) \\
 &= 1 - [\delta_j(X_1, X_2)\delta_j(X_1, X_3)\delta_j(X_1, X_4)\delta_j(X_1, X_5) \\
 &\quad \cdot \delta_j(X_2, X_3)\delta_j(X_2, X_4)\delta_j(X_2, X_5)\delta_j(X_3, X_2) \\
 &\quad \cdot \delta_j(X_3, X_4)\delta_j(X_3, X_5)\delta_j(X_4, X_5)\delta_j(X_6, X_1) \\
 &\quad \cdot \delta_j(X_6, X_2)\delta_j(X_6, X_3)\delta_j(X_6, X_4)\delta_j(X_6, X_5)] \\
 &= 1 - 0 \cdot 1 \cdot 1 \cdot 1 \cdot 0 \cdot 1 \cdot 1 \cdot 0 \cdot 1 \cdot 1 \cdot 0 \cdot 1 \cdot 1 \cdot 1 = 1.
 \end{aligned}$$

Hence the focal element  $X_{j_1} = A \cup E$  will be kept in the proportional redistribution of the conflicting mass  $\pi_j(\emptyset)$ .

- For the focal element  $X_{j_2} = B \cup C \cup E = X_2$  of  $\mathcal{X}_j$  having  $|X_{j_2}| = 3$ , we get

$$\begin{aligned}
 \kappa_j(X_{j_2}) &= 1 - \prod_{\substack{X_{l'}, X_l \in \mathcal{X}_j \\ X_{l'} \neq X_l \\ |X_{j_2}| \leq |X_l| \\ |X_{l'}| \leq |X_l|}} \delta_j(X_{l'}, X_l) \\
 &= 1 - [\delta_j(X_1, X_2)\delta_j(X_1, X_3)\delta_j(X_1, X_4)\delta_j(X_1, X_5) \\
 &\quad \cdot \delta_j(X_2, X_3)\delta_j(X_2, X_4)\delta_j(X_2, X_5)\delta_j(X_3, X_2) \\
 &\quad \cdot \delta_j(X_3, X_4)\delta_j(X_3, X_5)\delta_j(X_4, X_5)\delta_j(X_6, X_2) \\
 &\quad \cdot \delta_j(X_6, X_3)\delta_j(X_6, X_4)\delta_j(X_6, X_5)] \\
 &= 1 - 0 \cdot 1 \cdot 1 \cdot 1 \cdot 0 \cdot 1 \cdot 1 \cdot 0 \cdot 1 \cdot 1 \cdot 1 \cdot 0 \cdot 1 \cdot 1 \cdot 1 \\
 &= 1.
 \end{aligned}$$

Hence the focal element  $X_{j_2} = B \cup C \cup E$  will also be kept in the proportional redistribution of the conflicting mass  $\pi_j(\emptyset)$ .

- For the focal element  $X_{j_3} = A \cup C \cup E = X_3$  of  $\mathcal{X}_j$  having  $|X_{j_3}| = 3$ , we get

$$\begin{aligned}
 \kappa_j(X_{j_3}) &= 1 - \prod_{\substack{X_{l'}, X_l \in \mathcal{X}_j \\ X_{l'} \neq X_l \\ |X_{j_3}| \leq |X_l| \\ |X_{l'}| \leq |X_l|}} \delta_j(X_{l'}, X_l) \\
 &= 1 - [\delta_j(X_1, X_2)\delta_j(X_1, X_3)\delta_j(X_1, X_4)\delta_j(X_1, X_5) \\
 &\quad \cdot \delta_j(X_2, X_3)\delta_j(X_2, X_4)\delta_j(X_2, X_5)\delta_j(X_3, X_2) \\
 &\quad \cdot \delta_j(X_3, X_4)\delta_j(X_3, X_5)\delta_j(X_4, X_5)\delta_j(X_6, X_2) \\
 &\quad \cdot \delta_j(X_6, X_3)\delta_j(X_6, X_4)\delta_j(X_6, X_5)] \\
 &= 1 - 0 \cdot 1 \cdot 1 \cdot 1 \cdot 0 \cdot 1 \cdot 1 \cdot 0 \cdot 1 \cdot 1 \cdot 1 \cdot 0 \cdot 1 \cdot 1 \cdot 1 \\
 &= 1.
 \end{aligned}$$

Hence the focal element  $X_{j_3} = A \cup C \cup E$  is also kept in the redistribution.

- For the duplicate focal element  $X_{j_4} = B \cup C \cup E$  having  $|X_{j_4}| = 3$ , we have  $\kappa_j(X_{j_4}) = 1$  because  $X_{j_4} = X_{j_2}$  and  $\kappa_j(X_{j_2}) = 1$ .

- For the focal element  $X_{j_5} = A \cup B \cup C \cup E = X_4$  having  $|X_{j_5}| = 4$ , we get

$$\begin{aligned}
 \kappa_j(X_{j_5}) &= 1 - \prod_{\substack{X_{l'}, X_l \in \mathcal{X}_j \\ X_{l'} \neq X_l \\ |X_{j_5}| \leq |X_l| \\ |X_{l'}| \leq |X_l|}} \delta_j(X_{l'}, X_l) \\
 &= 1 - [\delta_j(X_1, X_4)\delta_j(X_1, X_5)\delta_j(X_2, X_4)\delta_j(X_2, X_5) \\
 &\quad \cdot \delta_j(X_3, X_4)\delta_j(X_3, X_5)\delta_j(X_4, X_5)\delta_j(X_6, X_4) \\
 &\quad \cdot \delta_j(X_6, X_5)] \\
 &= 1 - 1 \cdot 1 = 0.
 \end{aligned}$$

Hence the focal element  $X_{j_5} = A \cup B \cup C \cup E$  must be ignored in the proportional redistribution.

- For  $X_{j_6} = A \cup B \cup C \cup D \cup E = \Theta = X_5$  having  $|X_{j_6}| = 5$ , we get

$$\begin{aligned}
 \kappa_j(X_{j_6}) &= 1 - \prod_{\substack{X_{l'}, X_l \in \mathcal{X}_j \\ X_{l'} \neq X_l \\ |X_{j_6}| \leq |X_l| \\ |X_{l'}| \leq |X_l|}} \delta_j(X_{l'}, X_l) \\
 &= 1 - [\delta_j(X_1, X_5)\delta_j(X_2, X_5)\delta_j(X_3, X_5)\delta_j(X_4, X_5) \\
 &\quad \cdot \delta_j(X_6, X_5)] \\
 &= 1 - 1 \cdot 1 \cdot 1 \cdot 1 \cdot 1 = 0.
 \end{aligned}$$

This result illustrates the validity of the aforementioned remark 1. Hence the focal element  $X_{j_6} = A \cup B \cup C \cup D \cup E$  must be ignored in the proportional redistribution.

- For the focal element  $X_{j_7} = A = X_6$  having  $|X_{j_7}| = 1$ , we get naturally (see our previous remark 1)

$$\begin{aligned}
 \kappa_j(X_{j_7}) &= 1 - \prod_{\substack{X_{l'}, X_l \in \mathcal{X}_j \\ X_{l'} \neq X_l \\ |X_{j_7}| \leq |X_l| \\ |X_{l'}| \leq |X_l|}} \delta_j(X_{l'}, X_l) \\
 &= 1 - [\delta_j(X_1, X_2)\delta_j(X_1, X_3)\delta_j(X_1, X_4)\delta_j(X_1, X_5) \\
 &\quad \cdot \delta_j(X_2, X_3)\delta_j(X_2, X_4)\delta_j(X_2, X_5)\delta_j(X_3, X_2) \\
 &\quad \cdot \delta_j(X_3, X_4)\delta_j(X_3, X_5)\delta_j(X_4, X_5)\delta_j(X_6, X_2) \\
 &\quad \cdot \delta_j(X_6, X_3)\delta_j(X_6, X_4)\delta_j(X_6, X_5)] \\
 &= 1 - 0 \cdot 1 \cdot 1 \cdot 1 \cdot 0 \cdot 1 \cdot 1 \cdot 0 \cdot 1 \cdot 1 \cdot 1 \cdot 0 \cdot 1 \cdot 1 \cdot 1 \\
 &= 1.
 \end{aligned}$$

Hence the focal element  $X_{j_7} = A$  must be kept in the proportional redistribution.

In summary, the conflicting product  $\pi_j(\emptyset) = m_1(A \cup E)m_2(B \cup C \cup E)m_3(A \cup C \cup E)m_4(B \cup C \cup E)m_5(A \cup B \cup C \cup E)m_6(\Theta)m_7(A)$  will be redistributed only to focal elements  $A \cup E$ ,  $B \cup C \cup E$ ,  $A \cup C \cup E$  and  $A$  with the improved rules PCR5<sup>+</sup> and PCR6<sup>+</sup>, whereas it would have been redistributed to all focal elements  $A \cup E$ ,  $B \cup C \cup E$ ,  $A \cup C \cup E$ ,  $A \cup B \cup C \cup E$ ,  $\Theta$  and  $A$  with the classical PCR5 and PCR6 rules.

**Example 8:** This is a somehow simplified version of example 6. We consider the FoD  $\Theta = \{A, B, C, D\}$ , only five BBAs, and suppose that the  $j$ -th conflicting (assumed strictly positive) product is as follows

$$\pi_j(\emptyset) = m_1(A)m_2(B \cup C)m_3(A \cup C)m_4(B \cup C) \cdot m_5(A \cup B \cup C \cup D).$$

Based on (23), it can be verified<sup>14</sup> that the binary keeping-indexes of focal elements involved in conflicting products are

$$\begin{aligned} \kappa_j(A) &= 1, \\ \kappa_j(B \cup C) &= 1, \\ \kappa_j(A \cup C) &= 1, \\ \kappa_j(A \cup B \cup C \cup D) &= 0. \end{aligned}$$

**Example 9:** We consider the FoD  $\Theta = \{A, B, C, D\}$ , seven BBAs, and suppose that the  $j$ -th conflicting (assumed strictly positive) product is as follows

$$\pi_j(\emptyset) = m_1(A)m_2(B \cup C)m_3(A \cup C)m_4(B \cup C) \cdot m_5(A \cup B \cup C \cup D)m_6(A \cup B \cup C)m_7(A \cup B \cup C).$$

Based on (23), it can be verified that the binary keeping-indexes of focal elements involved in conflicting products are

$$\begin{aligned} \kappa_j(A) &= 1, \\ \kappa_j(B \cup C) &= 1, \\ \kappa_j(A \cup C) &= 1, \\ \kappa_j(A \cup B \cup C \cup D) &= 0, \\ \kappa_j(A \cup B \cup C) &= 0. \end{aligned}$$

**Example 10:** We consider the FoD  $\Theta = \{A, B, C\}$ , three BBAs, and suppose that the  $j$ -th conflicting (assumed strictly positive) product is as follows

$$\pi_j(\emptyset) = m_1(A)m_2(B \cup C)m_3(A \cup C).$$

Based on (23), it can be verified that the binary keeping-indexes of focal elements involved in conflicting products are

$$\begin{aligned} \kappa_j(A) &= 1, \\ \kappa_j(B \cup C) &= 1, \\ \kappa_j(A \cup C) &= 1. \end{aligned}$$

**Example 11:** We consider the FoD  $\Theta = \{A, B, C\}$ , four BBAs, and suppose that the  $j$ -th conflicting (assumed strictly positive) product is as follows

$$\pi_j(\emptyset) = m_1(A)m_2(B \cup C)m_3(A \cup C)m_4(A \cup B).$$

Based on (23), it can be verified that the binary keeping-indexes of focal elements involved in conflicting products are

$$\begin{aligned} \kappa_j(A) &= 1, \\ \kappa_j(B \cup C) &= 1, \\ \kappa_j(A \cup C) &= 1, \\ \kappa_j(A \cup B) &= 1. \end{aligned}$$

**Example 12:** We consider the FoD  $\Theta = \{A, B, C\}$ , three BBAs, and suppose that the  $j$ -th conflicting (assumed strictly positive) product is as follows

$$\pi_j(\emptyset) = m_1(A \cup B \cup C)m_2(A)m_3(B \cup C).$$

Based on (23), it can be verified that the binary keeping-indexes of focal elements involved in conflicting products are

$$\begin{aligned} \kappa_j(A \cup B \cup C) &= 0, \\ \kappa_j(A) &= 1, \\ \kappa_j(B \cup C) &= 1. \end{aligned}$$

**Example 13:** We consider the FoD  $\Theta = \{A, B, C, D\}$ , and the three following BBAs

$$\begin{aligned} m_1(A \cup B) &= 0.8, m_1(C \cup D) = 0.2, \\ m_2(A \cup B) &= 0.4, m_2(C \cup D) = 0.6, \\ m_3(B) &= 0.1, m_3(A \cup B \cup C \cup D) = 0.9. \end{aligned}$$

We have  $\mathcal{F} = |\mathcal{F}(m_1)| \cdot |\mathcal{F}(m_2)| \cdot |\mathcal{F}(m_3)| = 2 \cdot 2 \cdot 2 = 8$  products  $\pi_j$  ( $j = 1, \dots, \mathcal{F}$ ) entering in the fusion process as follows

$$\begin{aligned} \pi_1(B) &= m_1(A \cup B)m_2(A \cup B)m_3(B) = 0.032, \\ \pi_2(A \cup B) &= m_1(A \cup B)m_2(A \cup B)m_3(\Theta) = 0.288, \\ \pi_3(\emptyset) &= m_1(A \cup B)m_2(C \cup D)m_3(B) = 0.048, \\ \pi_4(\emptyset) &= m_1(A \cup B)m_2(C \cup D)m_3(\Theta) = 0.432, \\ \pi_5(\emptyset) &= m_1(C \cup D)m_2(A \cup B)m_3(B) = 0.008, \\ \pi_6(\emptyset) &= m_1(C \cup D)m_2(A \cup B)m_3(\Theta) = 0.072, \\ \pi_7(\emptyset) &= m_1(C \cup D)m_2(C \cup D)m_3(B) = 0.012, \\ \pi_8(C \cup D) &= m_1(C \cup D)m_2(C \cup D)m_3(\Theta) = 0.108. \end{aligned}$$

Based on (23), it can be verified<sup>15</sup> that the binary keeping-indexes of focal elements involved in conflicting products  $\pi_3(\emptyset)$  to  $\pi_7(\emptyset)$  are

$$\begin{aligned} \kappa_3(A \cup B) &= 1, \kappa_3(C \cup D) = 1, \kappa_3(B) = 1, \\ \kappa_4(A \cup B) &= 1, \kappa_4(C \cup D) = 1, \kappa_4(\Theta) = 0, \\ \kappa_5(C \cup D) &= 1, \kappa_5(A \cup B) = 1, \kappa_5(B) = 1, \\ \kappa_6(C \cup D) &= 1, \kappa_6(A \cup B) = 1, \kappa_6(\Theta) = 0, \\ \kappa_7(C \cup D) &= 1, \kappa_7(B) = 1. \end{aligned}$$

In summary, once the binary keeping-index of  $\kappa_j(X_{j_i})$  of all focal elements  $X_{j_i}$  involved in a conflicting product  $\pi_j(\emptyset)$  are calculated, we can apply PCR5, or PCR6 redistribution principle only with the focal elements for which  $\kappa_j(X_{j_i}) = 1$ .

<sup>14</sup>The verification is left to the reader.

<sup>15</sup>The verification is left to the reader.

With this new improved method of proportional redistribution PCR5<sup>+</sup> and PCR6<sup>+</sup> rules will never increase the mass of non conflicting elements involved in each  $\pi_j(\emptyset)$  (if any), and in doing this way we will preserve the neutrality of the vacuous belief assignment in the PCR5<sup>+</sup> and PCR6<sup>+</sup> fusion rules, which is a very desirable behavior.

### B. Expressions of PCR5<sup>+</sup> and PCR6<sup>+</sup> fusion rules

The expressions of PCR5<sup>+</sup> and PCR6<sup>+</sup> fusion rules are proper modifications of PCR5 and PCR6 formulas (14) and (15) taking into account the selection of focal elements on which the proportional redistribution must apply thanks to the value of their binary keeping-index.

The PCR5<sup>+</sup> fusion of  $S > 2$  BBAs is obtained by  $m_{1,2,\dots,S}^{\text{PCR5}^+}(\emptyset) = 0$ , and for all  $A \in 2^\Theta \setminus \{\emptyset\}$  by

$$m_{1,2,\dots,S}^{\text{PCR5}^+}(A) = m_{1,2,\dots,S}^{\text{Conj}}(A) + \sum_{j \in \{1,\dots,S\} | A \in \mathbf{X}_j \wedge \pi_j(\emptyset)} \left[ \left( \kappa_j(A) \prod_{i \in \{1,\dots,S\} | X_{j_i}=A} m_i(X_{j_i}) \right) \cdot \frac{\pi_j(\emptyset)}{\sum_{X \in \mathbf{X}_j} \left( \kappa_j(X) \prod_{i \in \{1,\dots,S\} | X_{j_i}=X} m_i(X_{j_i}) \right)} \right]. \quad (25)$$

The PCR6<sup>+</sup> fusion of  $S > 2$  BBAs is obtained by  $m_{1,2,\dots,S}^{\text{PCR6}^+}(\emptyset) = 0$ , and for all  $A \in 2^\Theta \setminus \{\emptyset\}$  by

$$m_{1,2,\dots,S}^{\text{PCR6}^+}(A) = m_{1,2,\dots,S}^{\text{Conj}}(A) + \sum_{j \in \{1,\dots,S\} | A \in \mathbf{X}_j \wedge \pi_j(\emptyset)} \left[ \left( \kappa_j(A) \sum_{i \in \{1,\dots,S\} | X_{j_i}=A} m_i(X_{j_i}) \right) \cdot \frac{\pi_j(\emptyset)}{\sum_{X \in \mathbf{X}_j} \left( \kappa_j(X) \sum_{i \in \{1,\dots,S\} | X_{j_i}=X} m_i(X_{j_i}) \right)} \right], \quad (26)$$

where  $\kappa_j(A)$  and  $\kappa_j(X)$  are respectively the binary keeping-indexes of elements  $A$  and  $X$  involved in the conflicting product  $\pi_j(\emptyset)$ , that are calculated by the formula (23) or (24).

**Remark 4:** It is worth mentioning that PCR5<sup>+</sup> formula (25) is totally consistent with PCR5 formula (14) when all binary keeping-indexes are equal to one. Similarly, the PCR6<sup>+</sup> formula (26) reduces to PCR6 formula (15) if all binary keeping-indexes equal one.

**Theorem:** The vacuous BBA  $m_v$  has a neutral impact in PCR5<sup>+</sup> and PCR6<sup>+</sup> rules of combination.

**Proof:** see appendix 2.

### C. On the complexity of PCR5<sup>+</sup> and PCR6<sup>+</sup> fusion rules

The complexity of PCR5 and PCR6 rules is difficult to establish precisely because the number of computations highly depends on the structure of focal elements of the BBAs to combine, but definitely it is higher than Dempster's rule of combination. What about the complexity of PCR5<sup>+</sup> and PCR6<sup>+</sup> fusion rules? On the one hand, PCR5<sup>+</sup> and PCR6<sup>+</sup> seem more complex than PCR5 and PCR6 rules because one needs extra computational burden with respect to PCR5 and

PCR6 rules to calculate the binary keeping-indexes. But in fact, the calculation of binary keeping-indexes do not depend on the mass values of focal elements but only on their structure. Hence, the binary keeping-indexes can be calculated off-line once for all for many possible structures of focal elements of BBAs to combine. On the other hand, if the binary keeping-index calculation is done off-line, then PCR5<sup>+</sup> and PCR6<sup>+</sup> become less complex than PCR5 and PCR6 rule because some elements are discarded with PCR5<sup>+</sup> and PCR6<sup>+</sup> making the redistribution simpler and more effective than with PCR5 and PCR6 rules. It is not possible to say for sure if globally PCR5<sup>+</sup> and PCR6<sup>+</sup> are more (or less) complex than PCR5 and PCR6 because it really depends on the fusion problem under consideration and the structure of focal elements of BBAs to combine. If the sources of evidence to combine generate many partial conflicts to redistribute including many elements to discard, then PCR5<sup>+</sup> and PCR6<sup>+</sup> are more advantageous than PCR5 and PCR6 in terms of reduction of complexity.

## VII. EXAMPLES FOR PCR5<sup>+</sup> AND PCR6<sup>+</sup> FUSION RULES

Here we compare the results obtained with PCR5<sup>+</sup> and PCR6<sup>+</sup> with respect to those drawn from PCR5 and PCR6 rules on the examples from 1 to 13 in the previous sections. Since these following examples, for PCR5<sup>+</sup> and PCR6<sup>+</sup> fusion rules, respectively consider the same FoD and BBAs as those presented, they will be denoted as "revisited examples".

**Example 1 (revisited):** Consider  $\Theta = \{A, B\}$  and two following BBAs

$$m_1(A) = 0.1, \quad m_1(B) = 0.2, \quad m_1(A \cup B) = 0.7, \\ m_2(A) = 0.4, \quad m_2(B) = 0.3, \quad m_2(A \cup B) = 0.3.$$

Because there is only two BBAs to combine, we have

$$\text{PCR5}(m_1, m_2) = \text{PCR6}(m_1, m_2) \\ \text{PCR5}^+(m_1, m_2) = \text{PCR6}^+(m_1, m_2).$$

We have  $m_{1,2}^{\text{Conj}}(A) = 0.35$ ,  $m_{1,2}^{\text{Conj}}(B) = 0.33$ , and  $m_{1,2}^{\text{Conj}}(\Theta) = 0.21$ , and we have the two conflicting products  $\pi_1(\emptyset) = m_1(A)m_2(B) = 0.03$  and  $\pi_2(\emptyset) = m_2(A)m_1(B) = 0.08$  to redistribute.

Applying PCR5 principle for  $\pi_1(\emptyset) = 0.03$  we get

$$\frac{x_1(A)}{m_1(A)} = \frac{x_1(B)}{m_2(B)} = \frac{\pi_1(\emptyset)}{m_1(A) + m_2(B)},$$

whence  $x_1(A) = 0.1 \cdot \frac{0.03}{0.1+0.3} = 0.0075$  and  $x_1(B) = 0.3 \cdot \frac{0.03}{0.1+0.3} = 0.0225$ .

Applying PCR5 principle for  $\pi_2(\emptyset) = 0.08$  we get

$$\frac{x_2(A)}{m_2(A)} = \frac{x_2(B)}{m_1(B)} = \frac{\pi_2(\emptyset)}{m_2(A) + m_1(B)},$$

whence  $x_2(A) = 0.4 \cdot \frac{0.08}{0.4+0.2} \approx 0.0533$  and  $x_2(B) = 0.2 \cdot \frac{0.08}{0.4+0.2} \approx 0.0267$ .

Therefore we get

$$\begin{aligned} m_{1,2}^{\text{PCR5}}(A) &= m_{1,2}^{\text{PCR6}}(A) = m_{1,2}^{\text{Conj}}(A) + x_1(A) + x_2(A) \\ &= 0.35 + 0.0075 + 0.0533 = 0.4108, \\ m_{1,2}^{\text{PCR5}}(B) &= m_{1,2}^{\text{PCR6}}(B) = m_{1,2}^{\text{Conj}}(B) + x_1(B) + x_2(B) \\ &= 0.33 + 0.0225 + 0.0267 = 0.3792, \\ m_{1,2}^{\text{PCR5}}(A \cup B) &= m_{1,2}^{\text{PCR6}}(A \cup B) = m_{1,2}^{\text{Conj}}(A \cup B) = 0.21. \end{aligned}$$

If we want to apply  $\text{PCR5}^+$ , or  $\text{PCR6}^+$ , rule we need to compute the binary keeping-indexes of each focal element entering in the conflicting products  $\pi_1(\emptyset)$  and  $\pi_2(\emptyset)$ . In this example for  $\pi_1(\emptyset) = m_1(A)m_2(B)$  we have  $\mathcal{X}_1 = \{A, B\}$ , and for  $\pi_2(\emptyset) = m_2(A)m_1(B)$  we have  $\mathcal{X}_2 = \{A, B\}$ . Applying formula (22), we get  $\delta_1(A, B) = 0$  because  $A \not\subseteq B$ , and  $\delta_1(B, A) = 0$  because  $B \not\subseteq A$  (and also  $\delta_2(A, B) = 0$  and  $\delta_2(B, A) = 0$ ). Applying formula (23) we get the binary keeping-indexes  $\kappa_1(A) = 1$ ,  $\kappa_1(B) = 1$ ,  $\kappa_2(A) = 1$ , and  $\kappa_2(B) = 1$  indicating that the redistribution of  $\pi_1(\emptyset)$  must operate on all elements of  $\mathcal{X}_1 = \{A, B\}$ , and the redistribution of  $\pi_2(\emptyset)$  must also operate on all elements of  $\mathcal{X}_2 = \{A, B\}$ , so there is no element that must be discarded for making the improved redistribution in this example. Therefore  $\text{PCR5}^+$ , or  $\text{PCR6}^+$  results coincide with  $\text{PCR5}$  and  $\text{PCR6}$  results, that is  $m^{\text{PCR5}}(\cdot) = m^{\text{PCR6}}(\cdot) = m^{\text{PCR5}^+}(\cdot) = m^{\text{PCR6}^+}(\cdot)$  which is normal.

**Example 2** (revisited): Consider  $\Theta = \{A, B\}$  and the three following BBAs

$$\begin{aligned} m_1(A) &= 0.6, m_1(B) = 0.1, m_1(A \cup B) = 0.3, \\ m_2(A) &= 0.5, m_2(B) = 0.3, m_2(A \cup B) = 0.2, \\ m_3(A) &= 0.4, m_3(B) = 0.1, m_3(A \cup B) = 0.5. \end{aligned}$$

As shown in Section IV, for this example one has the following twelve conflicting products to redistribute when applying  $\text{PCR5}$ , or  $\text{PCR6}$  fusion formulas.

$$\begin{aligned} \pi_1(\emptyset) &= m_1(A)m_2(A)m_3(B) = 0.0300, \\ \pi_2(\emptyset) &= m_1(A)m_2(B)m_3(A) = 0.0720, \\ \pi_3(\emptyset) &= m_1(B)m_2(A)m_3(A) = 0.0200, \\ \pi_4(\emptyset) &= m_1(B)m_2(B)m_3(A) = 0.0120, \\ \pi_5(\emptyset) &= m_1(B)m_2(A)m_3(B) = 0.0050, \\ \pi_6(\emptyset) &= m_1(A)m_2(B)m_3(B) = 0.0180, \\ \pi_7(\emptyset) &= m_1(A \cup B)m_2(A)m_3(B) = 0.0150, \\ \pi_8(\emptyset) &= m_1(A \cup B)m_2(B)m_3(A) = 0.0360, \\ \pi_9(\emptyset) &= m_1(B)m_2(A)m_3(A \cup B) = 0.0250, \\ \pi_{10}(\emptyset) &= m_1(A)m_2(B)m_3(A \cup B) = 0.0900, \\ \pi_{11}(\emptyset) &= m_1(A)m_2(A \cup B)m_3(B) = 0.0120, \\ \pi_{12}(\emptyset) &= m_1(B)m_2(A \cup B)m_3(A) = 0.0080. \end{aligned}$$

With  $\text{PCR5}$  and  $\text{PCR6}$  the products  $\pi_1(\emptyset)$  to  $\pi_6(\emptyset)$  are redistributed to  $A$  and  $B$  only, whereas the products  $\pi_7(\emptyset)$  to  $\pi_{12}(\emptyset)$  are redistributed to  $A$ ,  $B$  and  $A \cup B$ . Applying  $\text{PCR5}$  formula (14), and  $\text{PCR6}$  formula (15) we obtain  $m_{1,2,3}^{\text{PCR5}}(\emptyset) = m_{1,2,3}^{\text{PCR6}}(\emptyset) = 0$  and

$$\begin{cases} m_{1,2,3}^{\text{PCR5}}(A) \approx 0.723281, \\ m_{1,2,3}^{\text{PCR5}}(B) \approx 0.182460, \\ m_{1,2,3}^{\text{PCR5}}(A \cup B) \approx 0.094259, \end{cases} \quad \text{and} \quad \begin{cases} m_{1,2,3}^{\text{PCR6}}(A) \approx 0.743496, \\ m_{1,2,3}^{\text{PCR6}}(B) \approx 0.162245, \\ m_{1,2,3}^{\text{PCR6}}(A \cup B) \approx 0.094259. \end{cases}$$

The calculation of the binary keeping-indexes by the formula (23) gives in this example

$$\begin{cases} \kappa_j(A) = 1, \kappa_j(B) = 1, & \text{for } j = 1, \dots, 6 \\ \kappa_j(A) = 1, \kappa_j(B) = 1, \kappa_j(A \cup B) = 0, & \text{for } j = 7, \dots, 12 \end{cases}$$

Therefore, if we apply the  $\text{PCR5}^+$  and  $\text{PCR6}^+$  improved rules of combination, we redistribute the products  $\pi_1(\emptyset)$  to  $\pi_6(\emptyset)$  to  $A$  and  $B$  (as for  $\text{PCR5}$  and  $\text{PCR6}$  rule), but the products  $\pi_7(\emptyset)$  to  $\pi_{12}(\emptyset)$  will be redistributed to  $A$ ,  $B$  only, and not to  $A \cup B$  because  $\kappa_j(A \cup B) = 0$  for  $j = 7, \dots, 12$ . So finally, we obtain  $m_{1,2,3}^{\text{PCR5}^+}(\emptyset) = m_{1,2,3}^{\text{PCR6}^+}(\emptyset) = 0$  and

$$\begin{cases} m_{1,2,3}^{\text{PCR5}^+}(A) \approx 0.768631, \\ m_{1,2,3}^{\text{PCR5}^+}(B) \approx 0.201369, \\ m_{1,2,3}^{\text{PCR5}^+}(A \cup B) = 0.03, \end{cases} \quad \text{and} \quad \begin{cases} m_{1,2,3}^{\text{PCR6}^+}(A) \approx 0.788847, \\ m_{1,2,3}^{\text{PCR6}^+}(B) \approx 0.181153, \\ m_{1,2,3}^{\text{PCR6}^+}(A \cup B) = 0.03. \end{cases}$$

We can verify that we obtain a more precise redistribution with  $\text{PCR5}^+$  (resp.  $\text{PCR6}^+$ ) rule with respect to  $\text{PCR5}$  (resp.  $\text{PCR6}$ ) rule because  $m_{1,2,3}^{\text{PCR5}^+}(A \cup B) < m_{1,2,3}^{\text{PCR5}}(A \cup B)$  and also  $m_{1,2,3}^{\text{PCR6}^+}(A \cup B) < m_{1,2,3}^{\text{PCR6}}(A \cup B)$ .

**Example 3** (revisited): we consider  $\Theta = \{A, B, C\}$ , and the four very simple BBAs defined by

$$m_1(A \cup B) = 1, m_2(B) = 1, m_3(A \cup B) = 1, \text{ and } m_4(C) = 1$$

These four basic belief assignments are in total conflict because  $(A \cup B) \cap A \cap (A \cup B) \cap C = \emptyset$ , and one has only one product  $\pi(\emptyset) = m_1(A \cup B)m_2(A)m_3(A \cup B)m_4(C) = 1$  to consider, so  $j = 1$  in this case and it can be omitted in the notations of the binary keeping-indexes.

As shown previously, one has

$$\begin{cases} m_{1,2,3,4}^{\text{PCR5}}(A \cup B) = 1/3, \\ m_{1,2,3,4}^{\text{PCR5}}(B) = 1/3, \\ m_{1,2,3,4}^{\text{PCR5}}(C) = 1/3, \end{cases} \quad \text{and} \quad \begin{cases} m_{1,2,3,4}^{\text{PCR6}}(A \cup B) = 0.5, \\ m_{1,2,3,4}^{\text{PCR6}}(B) = 0.25, \\ m_{1,2,3,4}^{\text{PCR6}}(C) = 0.25. \end{cases}$$

Because all focal elements  $A \cup B$ ,  $A$  and  $C$  entering in  $\pi(\emptyset)$  are conflicting then one has the binary keeping-indexes  $\kappa(A \cup B) = 1$ ,  $\kappa(A) = 1$  and  $\kappa(C) = 1$  i.e. all these elements will receive a redistribution of the conflicting mass  $\pi(\emptyset)$ . Therefore there is no restriction for making the redistribution. Consequently,  $\text{PCR5}^+$  result coincides with  $\text{PCR5}$  result, and  $\text{PCR6}^+$  result coincides with  $\text{PCR6}$  result.

**Example 4** (revisited): we consider  $\Theta = \{A, B\}$ , and the following four BBAs

$$\begin{aligned} m_1(A) &= 0.6, m_1(B) = 0.1, m_1(A \cup B) = 0.3, \\ m_2(A) &= 0.5, m_2(B) = 0.3, m_2(A \cup B) = 0.2, \\ m_3(A) &= 0.4, m_3(B) = 0.1, m_3(A \cup B) = 0.5, \\ m_4(A \cup B) &= 1 \quad (m_4 \text{ is the vacuous BBA}). \end{aligned}$$

The BBAs  $m_1$ ,  $m_2$  and  $m_3$  are the same as in Example 2, and the BBA  $m_4$  is the vacuous BBA. We have already shown that  $\text{PCR5}(m_1, m_2, m_3) \neq \text{PCR5}(m_1, m_2, m_3, m_4)$  even if  $m_4$  is the vacuous BBA, and

$$\begin{cases} m_{1,2,3,4}^{\text{PCR5}}(A) \approx 0.654604, \\ m_{1,2,3,4}^{\text{PCR5}}(B) \approx 0.144825, \\ m_{1,2,3,4}^{\text{PCR5}}(A \cup B) \approx 0.200571. \end{cases}$$

Similarly,  $\text{PCR6}(m_1, m_2, m_3) \neq \text{PCR6}(m_1, m_2, m_3, m_4)$ , and

$$\begin{cases} m_{1,2,3,4}^{\text{PCR6}}(A) \approx 0.647113, \\ m_{1,2,3,4}^{\text{PCR6}}(B) \approx 0.128342, \\ m_{1,2,3,4}^{\text{PCR6}}(A \cup B) \approx 0.224545. \end{cases}$$

Applying the  $\text{PCR5}^+$  formula (25), and the  $\text{PCR6}^+$  formula (26) we will obtain  $m_{1,2,3}^{\text{PCR5}^+}(\emptyset) = m_{1,2,3,4}^{\text{PCR6}^+}(\emptyset) = 0$  and

$$\begin{cases} m_{1,2,3,4}^{\text{PCR5}^+}(A) \approx 0.768631, \\ m_{1,2,3,4}^{\text{PCR5}^+}(B) \approx 0.201369, \\ m_{1,2,3,4}^{\text{PCR5}^+}(A \cup B) = 0.03, \end{cases} \quad \text{and} \quad \begin{cases} m_{1,2,3,4}^{\text{PCR6}^+}(A) \approx 0.788847, \\ m_{1,2,3,4}^{\text{PCR6}^+}(B) \approx 0.181153, \\ m_{1,2,3,4}^{\text{PCR6}^+}(A \cup B) = 0.03. \end{cases}$$

One has  $\text{PCR5}^+(m_1, m_2, m_3, m_4) = \text{PCR5}^+(m_1, m_2, m_3)$  and also  $\text{PCR6}^+(m_1, m_2, m_3, m_4) = \text{PCR6}^+(m_1, m_2, m_3)$  because with the improved proportional redistribution of  $\text{PCR5}^+$  and  $\text{PCR6}^+$  rules the vacuous BBA has always a neutral impact in the fusion result, which is what we intuitively expect.

**Example 5** (revisited): we consider  $\Theta = \{A, B, C, D, E\}$ , and the following three BBAs

$$\begin{cases} m_1(A \cup B) = 0.70, \\ m_1(C \cup D) = 0.06, \\ m_1(A \cup B \cup C \cup D) = 0.15, \\ m_1(E) = 0.09, \end{cases}$$

and

$$\begin{cases} m_2(A \cup B) = 0.06, \\ m_2(C \cup D) = 0.50, \\ m_2(A \cup B \cup C \cup D) = 0.04, \\ m_2(E) = 0.40, \end{cases}$$

and

$$\begin{cases} m_3(B) = 0.01, \\ m_3(A \cup B \cup C \cup D \cup E) = 0.99. \end{cases}$$

Note that the BBA  $m_3$  is not equal to the vacuous BBA but it is very close to the vacuous BBA because  $m_3(\Theta)$  is close to one.

If we consider the fusion of only the two first BBAs  $m_1$  and  $m_2$ , we have  $\text{PCR6}(m_1, m_2) = \text{PCR6}^+(m_1, m_2) = \text{PCR5}(m_1, m_2) = \text{PCR5}^+(m_1, m_2)$  because all these rules coincide when combining two BBAs.

$$\begin{cases} m_{1,2}^{\text{PCR6}}(A \cup B) \approx 0.465309, \\ m_{1,2}^{\text{PCR6}}(C \cup D) \approx 0.296299, \\ m_{1,2}^{\text{PCR6}}(A \cup B \cup C \cup D) \approx 0.023471, \\ m_{1,2}^{\text{PCR6}}(E) \approx 0.214921. \end{cases}$$

If we make the  $\text{PCR5}$ ,  $\text{PCR5}^+$ ,  $\text{PCR6}$  and  $\text{PCR6}^+$  fusion of these three BBAs altogether we obtain now different results which is normal, because for  $S > 2$  one has  $\text{PCR5}^+(m_1, \dots, m_S) \neq \text{PCR5}(m_1, \dots, m_S)$  and  $\text{PCR6}^+(m_1, \dots, m_S) \neq \text{PCR6}(m_1, \dots, m_S)$  in general. So, in this example 5 we get results shown in Tables I and II.

Focal Elements	$m_{1,2,3}^{\text{PCR5}}(\cdot)$	$m_{1,2,3}^{\text{PCR5}^+}(\cdot)$
$B$	0.001103	0.001107
$A \cup B$	0.286107	0.464483
$C \cup D$	0.203385	0.296186
$A \cup B \cup C \cup D$	0.012203	0.023408
$E$	0.115966	0.214816
$A \cup B \cup C \cup D \cup E$	0.381236	0

Table I

$A \cup B \cup C \cup D \cup E$	0.381236	0

Table II  
EXAMPLE 5: RESULTS OF  $\text{PCR6}^+$  VERSUS  $\text{PCR6}$ .

These values highlight the great ignorance of the results proposed by  $\text{PCR5}$  and  $\text{PCR6}$  when the third (almost vacuous) source of information is taken into account. Indeed,  $m_{1,2,3}^{\text{PCR5}}(\Theta) = m_{1,2,3}^{\text{PCR6}}(\Theta)$  is the greatest mass among the set of hypotheses, whereas the results proposed with  $\text{PCR5}^+$  and  $\text{PCR6}^+$  combination rules discard the ignorant information and propose results closer to those obtained by merging two sources. Indeed, the largest mass is allocated to  $A \cup B$ .

The next examples 6 to 12 are very simple examples involving only categorical BBAs so that only one conflicting product (equals to one) needs to be redistributed based on  $\text{PCR5}$ ,  $\text{PCR6}$ ,  $\text{PCR5}^+$  and  $\text{PCR6}^+$  rules. These examples offer the possibility to the reader to do the derivations manually for making a verification of our results.

**Example 6** (revisited): we consider  $\Theta = \{A, B, C, D\}$ , and the following categorical BBAs  $m_1(A) = 1$ ,  $m_2(B \cup C) = 1$ ,  $m_3(A \cup C) = 1$ ,  $m_4(B \cup C) = 1$ ,  $m_5(A \cup B \cup C) = 1$  and  $m_6(A \cup B \cup C \cup D) = 1$ . If we make the  $\text{PCR5}$ ,  $\text{PCR5}^+$ ,  $\text{PCR6}$  and  $\text{PCR6}^+$  fusion of these six BBAs altogether we obtain results given in Tables III and IV.

In this example, we have only one conflicting product  $\pi_1(\emptyset)$  to redistribute which is given by

$$\pi_1(\emptyset) = m_1(A)m_2(B \cup C)m_3(A \cup C)m_4(B \cup C) \cdot m_5(A \cup B \cup C)m_6(A \cup B \cup C \cup D).$$

Because  $\kappa_1(A \cup B \cup C) = 0$  and  $\kappa_1(A \cup B \cup C \cup D) = 0$ , these two disjunctions are discarded and more mass is committed

Focal Elements	$m_{1,2,3,4,5,6}^{\text{PCR5}}(\cdot)$	$m_{1,2,3,4,5,6}^{\text{PCR5}^+}(\cdot)$
$A$	1/5	1/3

$A$	1/6	1/4
$A \cup C$	1/6	1/4
$B \cup C$	1/3	1/2
$A \cup B \cup C$	1/6	0
$A \cup B \cup C \cup D$	1/6	0

Table IV  
EXAMPLE 6: RESULTS OF PCR6<sup>+</sup> VERSUS PCR6.

to  $A$ ,  $A \cup C$  and  $B \cup C$  with PCR5<sup>+</sup> and PCR6<sup>+</sup> rules. There is more mass allocated to  $B \cup C$  with PCR6<sup>+</sup> and PCR6 than with PCR5<sup>+</sup> and PCR5 because two sources of information support this hypothesis.

**Example 7 (revisited):** we consider  $\Theta = \{A, B, C, D, E\}$ , and the following seven categorical BBAs  $m_1(A \cup E) = 1$ ,  $m_2(B \cup C \cup E) = 1$ ,  $m_3(A \cup C \cup E) = 1$ ,  $m_4(B \cup C \cup E) = 1$ ,  $m_5(A \cup B \cup C \cup E) = 1$ ,  $m_6(A \cup B \cup C \cup D \cup E) = 1$ , and  $m_7(A) = 1$ . If we make the PCR5, PCR5<sup>+</sup>, PCR6 and PCR6<sup>+</sup> fusion of these seven BBAs altogether we obtain results given in Tables V and VI.

Focal Elements	$m_{1,2,3,4,5,6,7}^{\text{PCR5}}(\cdot)$	$m_{1,2,3,4,5,6,7}^{\text{PCR5}^+}(\cdot)$
$A$	1/6	1/4
$A \cup E$	1/6	1/4
$A \cup C \cup E$	1/6	1/4
$B \cup C \cup E$	1/6	1/4
$A \cup B \cup C \cup E$	1/6	0
$A \cup B \cup C \cup D \cup E$	1/6	0

Table V  
EXAMPLE 7: RESULTS OF PCR5<sup>+</sup> VERSUS PCR5.

Focal Elements	$m_{1,2,3,4,5,6,7}^{\text{PCR6}}(\cdot)$	$m_{1,2,3,4,5,6,7}^{\text{PCR6}^+}(\cdot)$
$A$	1/7	1/5
$A \cup E$	1/7	1/5
$A \cup C \cup E$	1/7	1/5
$B \cup C \cup E$	2/7	2/5
$A \cup B \cup C \cup E$	1/7	0
$A \cup B \cup C \cup D \cup E$	1/7	0

Table VI  
EXAMPLE 7: RESULTS OF PCR6<sup>+</sup> VERSUS PCR6.

In this example 7, we have only one conflicting product  $\pi_1(\emptyset)$  to redistribute which is given by

$$\begin{aligned} \pi_1(\emptyset) = & m_1(A \cup E)m_2(B \cup C \cup E)m_3(A \cup C \cup E) \\ & \cdot m_4(B \cup C \cup E)m_5(A \cup B \cup C \cup E) \\ & \cdot m_6(A \cup B \cup C \cup D \cup E)m_7(A). \end{aligned}$$

Because  $\kappa_1(A \cup B \cup C \cup E) = 0$  and  $\kappa_1(A \cup B \cup C \cup D \cup E) = 0$ , these two disjunctions are discarded and more mass is committed to  $A$ ,  $A \cup E$ ,  $A \cup C \cup E$  and  $B \cup C \cup E$  with PCR5<sup>+</sup> and PCR6<sup>+</sup> rules. There is more mass allocated to  $B \cup C \cup E$  with PCR6<sup>+</sup> and PCR6 than with PCR5<sup>+</sup> and PCR5 because two sources of information support this hypothesis.

**Example 8 (revisited):** we consider  $\Theta = \{A, B, C, D\}$ , and the following categorical BBAs  $m_1(A) = 1$ ,  $m_2(B \cup C) = 1$ ,  $m_3(A \cup C) = 1$ ,  $m_4(B \cup C) = 1$  and  $m_5(A \cup B \cup C \cup D) = 1$ . If we make the PCR5, PCR5<sup>+</sup>, PCR6 and PCR6<sup>+</sup> fusion of these seven BBAs altogether we obtain results given in Tables VII and VIII.

Focal Elements	$m_{1,2,3,4,5}^{\text{PCR5}}(\cdot)$	$m_{1,2,3,4,5}^{\text{PCR5}^+}(\cdot)$
$A$	1/4	1/3
$A \cup C$	1/4	1/3
$B \cup C$	1/4	1/3
$A \cup B \cup C \cup D$	1/4	0

Table VII

$A$	1/5	1/4
$A \cup C$	1/5	1/4
$B \cup C$	2/5	1/2
$A \cup B \cup C \cup D$	1/5	0

Table VIII  
EXAMPLE 8: RESULTS OF PCR6<sup>+</sup> VERSUS PCR6.

Because  $\kappa_1(A \cup B \cup C \cup D) = 0$ , this disjunction is discarded and more mass is committed to  $A$ ,  $A \cup C$  and  $B \cup C$  with PCR5<sup>+</sup> and PCR6<sup>+</sup> rules. There is more mass allocated to  $B \cup C$  with PCR6<sup>+</sup> and PCR6 than with PCR5<sup>+</sup> and PCR5 because two sources of information support this hypothesis.

**Example 9 (revisited):** we consider  $\Theta = \{A, B, C, D\}$ , and the following seven categorical BBAs  $m_1(A) = 1$ ,  $m_2(B \cup C) = 1$ ,  $m_3(A \cup C) = 1$ ,  $m_4(B \cup C) = 1$ ,  $m_5(A \cup B \cup C \cup D) = 1$ ,  $m_6(A \cup B \cup C) = 1$ , and  $m_7(A \cup B \cup C) = 1$ . If we make the PCR5, PCR5<sup>+</sup>, PCR6 and PCR6<sup>+</sup> fusion of these seven BBAs altogether we obtain results given in Tables IX and X.

Focal Elements	$m_{1,2,3,4,5,6,7}^{\text{PCR5}}(\cdot)$	$m_{1,2,3,4,5,6,7}^{\text{PCR5}^+}(\cdot)$
$A$	1/5	1/3
$A \cup C$	1/5	1/3
$B \cup C$	1/5	1/3
$A \cup B \cup C$	1/5	0
$A \cup B \cup C \cup D$	1/5	0

Table IX  
EXAMPLE 9: RESULTS OF PCR5<sup>+</sup> VERSUS PCR5.

Because  $\kappa_1(A \cup B \cup C \cup D) = 0$  and  $\kappa_1(A \cup B \cup C) = 0$ , these disjunctions are discarded and more mass is committed

Focal Elements	$m_{1,2,3,4,5,6,7}^{\text{PCR6}}(\cdot)$	$m_{1,2,3,4,5,6,7}^{\text{PCR6}^+}(\cdot)$
$A$	1/7	1/4
$A \cup C$	1/7	1/4
$B \cup C$	2/7	1/2
$A \cup B \cup C$	2/7	0
$A \cup B \cup C \cup D$	1/7	0

Table X

 EXAMPLE 9: RESULTS OF PCR6<sup>+</sup> VERSUS PCR6.

to  $A$ ,  $A \cup C$  and  $B \cup C$  with PCR5<sup>+</sup> and PCR6<sup>+</sup> rules. There is more mass allocated to  $B \cup C$  with PCR6<sup>+</sup> and PCR6 than with PCR5<sup>+</sup> and PCR5 because two sources of information support this hypothesis. Similarly, more mass is allocated to  $(A \cup B \cup C)$  with PCR6 than PCR5 since two sources of information support this hypothesis.

**Example 10** (revisited): we consider  $\Theta = \{A, B, C\}$ , and the following three categorical BBAs  $m_1(A) = 1$ ,  $m_2(B \cup C) = 1$ , and  $m_3(A \cup C) = 1$ . We have only one conflicting product  $\pi_1(\emptyset) = m_1(A)m_2(B \cup C)m_3(A \cup C) = 1$  to redistribute, and for this example we have  $\kappa_1(A) = 1$ ,  $\kappa_1(A \cup C) = 1$  and  $\kappa_1(B \cup C) = 1$  which means that all focal elements  $A$ ,  $A \cup C$  and  $B \cup C$  must be kept, and they must receive a mass through the proportional redistribution principle. Hence in this example we have  $m_{1,2,3}^{\text{PCR5}} = m_{1,2,3}^{\text{PCR6}} = m_{1,2,3}^{\text{PCR5}^+} = m_{1,2,3}^{\text{PCR6}^+}$ , and the combined masses are evenly distributed as shown in the Table XI.

Focal Elements	$m_{1,2,3}^{\text{PCR5}}(\cdot)$	$m_{1,2,3}^{\text{PCR5}^+}(\cdot)$	$m_{1,2,3}^{\text{PCR6}}(\cdot)$	$m_{1,2,3}^{\text{PCR6}^+}(\cdot)$
$A$	1/3	1/3	1/3	1/3
$A \cup C$	1/3	1/3	1/3	1/3
$B \cup C$	1/3	1/3	1/3	1/3

Table XI

 EXAMPLE 10: RESULTS OF PCR5, PCR5<sup>+</sup>, PCR6, PCR6<sup>+</sup>.

**Example 11** (revisited): we consider  $\Theta = \{A, B, C\}$ , and the following four categorical BBAs  $m_1(A) = 1$ ,  $m_2(B \cup C) = 1$ ,  $m_3(A \cup C) = 1$ , and  $m_4(A \cup B) = 1$ . Because we have only one conflicting product  $\pi_1(\emptyset) = m_1(A)m_2(B \cup C)m_3(A \cup C)m_4(A \cup B) = 1$  and  $\kappa_1(A) = 1$ ,  $\kappa_1(A \cup B) = 1$ ,  $\kappa_1(A \cup C) = 1$  and  $\kappa_1(B \cup C) = 1$  no hypothesis is discarded in the proportional conflict redistribution, and we get  $m_{1,2,3,4}^{\text{PCR5}} = m_{1,2,3,4}^{\text{PCR6}} = m_{1,2,3,4}^{\text{PCR5}^+} = m_{1,2,3,4}^{\text{PCR6}^+}$  with the merged masses being evenly distributed, that is  $m_{1,2,3,4}^{\text{PCR5}}(A) = 1/4$ ,  $m_{1,2,3,4}^{\text{PCR5}}(A \cup B) = 1/4$ ,  $m_{1,2,3,4}^{\text{PCR5}}(A \cup C) = 1/4$ , and  $m_{1,2,3,4}^{\text{PCR5}}(B \cup C) = 1/4$ .

**Example 12** (revisited): we consider  $\Theta = \{A, B, C\}$ , and the following three categorical BBAs  $m_1(A \cup B \cup C) = 1$ ,  $m_2(A) = 1$ ,  $m_3(B \cup C) = 1$ . If we make the PCR5 fusion, and the PCR5<sup>+</sup> fusion, of these three BBAs altogether we obtain results given in Table XII. Because  $\pi_1(\emptyset) = m_1(A \cup B \cup C)m_2(A)m_3(B \cup C)$ , we get  $\kappa_1(A \cup B \cup C) = 0$ ,  $\kappa_1(A) = 1$  and  $\kappa_1(B \cup C) = 1$  based on (23). Therefore, using the PCR5<sup>+</sup> combination rule, we get a

Focal Elements	$m_{1,2,3}^{\text{PCR5}}(\cdot)$	$m_{1,2,3}^{\text{PCR5}^+}(\cdot)$
$A$	1/3	1/2
$B \cup C$	1/3	1/2
$A \cup B \cup C$	1/3	0

Table XII

 EXAMPLE 12: RESULTS OF PCR5, PCR5<sup>+</sup>.

redistribution of the conflicting mass  $\pi_1(\emptyset) = 1$  only between  $A$  and  $B \cup C$ . In this example we have  $m_{1,2,3}^{\text{PCR5}} = m_{1,2,3}^{\text{PCR6}}$ , and  $m_{1,2,3}^{\text{PCR5}^+} = m_{1,2,3,4}^{\text{PCR6}^+}$  because no mass is allocated on the same hypothesis by two different sources.

**Example 13** (revisited): we consider  $\Theta = \{A, B, C, D\}$ , and the three following BBAs

$$\begin{aligned} m_1(A \cup B) &= 0.8, m_1(C \cup D) = 0.2, \\ m_2(A \cup B) &= 0.4, m_2(C \cup D) = 0.6, \\ m_3(B) &= 0.1, m_3(A \cup B \cup C \cup D) = 0.9. \end{aligned}$$

If we make the PCR5, PCR5<sup>+</sup>, PCR6 and PCR6<sup>+</sup> fusion of these seven BBAs altogether we obtain results given in Tables XIII and XIV.

Focal Elements	$m_{1,2,3}^{\text{PCR5}}(\cdot)$	$m_{1,2,3}^{\text{PCR5}^+}(\cdot)$
$B$	0.041797	0.041797
$A \cup B$	0.487632	0.613029
$C \cup D$	0.258327	0.345174
$A \cup B \cup C \cup D$	0.212244	0

Table XIII

Focal Elements	$m_{1,2,3}^{\text{PCR6}}(\cdot)$	$m_{1,2,3}^{\text{PCR6}^+}(\cdot)$
$B$	0.037676	0.037676
$A \cup B$	0.487632	0.613029
$C \cup D$	0.262448	0.349295
$A \cup B \cup C \cup D$	0.212244	0

Table XIV

 EXAMPLE 13: RESULTS OF PCR6<sup>+</sup> VERSUS PCR6.

Because  $\kappa_j(\Theta) = 0$  for any conflicting product  $\pi_j(\emptyset)$  involving  $\Theta$ , this hypothesis is discarded in the redistribution of  $\pi_4(\emptyset)$  and of  $\pi_6(\emptyset)$  (see Example 13 in subsection VI-A for details), and therefore more mass is redistributed to  $A \cup B$  and  $C \cup D$  with PCR5<sup>+</sup> and PCR6<sup>+</sup> rules. No more mass is committed to  $B$  with PCR5<sup>+</sup> and PCR6<sup>+</sup> respectively in comparison with PCR5 and PCR6. This is because  $B$  is not implied in any partial conflict with  $\Theta$  (cf. subsection VI-A for details).

## VIII. CONCLUSION

In this paper, after having demonstrated the flawed behavior of PCR5 and PCR6 rules of combination for  $S > 2$  BBAs (including possibly vacuous BBAs), we proposed improvements to correct these behaviors. A computation of a binary keeping-index has been detailed which makes it possible to discard

ignorant information sources for the calculation of each partial conflict. This binary keeping-index has been integrated into the original formulations of PCR5 and PCR6 in order to ensure the neutrality property of the vacuous BBA and to propose two new combination rules for a number of sources greater than 2: PCR5<sup>+</sup> and PCR6<sup>+</sup> rules. The interest of such combination rules could prove to be particularly important in an application case identifying many ignorant sources of information. In such a scenario, the preponderant ignorance of a certain number of sources will no longer obscure a more precise characterization provided by other sources. These new rules of combination have been already applied to risk analysis issues for geophysical and geotechnical data fusion in order to reinforce the levee protection characterizations [48].

#### APPENDIX 1: PROOF OF THE LEMMA 1

We prove that:  $m_{1,2,\dots,S,S+1}^{\text{Conj}}(A) = m_{1,2,\dots,S}^{\text{Conj}}(A)$ , for any  $A \in 2^\Theta \setminus \{\emptyset\}$ , where  $m_{S+1}(\Theta) = 1$  is the vacuous BBA  $m_v$ . The set of focal elements of  $m_{S+1}(\cdot)$  is  $\mathcal{F}(m_{S+1}) = \{\Theta\}$ , therefore  $\mathcal{F}_{m_{S+1}} = 1$  and  $X_{j_{S+1}} = \Theta$ . Based on the formula (6) written for  $S+1$  BBAs, we have

$$\begin{aligned} m_{1,2,\dots,S,S+1}^{\text{Conj}}(A) &= \sum_{\substack{\mathbf{X}_j \in \mathcal{F}(m_1, \dots, m_S, m_{S+1}) \\ X_{j_1} \cap \dots \cap X_{j_S} \cap X_{j_{S+1}} = A}} \pi_j(X_{j_1} \cap \dots \cap X_{j_S} \cap X_{j_{S+1}}) \\ &= \sum_{\substack{\mathbf{X}_j \in \mathcal{F}(m_1, \dots, m_S, m_{S+1}) \\ X_{j_1} \cap \dots \cap X_{j_S} \cap \Theta = A}} \prod_{i=1}^{S+1} m_i(X_{j_i}) \quad (27) \end{aligned}$$

Because  $X_{j_{S+1}} = \Theta$  is constant and  $m_{S+1}(X_{j_{S+1}}) = m_{S+1}(\Theta) = 1$ , one has

$$\prod_{i=1}^{S+1} m_i(X_{j_i}) = \left( \prod_{i=1}^S m_i(X_{j_i}) \right) \cdot m_{S+1}(\Theta) = \prod_{i=1}^S m_i(X_{j_i})$$

and  $X_{j_1} \cap \dots \cap X_{j_S} \cap X_{j_{S+1}} = X_{j_1} \cap \dots \cap X_{j_S} \cap \Theta = X_{j_1} \cap \dots \cap X_{j_S}$ . Therefore the formula (27) becomes

$$\begin{aligned} m_{1,2,\dots,S,S+1}^{\text{Conj}}(A) &= \sum_{\substack{\mathbf{X}_j \in \mathcal{F}(m_1, \dots, m_S, m_{S+1}) \\ X_{j_1} \cap \dots \cap X_{j_S} \cap \Theta = A}} \prod_{i=1}^{S+1} m_i(X_{j_i}) \\ &= \sum_{\substack{\mathbf{X}_j \in \mathcal{F}(m_1, \dots, m_S) \\ X_{j_1} \cap \dots \cap X_{j_S} = A}} \prod_{i=1}^S m_i(X_{j_i}) \\ &= m_{1,2,\dots,S}^{\text{Conj}}(A) \end{aligned}$$

which completes the proof of the Lemma 1.

#### APPENDIX 2: PROOF OF THE THEOREM

We prove that  $\text{PCR5}^+(m_1, \dots, m_S, m_{S+1}) = \text{PCR5}^+(m_1, \dots, m_S)$ , or equivalently that  $m_{1,2,\dots,S,S+1}^{\text{PCR5}^+}(A) = m_{1,2,\dots,S}^{\text{PCR5}^+}(A)$  for any  $A \in 2^\Theta \setminus \{\emptyset\}$ , where  $m_{S+1}(X_{j_{S+1}}) = m_{S+1}(\Theta) = 1$  is the vacuous BBA. It is worth noting that  $m_{1,2,\dots,S,S+1}^{\text{Conj}}(A) = m_{1,2,\dots,S}^{\text{Conj}}(A)$  for any  $A \in 2^\Theta \setminus \{\emptyset\}$  because the vacuous BBA  $m_{S+1}(\cdot)$  is the

neutral element of the conjunctive rule (see Lemma 1). It is important to note that when considering  $A = \Theta$ , we have always  $m_{1,2,\dots,S,S+1}^{\text{PCR5}^+}(\Theta) = m_{1,2,\dots,S,S+1}^{\text{Conj}}(\Theta) = m_{1,2,\dots,S}^{\text{Conj}}(\Theta) = m_{1,2,\dots,S}^{\text{PCR5}^+}(\Theta)$  because the binary keeping-index of  $\Theta$  is always equal to zero (see remark 1), i.e.  $\kappa_j(\Theta) = 0$ . Therefore all the redistribution terms to  $\Theta$  in PCR5<sup>+</sup> (and in PCR6<sup>+</sup>) formula are equal to zero when  $A = \Theta$ . So, we just have to consider  $A \neq \Theta$  to make the proof.

Because  $m_{S+1}(\cdot)$  is the vacuous BBA, its set of focal elements is  $\mathcal{F}(m_{S+1}) = \{\Theta\}$  and it contains only one focal element, i.e.  $|\mathcal{F}(m_{S+1})| = 1$ . Therefore

$$\begin{aligned} \mathcal{F} &= |\mathcal{F}(m_1)| \cdot |\mathcal{F}(m_2)| \cdot \dots \cdot |\mathcal{F}(m_S)| \cdot |\mathcal{F}(m_{S+1})| \quad (28) \\ &= |\mathcal{F}(m_1)| \cdot |\mathcal{F}(m_2)| \cdot \dots \cdot |\mathcal{F}(m_S)| \quad (29) \end{aligned}$$

This means that the number of conflicting products  $\pi_j(\emptyset)$  associated to the  $S+1$ -tuple  $\mathbf{X}_j = (X_{j_1}, \dots, X_{j_S}, \Theta) \in \mathcal{F}(m_1, \dots, m_S, m_{S+1})$  is equal to the number of conflicting products  $\pi_j(\emptyset)$  associated to  $S$ -tuple  $\mathbf{X}_j = (X_{j_1}, \dots, X_{j_S}) \in \mathcal{F}(m_1, \dots, m_S)$ . Moreover, we always have

$$\prod_{i=1}^{S+1} m_i(X_{j_i}) = \left( \prod_{i=1}^S m_i(X_{j_i}) \right) \cdot m_{S+1}(\Theta) = \prod_{i=1}^S m_i(X_{j_i})$$

Hence, we always have

$$\pi_j(X_{j_1} \cap \dots \cap X_{j_S} \cap \Theta = \emptyset) = \pi_j(X_{j_1} \cap \dots \cap X_{j_S} = \emptyset)$$

because  $X_{j_1} \cap \dots \cap X_{j_S} \cap \Theta = X_{j_1} \cap \dots \cap X_{j_S}$ .

Based on the formula (25) written for  $S+1$  BBAs, we have

$$\begin{aligned} m_{1,2,\dots,S,S+1}^{\text{PCR5}^+}(A) &= m_{1,2,\dots,S,S+1}^{\text{Conj}}(A) \\ &+ \sum_{j \in \{1, \dots, \mathcal{F}\} | A \in \mathbf{X}_j \wedge \pi_j(\emptyset)} \left[ \left( \kappa_j(A) \prod_{i \in \{1, \dots, S+1\} | X_{j_i} = A} m_i(X_{j_i}) \right) \right. \\ &\left. \cdot \frac{\pi_j(X_{j_1} \cap \dots \cap X_{j_S} \cap \Theta = \emptyset)}{\sum_{X \in \mathbf{X}_j} \left( \kappa_j(X) \prod_{i \in \{1, \dots, S+1\} | X_{j_i} = X} m_i(X_{j_i}) \right)} \right] \quad (30) \end{aligned}$$

where  $\mathcal{F}$  is given by (28).

Because  $X_{j_{S+1}} = \Theta$  and because we consider  $A \neq \Theta$ , we have always

$$\prod_{i \in \{1, \dots, S+1\} | X_{j_i} = A} m_i(X_{j_i}) = \prod_{i \in \{1, \dots, S\} | X_{j_i} = A} m_i(X_{j_i})$$

Whether  $X \in \mathbf{X}_j = (X_{j_1}, \dots, X_{j_S})$  or  $X \in \mathbf{X}_j = (X_{j_1}, \dots, X_{j_S}, \Theta)$  the value of  $\kappa_j(X)$  is the same since the additional binary *containing indicator*  $\delta_j(X, \Theta)$  entering in the product of the computation of the binary *keeping-index* is always equal to 1 and does not modify  $\kappa_j(X)$  value, and of course when  $X = A$ . Because the binary *keeping-index* entering in the numerator and denominator of formula (30) removes the factor  $m_{S+1}(\Theta)$  from all products it belongs to

(since  $\Theta$  includes all elements of the product it belongs to), the formula (30) reduces to the following formula

$$\begin{aligned}
 m_{1,2,\dots,S,S+1}^{\text{PCR5}^+}(A) &= m_{1,2,\dots,S}^{\text{Conj}}(A) \\
 + \sum_{j \in \{1,\dots,S\} | A \in \mathbf{X}_j \wedge \pi_j(\emptyset)} & \left[ \left( \kappa_j(A) \prod_{i \in \{1,\dots,S\} | X_{j_i} = A} m_i(X_{j_i}) \right) \right. \\
 \cdot \frac{\pi_j(X_{j_1} \cap \dots \cap X_{j_S} = \emptyset)}{\sum_{X \in \mathbf{X}_j} \left( \kappa_j(X) \prod_{i \in \{1,\dots,S\} | X_{j_i} = X} m_i(X_{j_i}) \right)} & \left. \right] \\
 &= m_{1,2,\dots,S}^{\text{PCR5}^+}(A) \quad (31)
 \end{aligned}$$

where  $\mathbf{X}_j$  represents now the  $S$ -tuple  $(X_{j_1}, \dots, X_{j_S})$ , and  $\pi_j(\emptyset) = \pi_j(X_{j_1} \cap \dots \cap X_{j_S} = \emptyset)$ .

So, we have proved  $\text{PCR5}^+(m_1, \dots, m_S, m_{S+1}) = \text{PCR5}^+(m_1, \dots, m_S)$  when  $m_{S+1}$  is the vacuous BBA. Similarly, we can prove that  $\text{PCR6}^+(m_1, \dots, m_S, m_{S+1}) = \text{PCR6}^+(m_1, \dots, m_S)$  when  $m_{S+1}$  is the vacuous BBA. This completes the proof of the theorem.

### APPENDIX 3: CODES OF $\text{PCR5}^+$ AND $\text{PCR6}^+$ RULES

For convenience, we provide two basic Matlab<sup>TM</sup> codes for  $\text{PCR5}^+$  and  $\text{PCR6}^+$  for the fusion of  $S \geq 2$  BBAs for working with  $2^\Theta$ , i.e. working with Shafer's model. No input verification of input is done in the routines. It is assumed that the input matrix BBA is correct, both in dimension and in content. The derivation of all possible combinations is done with `combvec(Combinations,vec)` instruction which is included in the Matlab<sup>TM</sup> neural networks toolbox. This `combvec` call can be a very time-consuming task when the size of the problem increases. A standalone version of these codes is also available upon request to the authors. The  $j$ -th column of the BBA input matrix corresponds to the (vertical) BBA vector  $m_j(\cdot)$  associated with the  $j$ -th source  $s_j$ . Each element of a BBA matrix is in  $[0, 1]$  and the sum of each column must be one. If  $N$  is the cardinality of the frame  $\Theta$  and if  $S$  is the number of sources, then the size of the BBA input matrix is  $((2^N) - 1) \times S$ . Each column of the BBA matrix must use the classical binary encoding of elements. For example, if  $\Theta = \{A, B, C\}$ , then we encode the elements of  $2^\Theta \setminus \{\emptyset\}$  by the binary sequence  $001 \equiv A$ ,  $010 \equiv B$ ,  $011 \equiv A \cup B$ ,  $\dots$ ,  $111 \equiv A \cup B \cup C$ . The mass of empty set is not included in the BBA vector because it is always set to zero.

These codes can be used and shared for free for research purposes only. Commercial uses of these codes, or adaptation of them in any programming language, is not allowed without written agreement of the authors. These codes are provided by the copyright holders "as is" and any express or implied warranties are disclaimed. The copyright holder will not be liable for any direct, or indirect damages of the use of these codes. The authors would appreciate any feedback in the use of these codes, and publication using these codes should cite this paper in agreement for their use.

**Abstract**—This short paper presents the explicit formulas of the PCR5 and PCR6 rules of combination for three Bayesian basic belief assignments. We give a simple example to show how to apply them.

**Keywords:** information fusion, belief functions, PCR5, PCR6, PCR5<sup>+</sup>, PCR6<sup>+</sup> fusion rules..

## I. INTRODUCTION

Among many existing rules of combination of Basic Belief Assignments (BBAs), the conjunctive rule, Dempster-Shafer (DS) rule [1], and the Proportional Conflict Redistribution rules no 5 (PCR5) and no 6 (PCR6) are the most used rules of combination. While the conjunctive rule makes it possible to combine information between different sources of information represented by belief functions by estimating the level of existing conflict, DS rule [1], [2] proposes a distribution of this conflict on the hypotheses characterized by the sources of information. The normalization carried out by the DS rule may however be considered counter-intuitive especially when the level of conflict between the sources of information is high [3], [4], but also in some situations where the level of conflict between sources is low as shown in [5] showing a dictatorial behavior of DS rule. The Proportional Conflict Redistribution rules (PCR5 [6] and PCR6 [7], [8]) have been proposed to circumvent the problem of the DS rule to make a more judicious management of the conflict. Moreover, improved versions of PCR5 and PCR6 rules preserving the neutrality of a vacuous (i.e. a totally ignorant) source of evidence in the PCR process have been recently proposed in [9]. They are denoted by PCR5<sup>+</sup> and PCR6<sup>+</sup> fusion rules. We will not present in detail these improved rules here because we address the problem of fusing only Bayesian BBAs and for these particular type of BBAs PCR5<sup>+</sup> coincides with PCR5, and PCR6<sup>+</sup> coincides with PCR6 because there is no mass committed to partial and to total ignorances (i.e. to all possible disjunctions) involved in partial conflict to redistribute thanks to PCR5 and PCR6 principles.

After a brief recall of basics of belief functions in section II, we present the general formulas for PCR5 and PCR6 fusion rules in section III based on [9], with a simple example in section IV. In section V we present the direct formulas for PCR5 and PCR6 rules for three general (i.e. non-Bayesian)

BBAs, and the direct formulas for PCR5 and PCR6 rules for three Bayesian BBAs in section VI. A simple example of application of these formulas for the fusion of three Bayesian BBAs defined on the simple frame of discernment with two elements is given in section VII with complete calculation for convenience. Section VIII concludes this paper.

## II. BASICS OF BELIEF FUNCTIONS

We consider a given finite set  $\Theta$  of  $n > 1$  distinct elements  $\Theta = \{\theta_1, \theta_2, \dots, \theta_n\}$  corresponding to the frame of discernment (FoD) of the fusion problem, or the decision-making problem, under concern. All elements of  $\Theta$  are mutually exclusive<sup>1</sup> and each element is an elementary choice of the potential decision to take. The power set of  $\Theta$  is the set of all subsets of  $\Theta$  (including empty set  $\emptyset$  and  $\Theta$ ) and it is usually denoted  $2^\Theta$  because its cardinality equals  $2^{|\Theta|}$ . A Basic Belief Assignment (BBA) given by a source of evidence is defined by Shafer [1] in his Mathematical Theory of Evidence (known also as Dempster-Shafer Theory, or DST) as  $m(\cdot) : 2^\Theta \rightarrow [0, 1]$  satisfying

$$\begin{cases} m(\emptyset) = 0, \\ \sum_{A \in 2^\Theta} m(A) = 1, \end{cases} \quad (1)$$

where  $m(A)$  is the mass of belief exactly committed to  $A$ , what we usually call the mass of  $A$ . A BBA is said proper (or normal) if it satisfies Shafer's definition (1). The subset  $A \subseteq \Theta$  is called a Focal Element (FE) of the BBA  $m(\cdot)$  if and only if  $m(A) > 0$ . The empty set is not a focal element of a BBA because  $m(\emptyset) = 0$  according to definition (1). The set of all focal elements of a BBA  $m(\cdot)$  is denoted  $\mathcal{F}(m)$ . Its mathematical definition is  $\mathcal{F}(m) = \{X \in 2^\Theta | m(X) > 0\}$ . The cardinality  $|\mathcal{F}(m)|$  of the set  $\mathcal{F}(m)$  is denoted  $\mathcal{F}_m$ . The order of focal elements of  $\mathcal{F}(m)$  does not matter and all the focal elements are different. The set  $\mathcal{F}(m)$  of focal elements of  $m(\cdot)$  has at least one focal element, and at most  $2^{|\Theta|} - 1$  focal elements.

<sup>1</sup>This standard assumption is called *Shafer's model of FoD* in DSMT (Dezert-Smarandache Theory) framework [10].

Belief and plausibility functions are respectively defined from  $m(\cdot)$  by [1]

$$Bel(A) = \sum_{X \in 2^\Theta | X \subseteq A} m(X), \quad (2)$$

and

$$Pl(A) = \sum_{X \in 2^\Theta | A \cap X \neq \emptyset} m(X) = 1 - Bel(\bar{A}). \quad (3)$$

where  $\bar{A}$  represents the complement of  $A$  in  $\Theta$ .

$Bel(A)$  and  $Pl(A)$  are usually interpreted respectively as lower and upper bounds of an unknown (subjective) probability measure  $P(A)$  [11], [12]. The functions  $m(\cdot)$ ,  $Bel(\cdot)$  and  $Pl(\cdot)$  are one-to-one. A belief function  $Bel(\cdot)$  is *Bayesian* if all Bel's focal elements are singletons [1] (Theorem 2.8 p. 45). In this case,  $m(X) = Bel(X)$  for any (singleton) focal element  $X$ , and  $m(\cdot)$  is called a *Bayesian BBA*. Corresponding  $Bel(\cdot)$  function is equal to  $Pl(\cdot)$  and these functions can be interpreted as a same (possibly subjective) probability measure  $P(\cdot)$ . The vacuous BBA (VBBA for short) representing a totally ignorant source is defined as  $m_v(\Theta) = 1$ .

### III. PCR5 AND PCR6 RULES OF COMBINATION

#### A. The PCR5 rule of combination

The PCR5 rule [6] transfers the conflicting mass to all the elements involved in this conflict and proportionally to their individual masses, so that a more sophisticate and specific distribution is done with the PCR5 fusion process with respect to other existing rules (including Dempster's rule). The PCR5 rule is presented in details (with justification and examples) in [10], Vol. 2 and Vol. 3.

A simple formulation of the general expression of the PCR5 fusion of  $S > 2$  basic belief assignments is obtained by redistributing each conflicting product defined by

$$\pi_j(\emptyset) = \pi_j(X_{j_1} \cap \dots \cap X_{j_S} = \emptyset) = \prod_{i=1}^S m_i(X_{j_i}), \quad (4)$$

to some elements of the power set of the FoD that are involved in the conflict  $X_{j_1} \cap \dots \cap X_{j_S} = \emptyset$ . Each  $\pi_j(\emptyset)$  is redistributed proportionally to elements involved in this conflict based on the PCR5 redistribution principle. When an element  $A \in 2^\Theta$  is not involved in a conflicting product  $\pi_j(\emptyset)$ , i.e.  $A \notin \mathbf{X}_j$ , the conflicting product  $\pi_j(\emptyset)$  is not redistributed to  $A$ . If an element  $A$  is involved in the conflict  $X_{j_1} \cap \dots \cap X_{j_S} = \emptyset$ , i.e.  $A \in \mathbf{X}_j$  and  $\pi_j(\emptyset)$  occur, then the proportional redistribution of  $\pi_j(\emptyset)$  to  $A$  is given by

$$x_j(A) \triangleq \left( \prod_{i \in \{1, \dots, S\} | X_{j_i} = A} m_i(X_{j_i}) \right) \cdot \frac{\pi_j(\emptyset)}{\sum_{X \in \mathbf{X}_j} \left( \prod_{i \in \{1, \dots, S\} | X_{j_i} = X} m_i(X_{j_i}) \right)}, \quad (5)$$

where  $A \in \mathbf{X}_j$  means that at least one component of the  $S$ -tuple  $\mathbf{X}_j$  equals  $A$ , with

$$\mathbf{X}_j \triangleq (X_{j_1}, X_{j_2}, \dots, X_{j_S}) \in \mathcal{F}(m_1, \dots, m_S),$$

where

- $j_1 \in \{1, 2, \dots, \mathcal{F}_{m_1}\}$ ,
- $j_2 \in \{1, 2, \dots, \mathcal{F}_{m_2}\}$ ,
- $\dots$ ,
- $j_S \in \{1, 2, \dots, \mathcal{F}_{m_S}\}$ ,
- and

$$\mathcal{F}(m_1, \dots, m_S) \triangleq \mathcal{F}(m_1) \times \mathcal{F}(m_2) \times \dots \times \mathcal{F}(m_S),$$

$$\mathcal{F} \triangleq |\mathcal{F}(m_1, \dots, m_S)| = \prod_{i=1}^S |\mathcal{F}(m_i)| = \prod_{i=1}^S \mathcal{F}_{m_i}.$$

The element  $X_{j_i}$  is the focal element of  $m_i(\cdot)$  that makes the  $i$ -th component of the  $j$ -th  $S$ -tuple  $\mathbf{X}_j$ .

The mass of  $A$  obtained by the PCR5 rule is

$$m_{1,2,\dots,S}^{\text{PCR5}}(A) = m_{1,2,\dots,S}^{\text{Conj}}(A) + \sum_{j \in \{1, \dots, \mathcal{F}\} | A \in \mathbf{X}_j \wedge \pi_j(\emptyset)} x_j(A), \quad (6)$$

where  $A \in \mathbf{X}_j \wedge \pi_j(\emptyset)$  is a shorthand notation meaning that at least one component of the  $S$ -tuple  $\mathbf{X}_j$  equals  $A$  and the components of  $\mathbf{X}_j$  are conflicting, i.e.  $X_{j_1} \cap \dots \cap X_{j_S} = \emptyset$ .

The general PCR5 formula can be expressed as  $m_{1,2,\dots,S}^{\text{PCR5}}(\emptyset) = 0$ , and for  $A \in 2^\Theta \setminus \{\emptyset\}$  by

$$m_{1,2,\dots,S}^{\text{PCR5}}(A) = m_{1,2,\dots,S}^{\text{Conj}}(A) + \sum_{j \in \{1, \dots, \mathcal{F}\} | A \in \mathbf{X}_j \wedge \pi_j(\emptyset)} \left[ \left( \prod_{i \in \{1, \dots, S\} | X_{j_i} = A} m_i(X_{j_i}) \right) \cdot \frac{\pi_j(\emptyset)}{\sum_{X \in \mathbf{X}_j} \left( \prod_{i \in \{1, \dots, S\} | X_{j_i} = X} m_i(X_{j_i}) \right)} \right]. \quad (7)$$

where  $m_{1,2,\dots,S}^{\text{Conj}}(A)$  is the mass of  $A$  obtained by the conjunctive rule, that is

$$\begin{aligned} m_{1,2,\dots,S}^{\text{Conj}}(A) &= \sum_{\substack{\mathbf{X}_j \in \mathcal{F}(m_1, \dots, m_S) \\ X_{j_1} \cap \dots \cap X_{j_S} = A}} \pi_j(X_{j_1} \cap X_{j_2} \cap \dots \cap X_{j_S}) \\ &= \sum_{\substack{\mathbf{X}_j \in \mathcal{F}(m_1, \dots, m_S) \\ X_{j_1} \cap \dots \cap X_{j_S} = A}} \prod_{i=1}^S m_i(X_{j_i}). \end{aligned} \quad (8)$$

The total conflicting mass between the  $S$  sources of evidence, denoted  $m_{1,2,\dots,S}^{\text{Conj}}(\emptyset)$ , is nothing but the sum of all existing conflicting mass products, that is

$$\begin{aligned} m_{1,2,\dots,S}^{\text{Conj}}(\emptyset) &= \sum_{\substack{\mathbf{X}_j \in \mathcal{F}(m_1, \dots, m_S) \\ X_{j_1} \cap \dots \cap X_{j_S} = \emptyset}} \pi_j(X_{j_1} \cap X_{j_2} \cap \dots \cap X_{j_S}) \\ &= 1 - \sum_{A \in 2^\Theta \setminus \{\emptyset\}} m_{1,2,\dots,S}^{\text{Conj}}(A). \end{aligned} \quad (9)$$

Note that the combined BBA  $m_{1,2,\dots,S}^{\text{Conj}}(\cdot)$  given in (8) is not a proper BBA because it does not satisfy Shafer's definition (1). In general the  $S$  sources of evidence to combine do not fully agree, and we have consequently  $m_{1,2,\dots,S}^{\text{Conj}}(\emptyset) > 0$ .

### B. The PCR6 rule of combination

A variant of PCR5 rule, called PCR6 rule, has been proposed by Martin and Osswald in [7], [8] for combining  $S > 2$  sources. The difference between PCR5 and PCR6 lies in the way the proportional conflict redistribution is done as soon as three (or more) sources are involved in the fusion. The PCR6 fusion of  $S > 2$  BBAs is obtained by  $m_{1,2,\dots,S}^{\text{PCR6}}(\emptyset) = 0$ , and for all  $A \in 2^\Theta \setminus \{\emptyset\}$  by<sup>2</sup>

$$m_{1,2,\dots,S}^{\text{PCR6}}(A) = m_{1,2,\dots,S}^{\text{Conj}}(A) + \sum_{j \in \{1,\dots,S\} | A \in \mathbf{X}_j \wedge \pi_j(\emptyset)} \left[ \left( \sum_{i \in \{1,\dots,S\} | X_{j_i} = A} m_i(X_{j_i}) \right) \cdot \frac{\pi_j(\emptyset)}{\sum_{X \in \mathbf{X}_j} \left( \sum_{i \in \{1,\dots,S\} | X_{j_i} = X} m_i(X_{j_i}) \right)} \right]. \quad (10)$$

The difference between the general PCR5 and PCR6 formulas is that the PCR5 proportional redistribution involves the products  $\prod_{i \in \{1,\dots,S\} | X_{j_i} = A} m_i(X_{j_i})$  of multiple same focal elements  $A$  (if any) in the conflict, whereas the PCR6 conflict redistribution principle works with their sum  $\sum_{i \in \{1,\dots,S\} | X_{j_i} = A} m_i(X_{j_i})$  instead.

PCR6 coincides with PCR5 when one combines two sources of evidence.

### IV. SIMPLE EXAMPLE OF PCR5 AND PCR6 FUSION RULES

Here we provide a simple example showing the difference of the results between PCR5 and PCR6 rules. This example has been already presented in [9]. For convenience, all numerical values have been rounded to six decimal places when necessary.

**Example 1:** We consider the simplest FoD  $\Theta = \{A, B\}$ , and the three following BBAs

$$\begin{aligned} m_1(A) &= 0.6, m_1(B) = 0.1, m_1(A \cup B) = 0.3, \\ m_2(A) &= 0.5, m_2(B) = 0.3, m_2(A \cup B) = 0.2, \\ m_3(A) &= 0.4, m_3(B) = 0.1, m_3(A \cup B) = 0.5. \end{aligned}$$

Because  $\mathcal{F}_{m_1} = |\mathcal{F}(m_1)| = 3$ ,  $\mathcal{F}_{m_2} = |\mathcal{F}(m_2)| = 3$  and  $\mathcal{F}_{m_3} = |\mathcal{F}(m_3)| = 3$ , we have  $\mathcal{F} = \mathcal{F}_{m_1} \cdot \mathcal{F}_{m_2} \cdot \mathcal{F}_{m_3} = 27$  non-zero products to consider. Fifteen products are non-conflicting and enter in the calculation of  $m_{1,2,3}^{\text{Conj}}(A)$ ,  $m_{1,2,3}^{\text{Conj}}(B)$  and  $m_{1,2,3}^{\text{Conj}}(A \cup B)$ , and twelve products are conflicting products

that need to be proportionally redistributed. The conjunctive combination of these three BBAs is

$$\begin{aligned} m_{1,2,3}^{\text{Conj}}(A) &= m_1(A)m_2(A)m_3(A) \\ &\quad + m_1(A)m_2(A)m_3(A \cup B) \\ &\quad + m_1(A)m_2(A \cup B)m_3(A) \\ &\quad + m_1(A \cup B)m_2(A)m_3(A) \\ &\quad + m_1(A)m_2(A \cup B)m_3(A \cup B) \\ &\quad + m_1(A \cup B)m_2(A)m_3(A \cup B) \\ &\quad + m_1(A \cup B)m_2(A \cup B)m_3(A) = 0.5370, \\ m_{1,2,3}^{\text{Conj}}(B) &= m_1(B)m_2(B)m_3(B) \\ &\quad + m_1(B)m_2(B)m_3(A \cup B) \\ &\quad + m_1(B)m_2(A \cup B)m_3(B) \\ &\quad + m_1(A \cup B)m_2(B)m_3(B) \\ &\quad + m_1(B)m_2(A \cup B)m_3(A \cup B) \\ &\quad + m_1(A \cup B)m_2(B)m_3(A \cup B) \\ &\quad + m_1(A \cup B)m_2(A \cup B)m_3(B) = 0.0900, \\ m_{1,2,3}^{\text{Conj}}(A \cup B) &= m_1(A \cup B)m_2(A \cup B)m_3(A \cup B) \\ &= 0.3 \cdot 0.2 \cdot 0.5 = 0.0300, \end{aligned}$$

and the total conflict between these three BBAs is given by

$$m_{1,2,3}^{\text{Conj}}(\emptyset) = 1 - m_{1,2,3}^{\text{Conj}}(A) - m_{1,2,3}^{\text{Conj}}(B) - m_{1,2,3}^{\text{Conj}}(A \cup B) = 0.3430.$$

In this example we have twelve partial conflicts, noted  $\pi_j(\emptyset)$  ( $j = 1, \dots, 12$ ), which correspond to the following products

$$\begin{aligned} \pi_1(\emptyset) &= m_1(A)m_2(A)m_3(B) = 0.0300, \\ \pi_2(\emptyset) &= m_1(A)m_2(B)m_3(A) = 0.0720, \\ \pi_3(\emptyset) &= m_1(B)m_2(A)m_3(A) = 0.0200, \\ \pi_4(\emptyset) &= m_1(B)m_2(B)m_3(A) = 0.0120, \\ \pi_5(\emptyset) &= m_1(B)m_2(A)m_3(B) = 0.0050, \\ \pi_6(\emptyset) &= m_1(A)m_2(B)m_3(B) = 0.0180, \\ \pi_7(\emptyset) &= m_1(A \cup B)m_2(A)m_3(B) = 0.0150, \\ \pi_8(\emptyset) &= m_1(A \cup B)m_2(B)m_3(A) = 0.0360, \\ \pi_9(\emptyset) &= m_1(B)m_2(A)m_3(A \cup B) = 0.0250, \\ \pi_{10}(\emptyset) &= m_1(A)m_2(B)m_3(A \cup B) = 0.0900, \\ \pi_{11}(\emptyset) &= m_1(A)m_2(A \cup B)m_3(B) = 0.0120, \\ \pi_{12}(\emptyset) &= m_1(B)m_2(A \cup B)m_3(A) = 0.0080. \end{aligned}$$

In applying the PCR5 formula (7), and the PCR6 formula (10) we obtain finally  $m_{1,2,3}^{\text{PCR5}}(\emptyset) = m_{1,2,3}^{\text{PCR6}}(\emptyset) = 0$ , and<sup>3</sup>

$$\begin{aligned} m_{1,2,3}^{\text{PCR5}}(A) &\approx 0.723281, \\ m_{1,2,3}^{\text{PCR5}}(B) &\approx 0.182460, \\ m_{1,2,3}^{\text{PCR5}}(A \cup B) &\approx 0.094259, \end{aligned}$$

and

$$\begin{aligned} m_{1,2,3}^{\text{PCR6}}(A) &\approx 0.743496, \\ m_{1,2,3}^{\text{PCR6}}(B) &\approx 0.162245, \\ m_{1,2,3}^{\text{PCR6}}(A \cup B) &\approx 0.094259. \end{aligned}$$

We see a difference between the BBAs  $m_{1,2,3}^{\text{PCR5}}$  and  $m_{1,2,3}^{\text{PCR6}}$  which is normal because the PCR principles are quite different.

<sup>2</sup>We wrote this PCR6 general formula in the style of PCR5 formula (7).

<sup>3</sup>The symbol  $\approx$  means "approximately equal to".

Using the PCR5 fusion rule the first partial conflicting mass  $\pi_1(\emptyset) = m_1(A)m_2(A)m_3(B) = 0.03$  is redistributed back to  $A$  and  $B$  proportionally to  $m_1(A)m_2(A)$  and to  $m_3(B)$  as follows

$$\frac{x_1(A)}{m_1(A)m_2(A)} = \frac{x_1(B)}{m_3(B)} = \frac{\pi_1(\emptyset)}{m_1(A)m_2(A) + m_3(B)},$$

whence

$$x_1(A) = \frac{m_1(A)m_2(A)\pi_1(\emptyset)}{m_1(A)m_2(A) + m_3(B)} = 0.0225,$$

$$x_1(B) = \frac{m_3(B)\pi_1(\emptyset)}{m_1(A)m_2(A) + m_3(B)} = 0.0075.$$

We can verify  $\pi_1(\emptyset) = x_1(A) + x_1(B) = 0.03$ .

Using the PCR6 fusion rule the first partial conflicting mass  $\pi_1(\emptyset) = 0.03$  is redistributed back to  $A$  and  $B$  proportionally to  $(m_1(A) + m_2(A))$  and to  $m_3(B)$ . So we get the following redistributions  $x_1(A) = 0.0275$  for  $A$  and  $x_1(B) = 0.0025$  for  $B$  because

$$\frac{x_1(A)}{m_1(A) + m_2(A)} = \frac{x_1(B)}{m_3(B)} = \frac{\pi_1(\emptyset)}{m_1(A) + m_2(A) + m_3(B)},$$

whence

$$x_1(A) = \frac{(m_1(A) + m_2(A))\pi_1(\emptyset)}{m_1(A) + m_2(A) + m_3(B)} = 0.0275,$$

$$x_1(B) = \frac{m_3(B)\pi_1(\emptyset)}{m_1(A) + m_2(A) + m_3(B)} = 0.0025.$$

We can verify  $\pi_1(\emptyset) = x_1(A) + x_1(B) = 0.03$ .

Note that for all the partial conflicts having no duplicate element involved in the conflicting product  $\pi_j(\emptyset)$  we make the same redistribution with PCR5 rule and with PCR6 rule. For instance, for  $\pi_7(\emptyset) = m_1(A \cup B)m_2(A)m_3(B) = 0.0150$  we get

$$\frac{x_7(A \cup B)}{m_1(A \cup B)} = \frac{x_7(A)}{m_2(A)} = \frac{x_7(B)}{m_3(B)}$$

$$= \frac{\pi_7(\emptyset)}{m_1(A \cup B) + m_2(A) + m_3(B)},$$

whence  $\pi_7(\emptyset) = x_7(A \cup B) + x_7(A) + x_7(B) = 0.0150$ , with

$$x_7(A \cup B) = \frac{m_1(A \cup B)\pi_7(\emptyset)}{m_1(A \cup B) + m_2(A) + m_3(B)} = 0.0050,$$

$$x_7(A) = \frac{m_2(A)\pi_7(\emptyset)}{m_1(A \cup B) + m_2(A) + m_3(B)} \approx 0.0083,$$

$$x_7(B) = \frac{m_3(B)\pi_7(\emptyset)}{m_1(A \cup B) + m_2(A) + m_3(B)} \approx 0.0017.$$

## V. PCR5 AND PCR6 RULES FOR THREE BBAS

The previous general formulas of PCR5 (7) and PCR6 (10) can be written more explicitly for the fusion of three BBAs

as follows (see [13] for details<sup>4</sup>) when working with a FoD  $\Theta$  with Shafer's model.

$$m_{1,2,3}^{\text{PCR5}}(A) = m_{1,2,3}^{\text{Conj}}(A)$$

$$+ \sum_{\substack{X, Y \in 2^\Theta \\ A \neq X, A \neq Y, X \neq Y \\ A \cap X \cap Y = \emptyset}} \left[ \frac{m_1(A)^2 m_2(X) m_3(Y)}{m_1(A) + m_2(X) + m_3(Y)} \right.$$

$$+ \frac{m_1(Y) m_2(A)^2 m_3(X)}{m_1(Y) + m_2(A) + m_3(X)}$$

$$+ \left. \frac{m_1(X) m_2(Y) m_3(A)^2}{m_1(X) + m_2(Y) + m_3(A)} \right]$$

$$+ \sum_{\substack{X \in 2^\Theta \\ A \cap X = \emptyset}} \left[ \frac{m_1(A)^2 m_2(X) m_3(X)}{m_1(A) + m_2(X) m_3(X)} \right.$$

$$+ \frac{m_1(X) m_2(A)^2 m_3(X)}{m_1(X) m_3(X) + m_2(A)}$$

$$+ \frac{m_1(X) m_2(X) m_3(A)^2}{m_1(X) m_2(X) + m_3(A)}$$

$$+ \sum_{\substack{X \in 2^\Theta \\ A \cap X = \emptyset}} \left[ \frac{m_1(A)^2 m_2(A)^2 m_3(X)}{m_1(A) m_2(A) + m_3(X)} \right.$$

$$+ \frac{m_1(X) m_2(A)^2 m_3(A)^2}{m_1(X) + m_2(A) m_3(A)}$$

$$+ \left. \frac{m_1(A)^2 m_2(X) m_3(A)^2}{m_1(A) m_3(A) + m_2(X)} \right]$$
(11)

and

$$m_{1,2,3}^{\text{PCR6}}(A) = m_{1,2,3}^{\text{Conj}}(A)$$

$$+ \sum_{\substack{X, Y \in 2^\Theta \\ A \neq X, A \neq Y, X \neq Y \\ A \cap X \cap Y = \emptyset}} \left[ \frac{m_1(A)^2 m_2(X) m_3(Y)}{m_1(A) + m_2(X) + m_3(Y)} \right.$$

$$+ \frac{m_1(Y) m_2(A)^2 m_3(X)}{m_1(Y) + m_2(A) + m_3(X)}$$

$$+ \left. \frac{m_1(X) m_2(Y) m_3(A)^2}{m_1(X) + m_2(Y) + m_3(A)} \right]$$

$$+ \sum_{\substack{X \in 2^\Theta \\ A \cap X = \emptyset}} \left[ \frac{m_1(A)^2 m_2(X) m_3(X)}{m_1(A) + m_2(X) + m_3(X)} \right.$$

$$+ \frac{m_1(X) m_2(A)^2 m_3(X)}{m_1(X) + m_2(A) + m_3(X)}$$

$$+ \frac{m_1(X) m_2(X) m_3(A)^2}{m_1(X) + m_2(X) + m_3(A)}$$

$$+ \sum_{\substack{X \in 2^\Theta \\ A \cap X = \emptyset}} \left[ \frac{(m_1(A) + m_2(A)) m_1(A) m_2(A) m_3(X)}{m_1(A) + m_2(A) + m_3(X)} \right.$$

$$+ \frac{(m_2(A) + m_3(A)) m_1(X) m_2(A) m_3(A)}{m_1(X) + m_2(A) + m_3(A)}$$

$$+ \left. \frac{(m_1(A) + m_3(A)) m_1(A) m_2(X) m_3(A)}{m_1(A) + m_2(X) + m_3(A)} \right]$$
(12)

It is worth mentioning that if some fractions involved in the formulas (11) and (12) have their denominators equal to zero,

<sup>4</sup>It is worth mentioning that PCR5 for three BBAs given in the section 2 of [13] is incorrect, and it must be replaced by formula (11) of this paper.

these fractions are just discarded. It can be easily verified on example 1 that PCR5 formula (11) gives the same result as with the formula (7), and that the PCR6 formula (12) gives the same result as with the formula (10).

## VI. PCR5 AND PCR6 RULES FOR THREE BAYESIAN BBAS

If we want to work with three Bayesian BBAs only, the focal elements of BBAs to combine are only singletons of the power set  $2^\Theta$ . In this particular case, the previous PCR5 and PCR6 formulas (11) and (12) can be simplified as

$$\begin{aligned}
 m_{1,2,3}^{\text{PCR5}}(A) &= m_1(A)m_2(A)m_3(A) \\
 &+ \sum_{\substack{X,Y \in \Theta \setminus \{A\} \\ X \neq Y}} \left[ \frac{m_1(A)^2 m_2(X) m_3(Y)}{m_1(A) + m_2(X) + m_3(Y)} \right. \\
 &\quad + \frac{m_1(Y) m_2(A)^2 m_3(X)}{m_1(Y) + m_2(A) + m_3(X)} \\
 &\quad \left. + \frac{m_1(X) m_2(Y) m_3(A)^2}{m_1(X) + m_2(Y) + m_3(A)} \right] \\
 &+ \sum_{X \in \Theta \setminus \{A\}} \left[ \frac{m_1(A)^2 m_2(X) m_3(X)}{m_1(A) + m_2(X) m_3(X)} \right. \\
 &\quad + \frac{m_1(X) m_2(A)^2 m_3(X)}{m_1(X) m_3(X) + m_2(A)} \\
 &\quad \left. + \frac{m_1(X) m_2(X) m_3(A)^2}{m_1(X) m_2(X) + m_3(A)} \right] \\
 &+ \sum_{X \in \Theta \setminus \{A\}} \left[ \frac{m_1(A)^2 m_2(A)^2 m_3(X)}{m_1(A) m_2(A) + m_3(X)} \right. \\
 &\quad + \frac{m_1(X) m_2(A)^2 m_3(A)^2}{m_1(X) + m_2(A) m_3(A)} \\
 &\quad \left. + \frac{m_1(A)^2 m_2(X) m_3(A)^2}{m_1(A) m_3(A) + m_2(X)} \right]
 \end{aligned} \tag{13}$$

$$\begin{aligned}
 m_{1,2,3}^{\text{PCR6}}(A) &= m_{1,2,3}^{\text{Conj}}(A) \\
 &+ \sum_{\substack{X,Y \in \Theta \setminus \{A\} \\ X \neq Y}} \left[ \frac{m_1(A)^2 m_2(X) m_3(Y)}{m_1(A) + m_2(X) + m_3(Y)} \right. \\
 &\quad + \frac{m_1(Y) m_2(A)^2 m_3(X)}{m_1(Y) + m_2(A) + m_3(X)} \\
 &\quad \left. + \frac{m_1(X) m_2(Y) m_3(A)^2}{m_1(X) + m_2(Y) + m_3(A)} \right] \\
 &+ \sum_{X \in \Theta \setminus \{A\}} \left[ \frac{m_1(A)^2 m_2(X) m_3(X)}{m_1(A) + m_2(X) + m_3(X)} \right. \\
 &\quad + \frac{m_1(X) m_2(A)^2 m_3(X)}{m_1(X) + m_3(X) + m_2(A)} \\
 &\quad \left. + \frac{m_1(X) m_2(X) m_3(A)^2}{m_1(X) + m_2(X) + m_3(A)} \right] \\
 &+ \sum_{X \in \Theta \setminus \{A\}} \left[ \frac{(m_1(A) + m_2(A)) m_1(A) m_2(A) m_3(X)}{m_1(A) + m_2(A) + m_3(X)} \right. \\
 &\quad + \frac{(m_1(A) + m_3(A)) m_1(A) m_2(X) m_3(A)}{m_1(A) + m_3(A) + m_2(X)} \\
 &\quad \left. + \frac{(m_2(A) + m_3(A)) m_1(X) m_2(A) m_3(A)}{m_1(X) + m_2(A) + m_3(A)} \right]
 \end{aligned} \tag{14}$$

In the formulas (13) and (14) the subset  $A$  is any singleton of  $2^\Theta$  (i.e. any element of  $\Theta$ ). For any non-singleton  $A$  of  $2^\Theta$  we have  $m_{1,2,3}^{\text{PCR5}}(A) = 0$  because the fusion of Bayesian BBAs by PCR5 and PCR6 always produces a Bayesian BBA. It is worth mentioning that if some fractions involved in the formulas (13) and (14) have their denominators equal to zero, these fractions are just discarded.

## VII. EXAMPLE OF PCR5 AND PCR6 FUSION OF THREE BAYESIAN BBAS

Here we provide a simple example showing the difference of the results between PCR5 and PCR6 rules for three Bayesian BBAs. For convenience, all numerical values have been rounded to six decimal places when necessary.

**Example 2:** We consider the simplest FoD  $\Theta = \{A, B\}$ , and the three following BBAs

$$\begin{aligned}
 m_1(A) &= 0.2, m_1(B) = 0.8, m_1(A \cup B) = 0, \\
 m_2(A) &= 0.1, m_2(B) = 0.9, m_2(A \cup B) = 0, \\
 m_3(A) &= 0.6, m_3(B) = 0.4, m_3(A \cup B) = 0.
 \end{aligned}$$

Because  $\mathcal{F}_{m_1} = |\mathcal{F}(m_1)| = 2$ ,  $\mathcal{F}_{m_2} = |\mathcal{F}(m_2)| = 2$  and  $\mathcal{F}_{m_3} = |\mathcal{F}(m_3)| = 2$ , we have  $\mathcal{F} = \mathcal{F}_{m_1} \cdot \mathcal{F}_{m_2} \cdot \mathcal{F}_{m_3} = 8$  non-zero products to consider. Two non-zero products are non-conflicting and enter in the calculation of  $m_{1,2,3}^{\text{Conj}}(A)$  and  $m_{1,2,3}^{\text{Conj}}(B)$ , and six non-zero products are conflicting products that need to be proportionally redistributed. The conjunctive combination of these three Bayesian BBAs is

$$\begin{aligned}
 m_{1,2,3}^{\text{Conj}}(A) &= m_1(A)m_2(A)m_3(A) = 0.012, \\
 m_{1,2,3}^{\text{Conj}}(B) &= m_1(B)m_2(B)m_3(B) = 0.288, \\
 m_{1,2,3}^{\text{Conj}}(A \cup B) &= m_1(A \cup B)m_2(A \cup B)m_3(A \cup B) = 0,
 \end{aligned}$$

and the total conflict between these three BBAs is

$$\begin{aligned}
 m_{1,2,3}^{\text{Conj}}(\emptyset) &= 1 - m_{1,2,3}^{\text{Conj}}(A) - m_{1,2,3}^{\text{Conj}}(B) - m_{1,2,3}^{\text{Conj}}(A \cup B) \\
 &= 0.70.
 \end{aligned}$$

In this example we have six partial conflicts, noted  $\pi_j(\emptyset)$  ( $j = 1, \dots, 6$ ), which are given by the following products

$$\begin{aligned}
 \pi_1(\emptyset) &= m_1(A)m_2(A)m_3(B) = 0.008, \\
 \pi_2(\emptyset) &= m_1(A)m_2(B)m_3(A) = 0.108, \\
 \pi_3(\emptyset) &= m_1(B)m_2(A)m_3(A) = 0.048, \\
 \pi_4(\emptyset) &= m_1(B)m_2(B)m_3(A) = 0.432, \\
 \pi_5(\emptyset) &= m_1(B)m_2(A)m_3(B) = 0.032, \\
 \pi_6(\emptyset) &= m_1(A)m_2(B)m_3(B) = 0.072.
 \end{aligned}$$

### A. PCR5 fusion of the three Bayesian BBAs of example 2

Using the general PCR5 fusion rule (7) with  $S = 3$  (i.e. 3 BBAs) we manage the the conflicting mass products as follows:

- Conflicting mass  $\pi_1(\emptyset) = m_1(A)m_2(A)m_3(B) = 0.008$  is redistributed back to  $A$  and  $B$  proportionally to  $m_1(A)m_2(A)$  and to  $m_3(B)$  as follows

$$\frac{x_1(A)}{m_1(A)m_2(A)} = \frac{x_1(B)}{m_3(B)} = \frac{\pi_1(\emptyset)}{m_1(A)m_2(A) + m_3(B)},$$

whence

$$x_1(A) = \frac{m_1(A)m_2(A)\pi_1(\emptyset)}{m_1(A)m_2(A) + m_3(B)} \approx 0.000381,$$

$$x_1(B) = \frac{m_3(B)\pi_1(\emptyset)}{m_1(A)m_2(A) + m_3(B)} \approx 0.007619.$$

We can verify  $\pi_1(\emptyset) = x_1(A) + x_1(B) = 0.008$ .

• Conflicting mass  $\pi_2(\emptyset) = m_1(A)m_2(B)m_3(A) = 0.108$  is redistributed back to  $A$  and  $B$  proportionally to  $m_1(A)m_3(A)$  and to  $m_2(B)$  as follows

$$\frac{x_2(A)}{m_1(A)m_3(A)} = \frac{x_2(B)}{m_2(B)} = \frac{\pi_2(\emptyset)}{m_1(A)m_3(A) + m_2(B)},$$

whence

$$x_2(A) = \frac{m_1(A)m_3(A)\pi_2(\emptyset)}{m_1(A)m_3(A) + m_2(B)} \approx 0.012706,$$

$$x_2(B) = \frac{m_2(B)\pi_2(\emptyset)}{m_1(A)m_3(A) + m_2(B)} \approx 0.095294.$$

• Conflicting mass  $\pi_3(\emptyset) = m_1(B)m_2(A)m_3(A) = 0.048$  is redistributed back to  $A$  and  $B$  proportionally to  $m_2(A)m_3(A)$  and to  $m_1(B)$  as follows

$$\frac{x_3(A)}{m_2(A)m_3(A)} = \frac{x_3(B)}{m_1(B)} = \frac{\pi_3(\emptyset)}{m_2(A)m_3(A) + m_1(B)},$$

whence

$$x_3(A) = \frac{m_2(A)m_3(A)\pi_3(\emptyset)}{m_2(A)m_3(A) + m_1(B)} \approx 0.003349,$$

$$x_3(B) = \frac{m_1(B)\pi_3(\emptyset)}{m_2(A)m_3(A) + m_1(B)} \approx 0.044651.$$

• Conflicting mass  $\pi_4(\emptyset) = m_1(B)m_2(B)m_3(A) = 0.432$  is redistributed back to  $A$  and  $B$  proportionally to  $m_3(A)$  and to  $m_1(B)m_2(B)$  as follows

$$\frac{x_4(A)}{m_3(A)} = \frac{x_4(B)}{m_1(B)m_2(B)} = \frac{\pi_4(\emptyset)}{m_3(A) + m_1(B)m_2(B)},$$

whence

$$x_4(A) = \frac{m_3(A)\pi_4(\emptyset)}{m_3(A) + m_1(B)m_2(B)} \approx 0.196364,$$

$$x_4(B) = \frac{m_1(B)m_2(B)\pi_4(\emptyset)}{m_3(A) + m_1(B)m_2(B)} \approx 0.235636.$$

• Conflicting mass  $\pi_5(\emptyset) = m_1(B)m_2(A)m_3(B) = 0.032$  is redistributed back to  $A$  and  $B$  proportionally to  $m_2(A)$  and to  $m_1(B)m_3(B)$  as follows

$$\frac{x_5(A)}{m_2(A)} = \frac{x_5(B)}{m_1(B)m_3(B)} = \frac{\pi_5(\emptyset)}{m_2(A) + m_1(B)m_3(B)},$$

whence

$$x_5(A) = \frac{m_2(A)\pi_5(\emptyset)}{m_2(A) + m_1(B)m_3(B)} \approx 0.007620,$$

$$x_5(B) = \frac{m_1(B)m_3(B)\pi_5(\emptyset)}{m_2(A) + m_1(B)m_3(B)} \approx 0.024380.$$

• Conflicting mass  $\pi_6(\emptyset) = m_1(A)m_2(B)m_3(B) = 0.072$  is redistributed back to  $A$  and  $B$  proportionally to  $m_1(A)$  and to  $m_2(B)m_3(B)$  as follows

$$\frac{x_6(A)}{m_1(A)} = \frac{x_6(B)}{m_2(B)m_3(B)} = \frac{\pi_6(\emptyset)}{m_1(A) + m_2(B)m_3(B)},$$

whence

$$x_6(A) = \frac{m_1(A)\pi_6(\emptyset)}{m_1(A) + m_2(B)m_3(B)} \approx 0.025714,$$

$$x_6(B) = \frac{m_2(B)m_3(B)\pi_6(\emptyset)}{m_1(A) + m_2(B)m_3(B)} \approx 0.046286.$$

Therefore in applying PCR5 formula we get

$$m_{1,2,3}^{\text{PCR5}}(A) = m_{1,2,3}^{\text{Conj}}(A) + x_1(A) + x_2(A) + x_3(A) \\ + x_4(A) + x_5(A) + x_6(A) \approx 0.258134,$$

$$m_{1,2,3}^{\text{PCR5}}(B) = m_{1,2,3}^{\text{Conj}}(B) + x_1(B) + x_2(B) + x_3(B) \\ + x_4(B) + x_5(B) + x_6(B) \approx 0.741866,$$

and because the result is a Bayesian BBA we have also

$$m_{1,2,3}^{\text{PCR5}}(A \cup B) = 0.$$

Now if we apply the PCR5 combination of the three Bayesian BBAs of example 2 using the direct formula (13), we have to work with  $\Theta = \{A, B\}$ . So, for the focal element  $A$  we must consider all  $X \in \Theta \setminus \{A\}$  in the second and third summations but  $\Theta \setminus \{A\} = \{B\}$ , hence  $X = B$  only. In the first summation there is no  $X, Y \in \Theta \setminus \{A\}$  such that  $X \neq Y$ , so the first summation does not exist for this example. For the focal element  $A$ , the formula (13) reduces to the simple expression

$$m_{1,2,3}^{\text{PCR5}}(A) = \underbrace{m_1(A)m_2(A)m_3(A)}_{m_{1,2,3}^{\text{Conj}}(A) = 0.012} \\ + \left[ \underbrace{\frac{m_1(A)^2 m_2(B)m_3(B)}{m_1(A) + m_2(B)m_3(B)}}_{x_6(A) \approx 0.025714} \right. \\ + \underbrace{\frac{m_1(B)m_2(A)^2 m_3(B)}{m_1(B)m_3(B) + m_2(A)}}_{x_5(A) \approx 0.007620} \\ + \left. \underbrace{\frac{m_1(B)m_2(B)m_3(A)^2}{m_1(B)m_2(B) + m_3(A)}}_{x_4(A) \approx 0.196364} \right] \\ + \left[ \underbrace{\frac{m_1(A)^2 m_2(A)^2 m_3(B)}{m_1(A)m_2(A) + m_3(B)}}_{x_1(A) \approx 0.000381} \right. \\ + \underbrace{\frac{m_1(A)^2 m_2(B)m_3(A)^2}{m_1(A)m_3(A) + m_2(B)}}_{x_2(A) \approx 0.012706} \\ + \left. \underbrace{\frac{m_1(B)m_2(A)^2 m_3(A)^2}{m_1(B) + m_2(A)m_3(A)}}_{x_3(A) \approx 0.003349} \right] \\ \approx 0.258134 \quad (15)$$

Similarly, for the example 2 and using the direct PCR5 formula (13) for three bayesian BBAs we have for the focal element  $B$

$$\begin{aligned}
 m_{1,2,3}^{\text{PCR5}}(B) &= \underbrace{m_1(B)m_2(B)m_3(B)}_{m_{1,2,3}^{\text{Conj}}(B)=0.288} \\
 &+ \left[ \underbrace{\frac{m_1(B)^2 m_2(A) m_3(A)}{m_1(B) + m_2(A) m_3(A)}}_{x_3(B) \approx 0.044651} \right. \\
 &\quad + \underbrace{\frac{m_1(A) m_2(B)^2 m_3(A)}{m_1(A) m_3(A) + m_2(B)}}_{x_2(B) \approx 0.095294} \\
 &\quad + \left. \underbrace{\frac{m_1(A) m_2(A) m_3(B)^2}{m_1(A) m_2(A) + m_3(B)}}_{x_1(B) \approx 0.007619} \right] \\
 &+ \left[ \underbrace{\frac{m_1(B)^2 m_2(B)^2 m_3(A)}{m_1(B) m_2(B) + m_3(A)}}_{x_4(B) \approx 0.235636} \right. \\
 &\quad + \underbrace{\frac{m_1(B)^2 m_2(A) m_3(B)^2}{m_1(B) m_3(B) + m_2(A)}}_{x_5(B) \approx 0.024380} \\
 &\quad + \left. \underbrace{\frac{m_1(A) m_2(B)^2 m_3(B)^2}{m_1(A) + m_2(B) m_3(B)}}_{x_6(B) \approx 0.046286} \right] \\
 &\approx 0.741866
 \end{aligned} \tag{16}$$

It is clear that the results obtained with the direct formula (13) are in agreement with those obtained by the general PCR5 formula (7) when  $S = 3$ .

### B. PCR6 fusion of the three Bayesian BBAs of example 2

Using the general PCR6 fusion rule (10) with  $S = 3$  (i.e. 3 BBAs) we manage the the conflicting mass products as follows:

- Conflicting mass  $\pi_1(\emptyset) = m_1(A)m_2(A)m_3(B) = 0.008$  is redistributed back to  $A$  and  $B$  proportionally to  $m_1(A) + m_2(A)$  and to  $m_3(B)$  as follows

$$\frac{x_1(A)}{m_1(A) + m_2(A)} = \frac{x_1(B)}{m_3(B)} = \frac{\pi_1(\emptyset)}{m_1(A) + m_2(A) + m_3(B)},$$

whence

$$\begin{aligned}
 x_1(A) &= \frac{(m_1(A) + m_2(A))\pi_1(\emptyset)}{m_1(A) + m_2(A) + m_3(B)} \approx 0.003429, \\
 x_1(B) &= \frac{m_3(B)\pi_1(\emptyset)}{m_1(A) + m_2(A) + m_3(B)} \approx 0.004571.
 \end{aligned}$$

We can verify  $\pi_1(\emptyset) = x_1(A) + x_1(B) = 0.008$ .

- Conflicting mass  $\pi_2(\emptyset) = m_1(A)m_2(B)m_3(A) = 0.108$  is redistributed back to  $A$  and  $B$  proportionally to  $m_1(A) + m_3(A)$  and to  $m_2(B)$  as follows

$$\frac{x_2(A)}{m_1(A) + m_3(A)} = \frac{x_2(B)}{m_2(B)} = \frac{\pi_2(\emptyset)}{m_1(A) + m_3(A) + m_2(B)},$$

whence

$$\begin{aligned}
 x_2(A) &= \frac{(m_1(A) + m_3(A))\pi_2(\emptyset)}{m_1(A) + m_3(A) + m_2(B)} \approx 0.050824, \\
 x_2(B) &= \frac{m_2(B)\pi_2(\emptyset)}{m_1(A) + m_3(A) + m_2(B)} \approx 0.057176.
 \end{aligned}$$

- Conflicting mass  $\pi_3(\emptyset) = m_1(B)m_2(A)m_3(A) = 0.048$  is redistributed back to  $A$  and  $B$  proportionally to  $m_2(A) + m_3(A)$  and to  $m_1(B)$  as follows

$$\frac{x_3(A)}{m_2(A) + m_3(A)} = \frac{x_3(B)}{m_1(B)} = \frac{\pi_3(\emptyset)}{m_2(A) + m_3(A) + m_1(B)},$$

whence

$$\begin{aligned}
 x_3(A) &= \frac{(m_2(A) + m_3(A))\pi_3(\emptyset)}{m_2(A) + m_3(A) + m_1(B)} \approx 0.022400, \\
 x_3(B) &= \frac{m_1(B)\pi_3(\emptyset)}{m_2(A) + m_3(A) + m_1(B)} \approx 0.025600.
 \end{aligned}$$

- Conflicting mass  $\pi_4(\emptyset) = m_1(B)m_2(B)m_3(A) = 0.432$  is redistributed back to  $A$  and  $B$  proportionally to  $m_3(A)$  and to  $m_1(B) + m_2(B)$  as follows

$$\frac{x_4(A)}{m_3(A)} = \frac{x_4(B)}{m_1(B) + m_2(B)} = \frac{\pi_4(\emptyset)}{m_3(A) + m_1(B) + m_2(B)},$$

whence

$$\begin{aligned}
 x_4(A) &= \frac{m_3(A)\pi_4(\emptyset)}{m_3(A) + m_1(B) + m_2(B)} \approx 0.112696, \\
 x_4(B) &= \frac{(m_1(B) + m_2(B))\pi_4(\emptyset)}{m_3(A) + m_1(B) + m_2(B)} \approx 0.319304.
 \end{aligned}$$

- Conflicting mass  $\pi_5(\emptyset) = m_1(B)m_2(A)m_3(B) = 0.032$  is redistributed back to  $A$  and  $B$  proportionally to  $m_2(A)$  and to  $m_1(B) + m_3(B)$  as follows

$$\frac{x_5(A)}{m_2(A)} = \frac{x_5(B)}{m_1(B) + m_3(B)} = \frac{\pi_5(\emptyset)}{m_2(A) + m_1(B) + m_3(B)},$$

whence

$$\begin{aligned}
 x_5(A) &= \frac{m_2(A)\pi_5(\emptyset)}{m_2(A) + m_1(B) + m_3(B)} \approx 0.002462, \\
 x_5(B) &= \frac{(m_1(B) + m_3(B))\pi_5(\emptyset)}{m_2(A) + m_1(B) + m_3(B)} \approx 0.029538.
 \end{aligned}$$

- Conflicting mass  $\pi_6(\emptyset) = m_1(A)m_2(B)m_3(B) = 0.072$  is redistributed back to  $A$  and  $B$  proportionally to  $m_1(A)$  and to  $m_2(B) + m_3(B)$  as follows

$$\frac{x_6(A)}{m_1(A)} = \frac{x_6(B)}{m_2(B) + m_3(B)} = \frac{\pi_6(\emptyset)}{m_1(A) + m_2(B) + m_3(B)},$$

whence

$$\begin{aligned}
 x_6(A) &= \frac{m_1(A)\pi_6(\emptyset)}{m_1(A) + m_2(B) + m_3(B)} \approx 0.009600, \\
 x_6(B) &= \frac{(m_2(B) + m_3(B))\pi_6(\emptyset)}{m_1(A) + m_2(B) + m_3(B)} \approx 0.062400.
 \end{aligned}$$

Therefore in applying PCR6 formula (10) with  $S = 3$  we get finally

$$\begin{aligned} m_{1,2,3}^{\text{PCR6}}(A) &= m_{1,2,3}^{\text{Conj}}(A) + x_1(A) + x_2(A) + x_3(A) \\ &\quad + x_4(A) + x_5(A) + x_6(A) \approx 0.213411, \\ m_{1,2,3}^{\text{PCR6}}(B) &= m_{1,2,3}^{\text{Conj}}(B) + x_1(B) + x_2(B) + x_3(B) \\ &\quad + x_4(B) + x_5(B) + x_6(B) \approx 0.786589, \end{aligned}$$

and because the result is a Bayesian BBA we have also

$$m_{1,2,3}^{\text{PCR6}}(A \cup B) = 0.$$

When using the direct formula (14) of PCR6 rule for the three bayesian BBAs of example 2 we obtain for the focal element  $A$

$$\begin{aligned} m_{1,2,3}^{\text{PCR6}}(A) &= \underbrace{m_1(A)m_2(A)m_3(A)}_{m_{1,2,3}^{\text{Conj}}(A)=0.012} \\ &+ \left[ \underbrace{\frac{m_1(A)^2m_2(B)m_3(B)}{m_1(A) + m_2(B) + m_3(B)}}_{x_6(A)\approx 0.009600} \right. \\ &\quad + \underbrace{\frac{m_1(B)m_2(A)^2m_3(B)}{m_1(B) + m_3(B) + m_2(A)}}_{x_5(A)\approx 0.002462} \\ &\quad \left. + \underbrace{\frac{m_1(B)m_2(B)m_3(A)^2}{m_1(B) + m_2(B) + m_3(A)}}_{x_4(A)\approx 0.112696} \right] \\ &+ \left[ \underbrace{\frac{(m_1(A) + m_2(A))m_1(A)m_2(A)m_3(B)}{m_1(A) + m_2(A) + m_3(B)}}_{x_1(A)\approx 0.003429} \right. \\ &\quad + \underbrace{\frac{(m_1(A) + m_3(A))m_1(A)m_2(B)m_3(A)}{m_1(A) + m_3(A) + m_2(B)}}_{x_2(A)\approx 0.050824} \\ &\quad \left. + \underbrace{\frac{(m_2(A) + m_3(A))m_1(B)m_2(A)m_3(A)}{m_1(B) + m_2(A) + m_3(A)}}_{x_3(A)\approx 0.022400} \right] \\ &\approx 0.213411 \end{aligned} \tag{17}$$

Similarly, for the example 2 and using the direct formula

(14) we have for the focal element  $B$

$$\begin{aligned} m_{1,2,3}^{\text{PCR6}}(B) &= \underbrace{m_1(B)m_2(B)m_3(B)}_{m_{1,2,3}^{\text{Conj}}(B)=0.288} \\ &+ \left[ \underbrace{\frac{m_1(B)^2m_2(A)m_3(A)}{m_1(B) + m_2(A) + m_3(A)}}_{x_3(B)\approx 0.025600} \right. \\ &\quad + \underbrace{\frac{m_1(A)m_2(B)^2m_3(A)}{m_1(A) + m_3(A) + m_2(B)}}_{x_2(B)\approx 0.057176} \\ &\quad \left. + \underbrace{\frac{m_1(A)m_2(A)m_3(B)^2}{m_1(A) + m_2(A) + m_3(B)}}_{x_1(B)\approx 0.004571} \right] \\ &+ \left[ \underbrace{\frac{(m_1(B) + m_2(B))m_1(B)m_2(B)m_3(A)}{m_1(B) + m_2(B) + m_3(A)}}_{x_4(B)\approx 0.319304} \right. \\ &\quad + \underbrace{\frac{(m_1(B) + m_3(B))m_1(B)m_2(A)m_3(B)}{m_1(B) + m_3(B) + m_2(A)}}_{x_5(B)\approx 0.029538} \\ &\quad \left. + \underbrace{\frac{(m_2(B) + m_3(B))m_1(A)m_2(B)m_3(B)}{m_1(A) + m_2(B) + m_3(B)}}_{x_6(B)\approx 0.062400} \right] \\ &\approx 0.786589 \end{aligned} \tag{18}$$

It is clear that the results obtained with the direct formula (14) are in agreement with those obtained by the general PCR6 formula (10) when  $S = 3$ .

## VIII. CONCLUSION

In this paper we have developed explicit formulas for the PCR5 and PCR6 fusion of three bayesian BBAs which work with any cardinality of the frame of discernment greater or equal to two. We have verified that our formulas are coherent with general PCR5 and PCR6 formulas. We have also provided the correct PCR5 formula for three BBAs which was erroneous in our 2010 original paper [13]. We hope that these formulas will be helpful for some users of belief functions working only with bayesian belief masses and with only three sources of evidence to combine because these direct formulas are much easier to implement than general PCR5 and PCR6 formulas.

**Abstract**—3D Building change detection has become a popular research topic along with the improvement of image quality and computer science. When only building changes are of interest, both the multi-temporal images and Digital Surface Models provide valuable but not comprehensive information in the change detection procedure. Therefore, in this paper, belief functions have been adopted for fusing information from these two sources. In the first step, two change indicators are proposed by focusing on building changes. Both indicators have been projected to a sigmoid curve, in which both the concordance and discordance indexes are considered. In order to fuse the concordance and discordance indexes and further fuse the two change indicators, two belief functions are considered. One is the original Dempster-Shafer Theory (DST), and the most recent one is Dezert-Smarandache Theory (DSMT). This paper shows how these belief-based frameworks can help in building change detection problem. Besides using different belief functions in obtaining the global BBAs, four decision-making criteria are tested to extract final building change masks. The results have been validated by compared to the manually extracted change reference mask.

**Keywords:** belief functions, DSMT, satellite imaging, building change detection.

## I. INTRODUCTION

Accurate and efficient detection of changes is of great importance for urban monitoring, which is also an important research field in remote sensing. Change detection methods on large scale land cover monitoring have been intensively studied and reviewed [1], [2]. Along with the ascending of image spectral and temporal resolution, the expectation on automatic change detection has progressively increased, not only on results accuracy, but also on the efficiency and robustness of the methods. Moreover, change detection for a specific target of interest, like buildings is becoming an important research topic. In small scale 2D change detection, which is performed based on only 2D multi-temporal spectral images, problems arise due to misdetections caused by irrelevant changes. The influence of these irrelevant changes is growing as higher resolution images showing more details. Therefore, in this paper, we will further work on satellite multispectral and stereo images, which provides both spectral and height change information.

Adopting satellite stereo imagery for 3D change detection is an exciting and challenging task. Benefiting from improved data quality and advanced computer vision technique, the quality of the generated Digital Surface Models (DSMs) has been largely improved and it is possible to detect changes even for small objects, like single buildings. On the other

side, the DSMs may still exhibit some outliers resulting in occlusions within the stereo/multi views. Several approaches have been proposed for DSM assisted change detection [3], [4], [5], [6]. According to our previous research results, the belief functions introduced in DST allow to work more efficiently and robustly in urban building change detection with very high resolution satellite images [7]. So far, only a basic DS fusion model has been proposed in [6] to define the Basic Belief Assignments (BBAs) thanks to a sigmoid curve considering only the concordance index. Improvement of this DS fusion model for BBAs construction is proposed in this paper to achieve better performance by considering both the concordance and discordance indexes. Since DSMT [8] has been developed in last years as an interesting alternative to DST to circumvent problems of Dempster-Shafer's (DS) rule of combination [9], we also investigate the possibility of using the Proportional Conflict Redistribution Rule #6 (PCR6) of DSMT in our application.

## II. BASICS OF BELIEF FUNCTIONS

Detailed presentations of DST and DSMT can be found in [8], [9] and [10]. Let  $\Theta$  be a frame of discernment of a problem under consideration.  $\Theta = \{\theta_1, \theta_2, \dots, \theta_N\}$  consists of a list of  $N$  exhaustive and mutually exclusive elements  $\theta_i$ ,  $i = 1, 2, \dots, N$ . Each  $\theta_i$  represents a possible state related to the problem we want to solve. The assumption of exhaustivity and mutual exclusivity of elements of  $\Theta$  is classically referred as *Shafer's model* of the frame  $\Theta$ . A BBA also called a belief mass function (or just a mass for short), is a mapping  $m(\cdot) : 2^\Theta \rightarrow [0, 1]$  from the power set<sup>1</sup> of  $\Theta$  denoted  $2^\Theta$  to  $[0, 1]$ , that verifies [10]:

$$m(\emptyset) = 0, \quad \text{and} \quad \sum_{X \in 2^\Theta} m(X) = 1; \quad (1)$$

$m(X)$  represents the mass of belief exactly committed to  $X$ . An element  $X \in 2^\Theta$  is called a focal element if and only if  $m(X) > 0$ . In DST, the combination (fusion) of several independent sources of evidences is done with Dempster-Shafer<sup>2</sup> (DS) rule of combination, assuming that the sources are not in total conflict<sup>3</sup>. DS combination of two independent BBAs  $m_1(\cdot)$  and  $m_2(\cdot)$ , denoted symbolically by  $DS(m_1, m_2)$ , is

<sup>1</sup>The power set is the set of all subsets of  $\Theta$ , empty set included.

<sup>2</sup>Although the rule has been proposed originally by Dempster, we call it Dempster-Shafer rule because it has been widely promoted by Shafer in DST.

<sup>3</sup>otherwise DS rule is mathematically not defined because of 0/0 indeterminacy.

defined by  $m^{DS}(\emptyset) = 0$ , and for all  $X \in 2^\Theta \setminus \{\emptyset\}$  by:

$$m^{DS}(X) = \frac{1}{1 - K^{DS}} \sum_{\substack{X_1, X_2 \in 2^\Theta \\ X_1 \cap X_2 = X}} m_1(X_1)m_2(X_2), \quad (2)$$

where the total degree of conflict  $K^{DS}$  is given by

$$K^{DS} \triangleq \sum_{\substack{X_1, X_2 \in 2^\Theta \\ X_1 \cap X_2 = \emptyset}} m_1(X_1)m_2(X_2). \quad (3)$$

A discussion on the validity of DS rule and its incompatibility with Bayes fusion rule for combining Bayesian BBAs can be found in [9], [11], [12]. To circumvent the problems of DS rule, Smarandache and Dezert (see [8], Vol. 2, Chap. 1), then Martin and Osswald (see [8], Vol. 2, Chap. 2) have developed in DSMT [8] two fusion rules called PCR5 and PCR6 based on the proportional conflict redistribution (PCR) principle which consists

- 1) to apply the conjunctive rule;
- 2) calculate the total or partial conflicting masses;
- 3) then redistribute the (total or partial) conflicting mass proportionally on non-empty sets according to the integrity constraints one has for the frame  $\Theta$ .

This PCR principle transfers the conflicting mass only to the elements involved in the conflict and proportionally to their individual masses, so that the specificity of the information is not degraded. Because the proportional transfer can be done in two different ways, this has yielded to two different fusion rules. It has been proved in [13] that only PCR6 rule is compatible with frequentist probability estimation, and that is why we recommend its use in the applications. PCR5 and PCR6 rules simplify greatly and coincide for the combination of two sources. In this case, the PCR6 combination is obtained by taking  $m^{PCR6}(\emptyset) = 0$ , and for all  $X \neq \emptyset$  in  $2^\Theta$  by

$$m^{PCR6}(X) = \sum_{\substack{X_1, X_2 \in 2^\Theta \\ X_1 \cap X_2 = X}} m_1(X_1)m_2(X_2) + \sum_{\substack{Y \in 2^\Theta \setminus \{X\} \\ X \cap Y = \emptyset}} \left[ \frac{m_1(X)^2 m_2(Y)}{m_1(X) + m_2(Y)} + \frac{m_2(X)^2 m_1(Y)}{m_2(X) + m_1(Y)} \right], \quad (4)$$

where all denominators in Eq. (4) are different from zero. If a denominator is zero, that fraction is discarded.

### III. BUILDING CHANGE DETECTION MODELS

#### A. Choice of the frame of discernment

We now use two sources (indicators) of evidences to solve our problem. As a preparation step, the indicators and focal elements have to be introduced. Two data sources are used for building change detection. One is the satellite images, which contain 2D spectral information. Here we use the Iteratively Reweighted Multivariate Alteration Detection (IRMAD) [14] to highlight changes from the spectral images. The other is the robust height difference which can be calculated from the two Digital Surface Models (DSMs) [6]. Detail of the DSM generation procedure and the characters of the DSMs quality have been described in [5]. As it has been explained in [6], we suppose that new, demolished or changed buildings

exhibit both height changes and spectral changes. The seasonal changes will only influence the spectral images. Therefore, for building change detection, we consider the following three classes (hypotheses) to define our frame of discernment satisfying Shafer's model:  $\Theta = \{\theta_1 \triangleq \text{Pixel} \in \text{BuildingChange}, \theta_2 \triangleq \text{Pixel} \in \text{OtherChange}, \theta_3 \triangleq \text{Pixel} \in \text{NoChange}\}$ .

#### B. Sigmoidal model for BBA construction

BBAs construction is a prerequisite for the combination of sources of evidence. In our previous works [6], the BBAs were built based on sigmoid curves related with the concordance index only. In this paper, we improve our model to construct the BBAs thanks to sigmoidal models for both concordance and discordance indexes following idea proposed in [15]. As explained in [6], the original sigmoid curve is defined as

$$f_{(\tau, T)}(x) = 0.99 / (1 + e^{-\frac{x-T}{\tau}}), \quad (5)$$

where  $x$  is the original value of each indicator. Two parameters  $T$  and  $\tau$  are used to control the symmetry point and the slope of the sigmoid function. The symmetry point indicates a certainty of 50%. The construction of BBAs is explained in [15] and adopted in this paper. In [15] these two parameters  $T$  and  $\tau$  are manually given to sigmoid curve. Here, the multi-level Otsu's thresholding method [16] is used to get symmetry points for both concordance index and discordance index. Otsu's algorithm defines that an image is composed of objects and background. A discriminant analysis is performed by minimizing the intra-class variance. When three classes are of interest, two threshold values are expected. Otsu's method can be extended to

$$\sigma_\omega^2(T_1, T_2) = \omega_1 \sigma_1^2(T_1, T_2) + \omega_2 \sigma_2^2(T_1, T_2) + \omega_3 \sigma_3^2(T_1, T_2). \quad (6)$$

The weights  $\omega_i$  are the probabilities obtained from the image histogram that are separated by the thresholds  $T_1$  and  $T_2$ .  $\sigma_i$  are the variances of the three classes.  $T_1$  and  $T_2$  can be used as the symmetry points of discordance and concordance index respectively. Thus, using height change index as example, the BBAs for discordance and concordance height change index are presented as  $a_{\Delta H}$  and  $b_{\Delta H}$

$$a_{\Delta H} = f_{\tau, T_1}(\Delta H), \quad \text{and} \quad b_{\Delta H} = f_{-\tau, T_2}(\Delta H). \quad (7)$$

The factor  $\tau$  is calculated with a sample value ( $\Delta H = 1$ ,  $a_{\Delta H} = 0.1$ ), which means 1 meter height change indicates 10% probability to be building changes. The BBAs for discordance and concordance image change index are built similarly. Differences appearing in 2D images give a concordance indication for all changes, which include the building changes and other changes ( $\theta_1 \cup \theta_2$ ). In this paper the changes from images are named  $\Delta Img$ .

#### C. BBAs construction using concordance and discordance

The BBAs related with the concordance and discordance indexes are combined to get the global BBA related to each source of evidence. These global BBAs will then be used as input for solving the change detection problem thanks to their combination. In the Tables I and II, we present the two ways of construction of the BBAs of the sources of evidence based either on DS or on PCR6 rules of combination for the height

TABLE I. BBA CONSTRUCTION FOR HEIGHT CHANGE INDICATOR  $\Delta H$ . [ $K_{\Delta H} = a_{\Delta H} b_{\Delta H}$ ]

Focal Elem.	$m_1(\cdot)$	$m'_1(\cdot)$	$m_1^{DS}(\cdot)$	$m_1^{PCR6}(\cdot)$
$\theta_1$	$a_{\Delta H}$	0	$\frac{a_{\Delta H}(1-b_{\Delta H})}{1-K_{\Delta H}}$	$a_{\Delta H}(1-b_{\Delta H}) + \frac{a_{\Delta H}K_{\Delta H}}{a_{\Delta H}+b_{\Delta H}}$
$\theta_2$	0	0	0	0
$\theta_3$	0	0	0	0
$\theta_1 \cup \theta_2$	0	0	0	0
$\theta_2 \cup \theta_3$	0	$b_{\Delta H}$	$\frac{(1-a_{\Delta H})b_{\Delta H}}{1-K_{\Delta H}}$	$(1-a_{\Delta H})b_{\Delta H} + \frac{b_{\Delta H}K_{\Delta H}}{a_{\Delta H}+b_{\Delta H}}$
$\theta_1 \cup \theta_2 \cup \theta_3$	$1-a_{\Delta H}$	$1-b_{\Delta H}$	$\frac{(1-a_{\Delta H})(1-b_{\Delta H})}{1-K_{\Delta H}}$	$(1-a_{\Delta H})(1-b_{\Delta H})$

 TABLE II. BBA CONSTRUCTION FOR IMAGE CHANGE INDICATOR  $\Delta Img$ . [ $K_{\Delta Img} = a_{\Delta Img} b_{\Delta Img}$ ]

Focal Elem.	$m_2(\cdot)$	$m'_2(\cdot)$	$m_2^{DS}(\cdot)$	$m_2^{PCR6}(\cdot)$
$\theta_1$	0	0	0	0
$\theta_2$	0	0	0	0
$\theta_3$	0	$b_{\Delta Img}$	$\frac{(1-a_{\Delta Img})b_{\Delta Img}}{1-K_{\Delta Img}}$	$(1-a_{\Delta Img})b_{\Delta Img} + \frac{b_{\Delta Img}K_{\Delta Img}}{a_{\Delta Img}+b_{\Delta Img}}$
$\theta_1 \cup \theta_2$	$a_{\Delta Img}$	0	$\frac{a_{\Delta Img}(1-b_{\Delta Img})}{1-K_{\Delta Img}}$	$a_{\Delta Img}(1-b_{\Delta Img}) + \frac{a_{\Delta Img}K_{\Delta Img}}{a_{\Delta Img}+b_{\Delta Img}}$
$\theta_2 \cup \theta_3$	0	0	0	0
$\theta_1 \cup \theta_2 \cup \theta_3$	$1-a_{\Delta Img}$	$1-b_{\Delta Img}$	$\frac{(1-a_{\Delta Img})(1-b_{\Delta Img})}{1-K_{\Delta Img}}$	$(1-a_{\Delta Img})(1-b_{\Delta Img})$

change indicator (i.e. the first source of evidence) and the image change indicator (i.e. the second source of evidence). In Table I,  $m_1(\cdot)$  and  $m'_1(\cdot)$  represent the concordance and discordance BBAs from  $\Delta H$ , whereas in Table II  $m_2(\cdot)$  and  $m'_2(\cdot)$  represent the concordance and discordance BBAs from images.

Here for comparison of the two belief functions, these two BBAs are fused with both DS and PCR6 fusion rules. The fusion rules for height change indicator and image change indicator are explained in Table I and Table II. In Table I, the  $m_1$  and  $m'_1$  represent the concordance and discordance BBAs from  $\Delta H$ . In Table II we use  $m_2$  and  $m'_2$  to represent the concordance and discordance BBAs from images.

#### D. BBAs combination for building change detection

From the previous step of BBAs modelings, each pixel will get two sets of BBAs to combine resulting from Table I and II. More precisely, we will have to combine either  $\{m_1^{DS}(\cdot), m'_1^{DS}(\cdot)\}$  if DS rule is preferred for the BBA modeling, or  $\{m_1^{PCR6}(\cdot), m'_1^{PCR6}(\cdot)\}$  if PCR6 rule is adopted. These BBAs have been represented by  $a_1, b_1, c_1$  and  $a_2, b_2, c_2$  in Table III.

TABLE III. FUSION MODELS FOR BUILDING CHANGE DETECTION.

Focal Elem.	$m_1(\cdot)$	$m_2(\cdot)$	$m_{12}^{DS}(\cdot)$	$m_{12}^{PCR6}(\cdot)$
$\theta_1$	$a_1$	0	$\frac{a_1(b_1+b_3)}{1-a_1b_2}$	$a_1(b_1+b_3) + \frac{a_1a_1b_2}{a_1+b_2}$
$\theta_2$	0	0	$\frac{a_2b_1}{1-a_1b_2}$	$a_2b_1$
$\theta_3$	0	$b_2$	$\frac{(a_2+a_3)b_2}{1-a_1b_2}$	$(a_2+a_3)b_2 + \frac{b_2a_1b_2}{a_1+b_2}$
$\theta_1 \cup \theta_2$	0	$b_1$	$\frac{a_3b_1}{1-a_1b_2}$	$a_3b_1$
$\theta_2 \cup \theta_3$	$a_2$	0	$\frac{a_2b_3}{1-a_1b_2}$	$a_2b_3$
$\Theta$	$a_3$	$b_3$	$\frac{a_3b_3}{1-a_1b_2}$	$a_3b_3$

Based on different BBAs and fusion methods, four sets of global BBAs can be computed from Table III.

$$\begin{aligned}
 G_1 &= DS\{m_1^{DS}(\cdot), m'_1^{DS}(\cdot)\}, \\
 G_2 &= PCR6\{m_1^{DS}(\cdot), m'_1^{DS}(\cdot)\}, \\
 G_3 &= DS\{m_1^{PCR6}(\cdot), m'_1^{PCR6}(\cdot)\}, \\
 G_4 &= PCR6\{m_1^{PCR6}(\cdot), m'_1^{PCR6}(\cdot)\}.
 \end{aligned} \tag{8}$$

After the fusion step, each pixel in the images will get a certain degree of belief for all focal elements. Based on the

these BBAs, a final decision can be made. DST and DSMT have different approaches to get this final decision. In this paper four decision criteria are tested. More precisely, we have evaluated the maximum of global BBAs (Max\_Bel), maximum of plausibility (Max\_Pl), maximum of betting probabilities (Max\_BetP) and the maximum of DSMT (Max\_DSMT), see [8] (Vol. 3, Chap. 3) and [10] for the mathematical definitions of  $Bel(\cdot)$ ,  $Pl(\cdot)$ ,  $BetP(\cdot)$  and  $DSMT(\cdot)$  functions.

#### IV. EXPERIMENTS

The two proposed BBAs modelings and fusion methods (based on DS and PCR6 rules) have been tested on one real dataset. The dataset and the results from each step are detailed in this section.

##### A. Datasets

The experimental dataset for this research work are displayed in Fig.1. It consists of two pairs of IKONOS stereo imagery captured at February 2006 and May 2011 respectively. As a pre-processing step, all data have been correctly radiometrically and geographically co-registered as described in [6]. As shown in Fig. 1, this is a normal building change example. Several buildings have been built on flat surface. The generated DSMs are displayed in Fig. 1c and d.

##### B. Results and evaluation

As the first step, BBAs from image change and height change are extracted and refined based on DS fusion and PCR6 fusion rules. The four sets of global BBAs are prepared corresponding to Eq. (8). Among them the BBA for the focal element  $\theta_1$  (Building change) are shown in Fig. 2. The accuracy of these BBAs have been evaluated by area under Receiver Operating Characteristic curve (AUC). The AUC has been recorded on this figure as the caption of each subfigure. An advantage of PCR6 can be proved here. It has to be noted that the AUCs obtained here are much higher than using only height (AUC = 0.9299) [6] or spectral information (AUC=0.8823), and generally better than the fusion result described in [6] (AUC=0.9621).

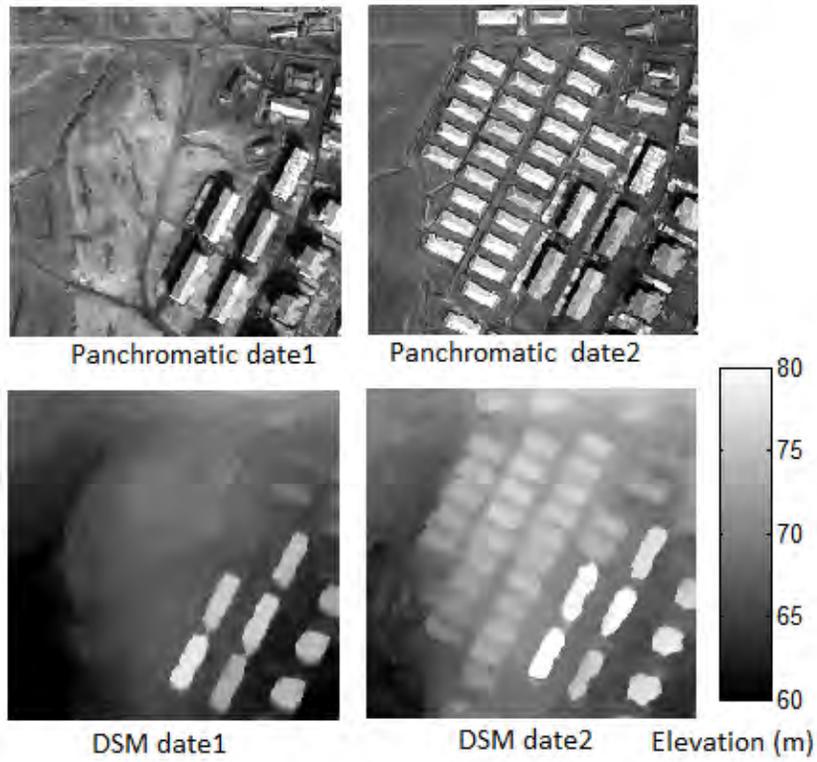

Fig. 1. Experimental dataset: a) panchromatic image from date1; b) panchromatic image from date2; c) DSM from date1; (d) DSM from date2.

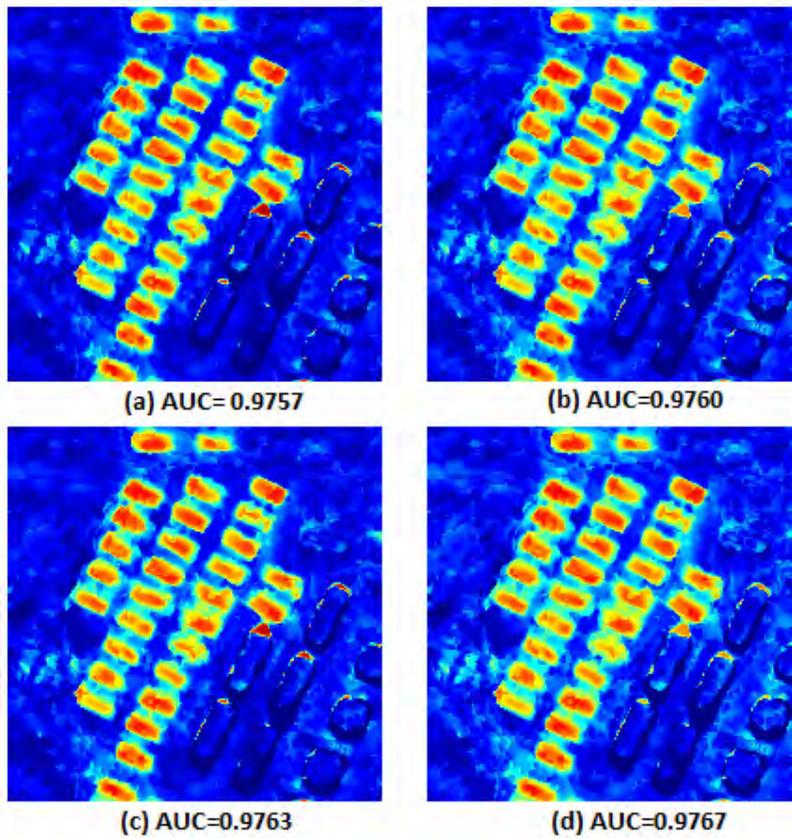

Fig. 2. Four global BBAs sets (a)  $G_1$ ; (b)  $G_2$ ; (c)  $G_3$ ; (d)  $G_4$ .

Besides the AUC comparison, the building change masks extracted from these four global BBAs sets are compared and evaluated. Each global BBA set can generate four building change mask based on these four decision make criteria. These building change masks are evaluated based on Kappa statistic (KA) and true detected rate (TR). In this paper  $TR = \frac{\text{detected positive}}{\text{true positive}} \times 100$  (in %). The comparison results of TR and KA values are shown in Table IV. From Table IV, one sees that,  $G_3$  and  $G_4$  are more advantageous than  $G_1$  and  $G_2$ . However, the highest KA is obtained by  $G_1$  by taking the Max\_Pl. However, in this paper, only the reference data for building changes are available. For better understanding these four global BBAs and decision making criteria, reference data of all three focal elements  $\theta_1$ ,  $\theta_2$  and  $\theta_3$  are required.

TABLE IV. CHANGE MASKS EVALUATION FROM FOUR GLOBAL BBAS.

	$G_1$		$G_2$		$G_3$		$G_4$	
	TR [%]	KA	TR[%]	KA	TR [%]	KA	TR [%]	KA

## V. CONCLUSIONS

Belief functions are good choices for DSM assisted change detection. Firstly, once the BBA construction is well done, it can be robustly used for other images in other regions efficiently. Secondly, this fusion approach matches well with the characteristics of our research topic. Since height information is important for separating high/low level objects. Satellite images directly highlight all changes on the land surface. None of these two sources of information can easily and directly lead to a reliable decision on building changes, which matches with the initial idea of belief functions. Generally speaking, both DST and DSMT frameworks offer the possibility to reach a high accuracy result, and PCR6 looks advantageous when a larger conflict exists between the different sources of evidence. More experiments are under progress to provide a finer quantitative comparative analysis in a forthcoming publication.

**Abstract**—Digital Surface Models (DSMs) generated from satellite stereo imagery provide valuable but not comprehensive information for building change detection. Therefore, belief functions have been introduced to solve this problem by fusing DSM information with changes extracted from images. However, miss-detection can not be avoided if the DSMs are containing large region of wrong height values. A refined workflow is thereby proposed by adopting the initial disparity map to generate a reliability map. This reliability map is then built in the fusion model. The reliability map has been tested in both Dempster-Shafer Theory (DST), and Dezert-Smarandache Theory (DSMT) frameworks. The results have been validated by comparing to the manually extracted change reference mask.

**Keywords:** belief functions, DSMT, satellite imaging, building change detection.

## I. INTRODUCTION

In our previous research [1] [2], belief functions have performed very well for 3D building change detection. As we have mentioned, the accuracy of 2D change detection is limited due to the misdetections caused by irrelevant changes. These irrelevant changes have a larger effect on very high resolution (VHR) images since many details of building changes are expected. The DSMs generated from satellite stereo imagery can largely help to solve this problem. However, the DSMs may still exhibit some outliers resulting in occlusions within the stereo/multi views and due to matching mistakes. In this case, change information from spectral information of the original stereo imagery can and should be used together with height changes to eventually highlight building changes. For this purpose proper fusion theories and approaches are needed.

In paper [2], the belief functions introduced in the Dempster-Shafer Theory (DST) [3] [4], and extended in Dezert-Smarandache Theory (DSMT) [5] are used to deal with the uncertainty information delivered from the DSMs. In [2] the possibility of using Dempster's fusion rule and the Proportional Conflict Redistribution Rule #6 (PCR6) of DSMT in our application have been tested. Though improvements have been proven by comparing to the method stated in [1], false alarms can not be avoided in case of large regions of wrong height change values. Thereupon, in this paper the reliability map is adopted as an additional source of evidence to correct the basic Belief Assignments (BBAs) and thus refine the fusion model.

This paper is organized as follow. Firstly, the belief functions and building change detection fusion models are

briefly reviewed. Then, the reliability discounting techniques are presented and the reliability map is generated. Later, the final four global BBAs are described together with the four decision criteria with which the final change detection mask can be generated. In the end, these refined fusion models are tested on two sets of satellite real data.

## II. BELIEF FUNCTION BASED BUILDING CHANGE DETECTION

### A. Basics of belief functions

Detailed presentations of DST and DSMT can be found in [5], [6] and [3]. Let  $\Theta$  be a frame of discernment of a problem under consideration.  $\Theta = \{\theta_1, \theta_2, \dots, \theta_N\}$  consists of a list of  $N$  exhaustive and mutually exclusive elements  $\theta_i$ ,  $i = 1, 2, \dots, N$ . Each  $\theta_i$  represents a possible state related to the problem we want to solve. The assumption of exhaustivity and mutual exclusivity of elements of  $\Theta$  is classically referred as *Shafer's model* of the frame  $\Theta$ . A BBA also called a belief mass function (or just a mass for short), is a mapping  $m(\cdot) : 2^\Theta \rightarrow [0, 1]$  from the power set<sup>1</sup> of  $\Theta$  denoted  $2^\Theta$  to  $[0, 1]$ , that verifies [3]:

$$m(\emptyset) = 0, \quad \text{and} \quad \sum_{X \in 2^\Theta} m(X) = 1. \quad (1)$$

$m(X)$  represents the mass of belief exactly committed to  $X$ . An element  $X \in 2^\Theta$  is called a focal element if and only if  $m(X) > 0$ . In DST, the combination (fusion) of several independent sources of evidences is done with Dempster-Shafer<sup>2</sup> (DS) rule of combination, assuming that the sources are not in total conflict<sup>3</sup>. DS combination of two independent BBAs  $m_1(\cdot)$  and  $m_2(\cdot)$ , denoted symbolically by  $DS(m_1, m_2)$ , is defined by  $m^{DS}(\emptyset) = 0$ , and for all  $X \in 2^\Theta \setminus \{\emptyset\}$  by:

$$m^{DS}(X) = \frac{1}{1 - K^{DS}} \sum_{\substack{X_1, X_2 \in 2^\Theta \\ X_1 \cap X_2 = X}} m_1(X_1)m_2(X_2), \quad (2)$$

<sup>1</sup>The power set is the set of all subsets of  $\Theta$ , empty set included.

<sup>2</sup>Although the rule has been proposed originally by Dempster, we call it Dempster-Shafer rule because it has been widely promoted by Shafer in DST.

<sup>3</sup>otherwise DS rule is mathematically not defined because of 0/0 indeterminacy.

where the total degree of conflict  $K^{DS}$  is given by

$$K^{DS} \triangleq \sum_{\substack{X_1, X_2 \in 2^\Theta \\ X_1 \cap X_2 = \emptyset}} m_1(X_1)m_2(X_2). \quad (3)$$

A discussion on the validity of DS rule and its incompatibility with Bayes fusion rule for combining Bayesian BBAs can be found in [6], [7], [8]. To circumvent the problems of DS rule, Smarandache and Dezert (see [5], Vol. 2, Chap. 1), then Martin and Osswald (see [5], Vol. 2, Chap. 2) have developed in DSMT [5] two fusion rules called PCR5 and PCR6 based on the proportional conflict redistribution (PCR) principle which consists

- 1) to apply the conjunctive rule;
- 2) calculate the total or partial conflicting masses;
- 3) then redistribute the (total or partial) conflicting mass proportionally on non-empty sets according to the integrity constraints one has for the frame  $\Theta$ .

This PCR principle transfers the conflicting mass only to the elements involved in the conflict and proportionally to their individual masses, so that the specificity of the information is not degraded. Because the proportional transfer can be done in two different ways, this has yielded to two different fusion rules. It has been proved in [9] that only PCR6 rule is compatible with frequentest probability estimation, and that is why we recommend its use in the applications. PCR5 and PCR6 rules simplify greatly and coincide for the combination of two sources. In this case, the PCR6 combination is obtained by taking  $m^{PCR6}(\emptyset) = 0$ , and for all  $X \neq \emptyset$  in  $2^\Theta$  by

$$m^{PCR6}(X) = \sum_{\substack{X_1, X_2 \in 2^\Theta \\ X_1 \cap X_2 = X}} m_1(X_1)m_2(X_2) + \sum_{\substack{Y \in 2^\Theta \setminus \{X\} \\ X \cap Y = \emptyset}} \left[ \frac{m_1(X)^2 m_2(Y)}{m_1(X) + m_2(Y)} + \frac{m_2(X)^2 m_1(Y)}{m_2(X) + m_1(Y)} \right], \quad (4)$$

where all denominators in Eq. (4) are different from zero. If a denominator is zero, that fraction is discarded. If a denominator, e.g.,  $m_1(X) + m_2(Y)$  tends towards 0, then also the conflicting mass  $m_1(X)m_2(Y)$  that is transferable tends to zero because  $m_1(X)$  and  $m_2(Y)$  tend to zero (since they are positive), therefore the redistribution masses also tend to zero. That reflects the continuity of PCR6.

### B. BBAs for Building change detection

1) *Choice of the frame of discernment*: Focusing on building change detection, two change indicators, one from images and one from DSMs are used. Changes from spectral images are highlighted by using the Iteratively Reweighted Multivariate Alteration Detection (IRMAD) [10]. Consequently height changes from DSMs are shown after robust height difference [1]. Three classes are considered to define the frame of discernment satisfying Shafer's model:

$$\Theta = \{\theta_1 \triangleq \text{Pixel} \in \text{BuildingChange}, \\ \theta_2 \triangleq \text{Pixel} \in \text{OtherChange}, \\ \theta_3 \triangleq \text{Pixel} \in \text{NoChange}\}, \quad (5)$$

and

$$\theta_1 \cap \theta_2 \cap \theta_3 = \emptyset. \quad (6)$$

Based on the three classes, the set of focal elements  $FE$  that are of interest in our application is:

$$FE = \{\theta_1, \theta_2, \theta_3, \theta_1 \cup \theta_2, \theta_2 \cup \theta_3, \theta_1 \cup \theta_2 \cup \theta_3\}. \quad (7)$$

2) *BBAs construction*: Paper [2] constructed the sigmoidal model for both concordance and discordance indexes. The details and advantages of this approach are described in [11]. The concordance index measures the concordance of change indicator and BBA in the assertion, while the discordance measures the opposition of change indicator to the BBAs in the assertion. The original sigmoid curve is defined as

$$f_{(\tau, T)}(x) = 0.99 / (1 + e^{-\frac{x-T}{\tau}}), \quad (8)$$

where  $x$  is the original value of each indicator. Two parameters  $T$  and  $\tau$  are used to control the symmetry point and the slope of the sigmoid function. The symmetry point indicates a certainty of 50%. In [11] these two parameters  $T$  and  $\tau$  are manually given. Here, the multi-level Otsu's thresholding method [12] is used for automatically getting the symmetry points for both concordance index and discordance index. Otsu's algorithm defines that an image is composed of objects and background. A discriminant analysis is performed by minimizing the intra-class variance. When three classes are of interest, two threshold values are expected. Otsu's method can be extended to

$$\sigma_\omega^2(T_1, T_2) = \omega_1 \sigma_1^2(T_1, T_2) + \omega_2 \sigma_2^2(T_1, T_2) + \omega_3 \sigma_3^2(T_1, T_2). \quad (9)$$

The weights  $\omega_i$  are the probabilities obtained from the image histogram that are separated by the thresholds  $T_1$  and  $T_2$ .  $\sigma_i$  is the standard deviation of the  $i$ -th class, for  $i = 1, 2, 3$ .  $T_1$  and  $T_2$  can be used as the symmetry points of discordance and concordance index respectively. Thus, using height change index as example, the BBAs for discordance and concordance height change index are functions of values  $a_{\Delta H}$  and  $b_{\Delta H}$  defined by

$$a_{\Delta H} = f_{\tau, T_1}(\Delta H), \quad \text{and} \quad b_{\Delta H} = f_{-\tau, T_2}(\Delta H). \quad (10)$$

The factor  $\tau$  is calculated with a sample value ( $\Delta H = 1$ ,  $a_{\Delta H} = 0.1$ ), which means 1 meter height change indicates 10% probability to be building changes. The BBAs for discordance and concordance image change index are built similarly. Differences appearing in 2D images give a concordance indication for all changes, which include the building changes and other changes ( $\theta_1 \cup \theta_2$ ). In this paper the changes from images are named  $\Delta Img$ .

In the Tables I and II, we present the two ways of construction of the BBAs from the sources of evidence based either on DS or on PCR6 rules of combination for the height change indicator (i.e. the first source of evidence) and the image change indicator (i.e. the second source of evidence). In Table I,  $m_1(\cdot)$  and  $m'_1(\cdot)$  represent the concordance and discordance BBAs from  $\Delta H$ , whereas in Table II  $m_2(\cdot)$  and  $m'_2(\cdot)$  represent the concordance and discordance BBAs from images.

$\theta_1 \cup \theta_2 \cup \theta_3$	$1-a_{\Delta Img}$	$1-b_{\Delta Img}$	$\frac{(1-a_{\Delta Img})(1-b_{\Delta Img})}{1-K_{\Delta Img}}$	$(1-a_{\Delta Img})(1-b_{\Delta Img})$

### III. RELIABILITY DISCOUNTING

The reliability discounting has been described and discussed in the references [13] and [14]. Briefly said, if an additional knowledge about the reliability ( $\alpha$ ) of certain indicator ( $X$ ) is available, it can be adopted to refine the initial BBAs.  $\alpha$  would be a value ranging from 0 to 1. And  $\alpha = 1$  means fully reliable, while  $\alpha = 0$  means the indicator is totally unreliable. Based on Shafer's discounting model [3], the reliability discounting factor  $\alpha$  is introduced to discount any BBA  $m(\cdot)$  defined on the power set  $2^\Theta$  as follows:

$$\begin{cases} m_\alpha(X) = \alpha \cdot m(X), \text{ for } X \neq \Theta, \\ m_\alpha(\Theta) = \alpha \cdot m(\Theta) + (1 - \alpha). \end{cases} \quad (11)$$

In the DSM assisted building change detection, false alarms are detected if wrong heights are present in DSM for large regions [1]. And these wrong heights are mostly introduced not in the stereoscope images matching procedure, but in the gaps filling step. In our DSM generation procedure, the height of un-matched pixels are interpolated using the height values of neighborhood pixels. Therefore, a reliable height value can be achieved for small gaps. When large gaps turn up in the disparity map, for example, a whole building roof, the height of that building can not be correctly interpolated. Thus, the percentage of available correctly matched neighborhood pixels inside a predefined region can be used to generate the height reliability. Fig. 1 shows an example of the generated reliability map. Fig. 1a is the gaps mask. The gaps region of the disparity map is represented with black color. Pixels with proper elevation values are displayed with white color. It can be observed, based on our approach that pixels in the center of a gap get lower reliability factor values than pixels next to the gap boundary (see Fig.1b).

In the building change detection procedure, the reliability map of two DSMs ( $\alpha_{DSM1}$  and  $\alpha_{DSM2}$ ) are calculated respectively. They are then fused together to generate a final reliability map  $\alpha_{\Delta H}$  for the height change indicator.

$$\alpha_{\Delta H} = \alpha_{DSM1} \cdot \alpha_{DSM2}. \quad (12)$$

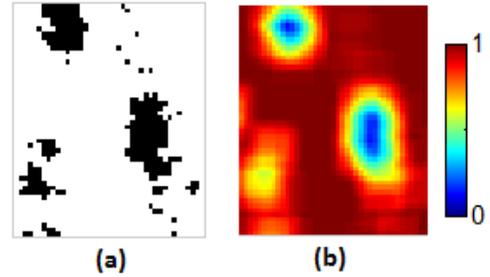

Fig. 1. Reliability map (b) generated from the gaps mask (a).

### IV. GLOBAL BBAs AND CHANGE DETECTION

#### A. Global BBAs generation

The BBAs related with the concordance and discordance indexes are combined to get the global BBA regarding to each source of evidence. These global BBAs will then be used as input for solving the change detection problem thanks to their combination. From the previous step of BBAs modelings, each pixel will get two sets of BBAs to combine results from Table I and II. More precisely, we will have to combine either  $\{m_1^{DS}(\cdot), m_2^{DS}(\cdot)\}$  if DS rule is preferred for the BBA modeling, or  $\{m_1^{PCR6}(\cdot), m_2^{PCR6}(\cdot)\}$  if the PCR6 rule is adopted. These BBAs from Table I and II have been represented by  $a_1, b_1, c_1$  and  $a_2, b_2, c_2$ . In this paper, the mass values  $a_1, b_1$ , and  $c_1$  are further discounted by the generated reliability map  $\alpha_{\Delta H}$  and denoted respectively as  $A_1, B_1$ , and  $C_1$ . More precisely, one computes

$$\begin{cases} A_1 = \alpha_{\Delta H} \cdot a_1, \\ B_1 = \alpha_{\Delta H} \cdot b_1, \\ C_1 = \alpha_{\Delta H} \cdot c_1 + (1 - \alpha_{\Delta H}). \end{cases} \quad (13)$$

In this application, only the reliability map for height change indicators is generated. The reliability map for image change indicators can also be constructed according to the change objects of interested. For instance, vegetation mask can be used to discount the reliability of building changes. However, this paper focuses on the reliability of height information.

When the reliability map of image changes is available, it could be used as the same way as height change reliability map. Table III and Table IV describe the final building change detection models based either on DS or on PCR6 rules. Here, the discounted height change indicators is denoted as  $m_{1\alpha\Delta H}(\cdot)$ .

TABLE III. DS FUSION MODEL FOR BUILDING CHANGE DETECTION.

Focal Elem.	$m_{1\alpha\Delta H}(\cdot)$	$m_2(\cdot)$	$m_{12}^{DS}(\cdot)$
$\theta_1$	$A_1$	0	$\frac{A_1(b_1+b_3)}{1-A_1b_2}$
$\theta_2$	0	0	$\frac{A_2b_1}{1-A_1b_2}$
$\theta_3$	0	$b_2$	$\frac{(A_2+a_3)b_2}{1-A_1b_2}$
$\theta_1 \cup \theta_2$	0	$b_1$	$\frac{A_3b_1}{1-A_1b_2}$
$\theta_2 \cup \theta_3$	$A_2$	0	$\frac{A_2b_3}{1-A_1b_2}$
$\Theta$	$A_3$	$b_3$	$\frac{A_3b_3}{1-A_1b_2}$

TABLE IV. PCR6 FUSION MODEL FOR BUILDING CHANGE DETECTION.

Focal Elem.	$m_{1\alpha\Delta H}(\cdot)$	$m_2(\cdot)$	$m_{12}^{PCR6}(\cdot)$
$\theta_1$	$A_1$	0	$A_1(b_1 + b_3) + \frac{A_1 A_1 b_2}{A_1 + b_2}$
$\theta_2$	0	0	$A_2 b_1$
$\theta_3$	0	$b_2$	$(A_2 + a_3)b_2 + \frac{b_2 A_1 b_2}{A_1 + b_2}$
$\theta_1 \cup \theta_2$	0	$b_1$	$A_3 b_1$
$\theta_2 \cup \theta_3$	$A_2$	0	$A_2 b_3$
$\Theta$	$A_3$	$b_3$	$A_3 b_3$

$m_{1\alpha\Delta H}(\cdot)$  can be obtained from the discounting of the fusion results presented in Table I. Thus they have been denoted respectively as  $m_{1\alpha\Delta H}^{DS}(\cdot)$  and  $m_{1\alpha\Delta H}^{PCR6}(\cdot)$ . This discounted height change indicators are fused in the second step with image change indicator  $m_2(\cdot)$  to generate the final global BBAs. From the tables III and IV, four sets of global BBAs can be computed based on different BBAs and fusion methods as follows:

$$\begin{aligned}
 G_1 &= DS\{m_{1\alpha\Delta H}^{DS}(\cdot), m_2^{DS}(\cdot)\}, \\
 G_2 &= PCR6\{m_{1\alpha\Delta H}^{DS}(\cdot), m_2^{DS}(\cdot)\}, \\
 G_3 &= DS\{m_{1\alpha\Delta H}^{PCR6}(\cdot), m_2^{PCR6}(\cdot)\}, \\
 G_4 &= PCR6\{m_{1\alpha\Delta H}^{PCR6}(\cdot), m_2^{PCR6}(\cdot)\}.
 \end{aligned} \tag{14}$$

For example, if both the BBA modeling procedure and global BBAs are constructed based on DS fusion rule, the generated global BBA is recorded as  $G_1$ .

### B. Change mask generation

After the fusion step, each pixel in the images will get a certain degree of belief for all focal elements. The value of global BBAs in  $\theta_1$  gives a direct building change probability map. A change mask can be generated after giving a threshold value. However, BBAs on the partial ignorance and full ignorance set should also be considered in the decision making procedure. DST and DSMT propose different approaches to take the final decision. In this work, the same decision criteria as used in [2] are tested. They are: 1) maximum of global BBAs (Max\_Bel), 2) maximum of plausibility (Max\_Pl), 3) maximum of betting probabilities (Max\_BetP) and 4) the maximum of DSMP (Max\_DSMP). The reader can refer to [3] and [5] (Vol. 3, Chap. 3) for the mathematical definitions of  $Bel(\cdot)$ ,  $Pl(\cdot)$ ,  $BetP(\cdot)$  and  $DSMP(\cdot)$  functions.

## V. EXPERIMENTS

The improved building change detection fusion models have been tested on satellite images. The datasets and the experiments are described in this section.

### A. Datasets

The experimental datasets consist of two pairs of IKONOS stereo imagery captured in February 2006 and May 2011 respectively shown in Fig. 2 and 3. The first two images in each figure are the panchromatic images of two dates. (c) and (d) are the generated DSMs. They have been generated based on the method explained in [15]. The colors represent the height range in this test region.

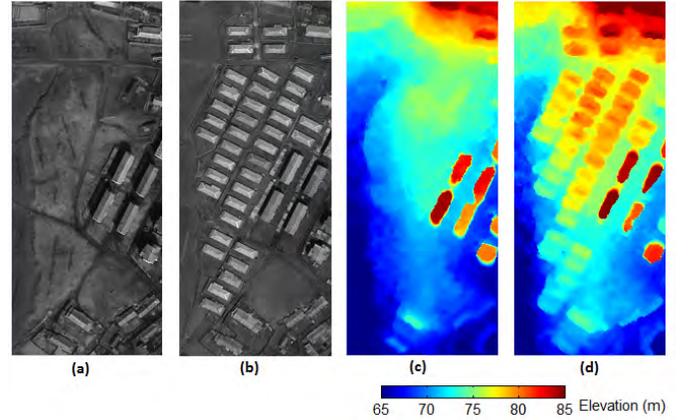

Fig. 2. Experimental dataset: a) panchromatic image from date1; b) panchromatic image from date2; c) DSM from date1; d) DSM from date2.

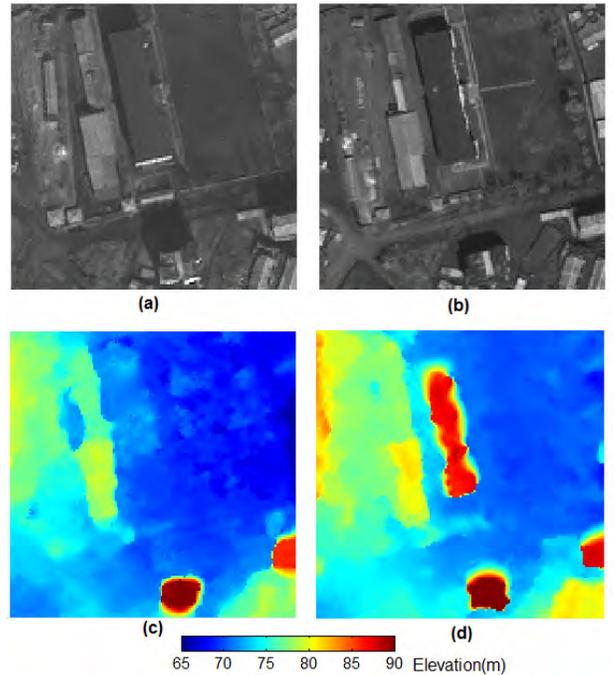

Fig. 3. Datasets of the 2nd test region; a) panchromatic image from date1; b) panchromatic image from date2; c) DSM from date1; d) DSM from date2.

The spatial co-registration is achieved through camera model parameter corrections before the DSM generation procedure [15]. The radiometrical co-registration method has been described in [1]. Fig. 2 shows a normal building change example. Several buildings have been built on flat surface. The generated DSMs are displayed in Fig. 2c and d. In the second example (shown in Fig. 3), a large percentage of pixels on the roof of the large building in the center appear as gaps in the disparity map. In the filling procedure, the large size of the gap in the date1 data lead to the missing of this building in the DSM (Fig. 3c).

### B. Results and evaluation

The refined DS fusion model and PCR6 fusion model have been applied to both datasets respectively. To show the improvement obtained by our method, we have compared its results with the original results we can obtain with the method in [2]. Firstly, the global BBAs of  $\theta_1$  are compared and displayed in Fig. 4 below.

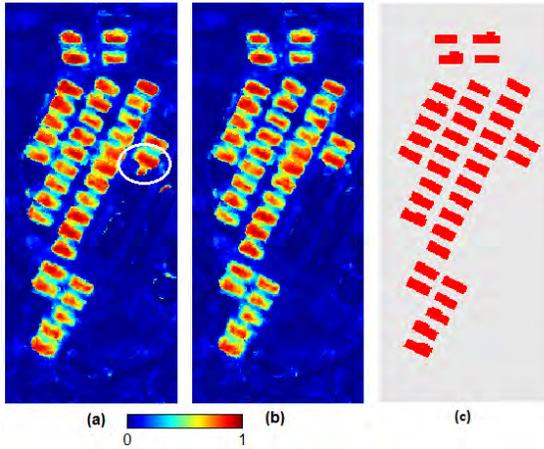

Fig. 4. Global Building change BBAs (a) Initial result; (b) Refined result; (c) Ground truth.

Fig. 4(a) corresponds to the original<sup>4</sup> result, and Fig. 4(b) shows the refined result based on  $G_1(\theta_1)$ . By comparing to the ground truth (Fig. 4(c)), the improvements can be clearly observed in the building boundary regions, especially the building marked with a white circle. In the initial result, the pixels next to this building are falsely detected as BuildingChange.

To evaluate quantitatively the performances of the different fusion approaches, the extracted BBAs from both approaches (original and refined) are compared to the manually extracted change reference masks. The results are analyzed in terms of Receiver Operating Characteristic (ROC) curve [16]. A larger area under the ROC curve (AUC) indicates a better accuracy of the building change map. The numerical evaluation results are described in Table V. The obtained AUC values prove a general improvement after reliability discounting is applied.

In addition to the AUC comparison, the building change masks extracted from these four global BBAs sets are compared and evaluated. Each global BBA set can generate four building change masks based on these four decision criteria.

<sup>4</sup>obtained without reliability discounting, as presented in [2].

TABLE V. QUALITY COMPARISON OF GLOBAL BBA (BUILDING CHANGE).

	Test Region 1		Test Region 2	
	Original	Refined	Original	Refined
$G_1$	0.9811	0.9833	0.9509	0.9950
$G_2$	0.9829	0.9839	0.9485	0.9931
$G_3$	0.9815	0.9837	0.9512	0.9955
$G_4$	0.9835	0.9844	0.9487	0.9939

These building change masks are compared with the masks from paper [2] based on Kappa statistic (KA). The comparison results of Test region 1 are shown in Table VI. Limited by the reference data we can get, only the building change frame is evaluated here. One sees the reliability discounting map helps to improve the result accuracy in all fusion and decision approaches.

In the second test region, there is actually no building changes. The purpose of showing this test region is to further prove the advantage of the extracted reliability map. Fig. 5 shows the extracted reliability discounting map of the height changes. The window size we selected for this test region is  $9 \times 9$ . By using this reliability map, final fusion result of  $G_1(\theta_1)$  is achieved and shown in Fig. 6(a). As a comparison, the  $G_1(\theta_1)$  of the initial fusion model is displayed in Fig. 6(b). This is the same building that we have discussed in paper [1]. It can be noted in Fig. 3, this building exists in both panchromatic images of two dates. However, only the DSM from date1 contains the correct height of this building. In Fig. 3c, this building can not be recognized. Therefore, a very high BBA would be achieved in the height change indicator. A high value in  $m_1(\cdot)$  leads to a high global BBAs in building changes (as shown in Fig. 6(a)). Thus this building would be falsely detected as building changes. However, after discounting this region has much lower global BBAs (see Fig. 6(b)), and can be further correctly detected as NoChange.

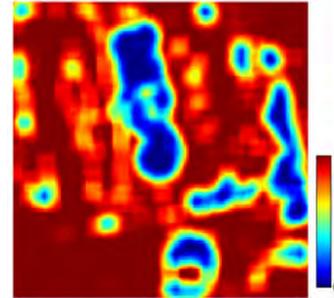

Fig. 5. Generated height change reliability map of the test region 2.

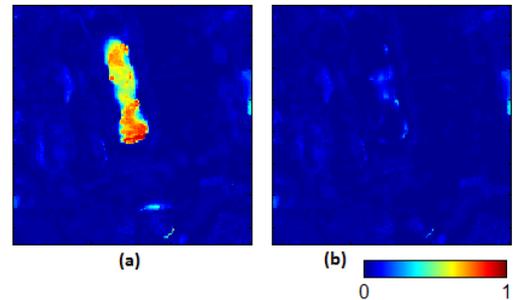

Fig. 6. Global Building change BBAs (a) Initial result; (b) Refined result.

TABLE VI. CHANGE MASKS EVALUATION FROM FOUR GLOBAL BBAS.

	$G_1$		$G_2$		$G_3$		$G_4$	
	Original	Refined	Original	Refined	Original	Refined	Original	Refined

Max_Pl	0.9291	0.9342	0.9288	0.9339	0.9287	0.9339	0.9284	0.9336
Max_BetP	0.9283	0.9335	0.9282	0.9334	0.9279	0.9333	0.9278	0.9333
Max_DSMP	0.9281	0.9333	0.9280	0.9331	0.9278	0.9331	0.9276	0.9330

## VI. CONCLUSIONS

Building change detection is a difficult topic, especially when the building changes happen together with other irrelevant changes. Our previous research has evidenced the performance of the belief functions in DSM assisted change detection [2]. In this paper, the change detection accuracy is further improved by adopting an additional reliability map. Height has proved to be an important feature for building change detection. However, the DSMs from satellite images do not always provide reliable height information, due to the occlusion and matching errors. The wrong height information will thus bring false alarms to the change detection procedure. Therefore, the original unfilled disparity maps are adopted to generate an height change reliability map, which is further used in the fusion models.

Our first experimental results have shown that this reliability map can improve the quality of all four global BBAs, and further influences the final change detection results from four decision criteria. However, the two test regions were quite small to draw a definitive conclusion that is why more experiments will be performed on a wider variety of regions with different types of backgrounds. A detailed statistical analysis and comparisons of the results with other techniques is under progress and they will be presented in a forthcoming publication.

Generally speaking, both DST and DSMT frameworks offer the possibility to reach a high accuracy result. The workflow proposed in this paper enables an automatic building change detection procedure. Other reliability maps from images would be further adopted in future work. Furthermore, besides building changes, more change objects will be considered in the fusion model.

**Abstract**—This paper proposes a new generic object recognition (GOR) method based on the multiple feature fusion of 2D and 3D SIFT (scale invariant feature transform) descriptors drawn from 2D images and 3D point clouds. We also use trained Support Vector Machine (SVM) classifiers to recognize the objects from the result of the multiple feature fusion. We analyze and evaluate different strategies for making this multiple feature fusion applied to real open-datasets. Our results show that this new GOR method has higher recognition rates than classical methods, even if one has large intra-class variations, or high inter-class similarities of the objects to recognize, which demonstrates the potential interest of this new approach.

**Keywords:** generic object recognition, point cloud, 2D SIFT, 3D SIFT, Feature fusion, BoW, SVM, belief functions, PCR.

## I. INTRODUCTION

Generic object recognition (GOR) in real environment plays a significant role in computer vision and artificial intelligence. It has important applications in intelligent monitoring, robotics, medical image processing, etc [1]–[3]. Contrariwise to specific object recognition<sup>1</sup>, GOR is much more difficult to accomplish. Mainly because the generic features of objects which express the common properties in the same class and help to make the difference between classes need to be found out, instead of defining characteristics of particular category as used in specific object recognition (SOR) methods. The current main techniques for GOR are based on local feature extraction algorithms on 2D images, typically the 2D SIFT (scale invariant feature transform) descriptors [4], [5]. However, 2D images lose the 3D information of the objects, and are susceptible to change due to various external illumination conditions. To solve this drawback, 3D SIFT descriptors based on volumes [3], [6]–[10], and 3D descriptors based on point cloud model [11]–[13] have been proposed recently by several researchers because point cloud model of object is obtained from the depth images which only depends on the geometry of the objects. Such point cloud model has nothing to do with the brightness and reflection features of the objects. That is the main reason why we are also interested by these technique in this paper. 3D SIFT descriptors have been applied successfully in motion

recognition of consecutive video frames by Scovanner et al. [6]. They show good performance in medical image processing [3], [7]–[9] as well. Object recognition has also be done with 3D SIFT in complex Computed Tomography (CT) for airport baggage inspection and security by Flitton et al. [10].

The object recognition algorithms based on single feature only often generate erroneous object recognitions, specially if there are big intra-class variations and some inter-class high similarities, or if there exist important changes in pose and appearance of objects. In these conditions, the use of a single feature is insufficient to make a reliable recognition and classification. To overcome this serious drawback, new recognition algorithms based on multiple features and fusion algorithms have been proposed recently in the literature [14]–[17]. Compared with the recognition algorithm using single feature only, the feature fusion algorithms combine multiple features information which can improve substantially the recognition rate.

In this paper, we propose a new method for GOR based on feature fusion of 2D and 3D SIFT descriptors, which consists of two main phases: 1) a training phase, and 2) a testing phase. In the both phases, we consider two types of inputs:

- 1) The first type of input is a database with 3D point cloud model representation of different objects from different categories (classes). In this work, our database has been just obtained from the web<sup>2</sup>. It is characterized by 3D SIFT descriptors adapted (in this paper) for point cloud – see the next section for details.
- 2) As second input, we use the same database with 2D images including some objects that are characterized by their 2D SIFT descriptors.

From these two inputs, the 2D and 3D SIFT feature descriptors are transformed into the corresponding Bag of Words (BoW) feature vector [18]. In the training phases, these two BoW feature vectors (drawn from the 2D and 3D SIFT) describing the object are used to train Support Vector Machines (SVMs) [19] to get the prediction functions. After this training phase, the system is used to recognize unknown objects in the testing phase. These two BoW feature vectors

<sup>1</sup>such as face recognition [1] (SOR) where only certain objects or certain categories need to be recognized, which can be accomplished by training mass samples.

<sup>2</sup><http://rgbd-dataset.cs.washington.edu/dataset.html>

describing the object are used to make the object recognition in the testing phase. In this paper, we test:

- 1) the feature-level fusion strategy, where we combine (fuse) directly the two BoW-based feature vectors and we feed the trained SVM with the fused vector to get the final recognition result.
- 2) the decision-level fusion strategy, where each of the two BoW-based feature vectors feeds its corresponding trained SVM to get the corresponding recognition result separately. Then we test different fusion rules to combine these two recognition results to get the final recognition result.

The paper is organized as follows. The recognition algorithm is described in details in section II. Section III evaluates the performances of this new method on real datasets. Conclusions with perspectives are given in section IV.

## II. NEW GENERIC OBJECT RECOGNITION METHOD

This new method of object recognition consists in three main steps (features extraction and representation, features fusion, and classifier design) that we present in details in this section. To achieve the good recognition of objects, we propose to combine 2D scale-invariant feature transform (2D SIFT) characterizing the object features, with 3D SIFT (based on point clouds model). We need at first to recall the principle of 2D SIFT [4], [5], and we explain improved 3D SIFT descriptors applied in point cloud.

### Step 1: Features extraction and representation

Feature extraction and representation are necessary for any object recognition algorithm. In many situations the object recognition task is very difficult because it is possible that some (partial) similarities exist in different classes of objects, as well as (partial) dissimilarities in the same class of objects. So the feature extraction process must be done as efficient as possible in order to help the recognition of objects by making the difference between object classes biggest, and by making the difference in the same class smallest. The objects need also to be represented at a certain level of semantic, using limited training objects to represent the class [2].

#### – 2D SIFT descriptor

In 1999, David Lowe [4] did present for the first time a new method to extract keypoints of objects in images, and to describe their local features that allows to make generic object recognition, for example in computer vision applications. His method has then been improved in [5], and extended to 3D by other authors (see next paragraph). The feature description of the object drawn from a training image is then used to identify the presence (if any) of the object in real (usually cluttered) observed scene. To get good object recognition performances, Lowe proposed a (2D) SIFT (scale-invariant feature transform) that warranties that the features extracted (i.e. the key-points) from the training image are detectable under changes in image orientation, scale, noise

and illumination, and even if partial object occlusions occur in the observed scene. Lowe's SIFT feature descriptor is invariant to uniform scaling, orientation, and partially invariant to illumination changes and robust to local geometric (affine) distortion. The stable key-points locations of SIFT are given by the detection of scale-space extrema in the Difference-of-Gaussian (DoG) function  $D(x, y, \sigma)$  convolved with the image  $I(x, y)$ . More precisely, one defines [5]

$$D(x, y, \sigma) \triangleq L(x, y, k\sigma) - L(x, y, \sigma), \quad (1)$$

where  $L(x, y, k\sigma) \triangleq G(x, y, k\sigma) * I(x, y)$  and  $L(x, y, \sigma) \triangleq G(x, y, \sigma) * I(x, y)$  are Gaussian-blurred images at nearby scale-space  $\sigma$  separated by a constant multiplicative factor<sup>3</sup>  $k$ , and where  $*$  is the convolution operator and  $G(x, y, \sigma)$  is the centered Gaussian kernel defined by

$$G(x, y, \sigma) \triangleq \frac{1}{2\pi\sigma^2} e^{-(x^2+y^2)/2\sigma^2}. \quad (2)$$

The local extreme points of  $D(x, y, \sigma)$  functions (DoG images) define the set of keypoint candidates (the SIFT descriptor). To detect the keypoints, each sample point (pixel) is compared to its eight neighbors in the current image and its nine neighbors in the scale below and above. The sample point under test is considered as a keypoint (local extrema) if its value is larger (or smaller) than all of its 26 neighbors. The localization of a candidate keypoint is done by the 2nd-order Taylor expansion of the DoG scale-space function  $D(x, y, \sigma)$  with the candidate keypoint taken as the origin [5]. However in general there are too many candidate keypoints and we need to identify and remove the bad candidates that have too low contrast<sup>4</sup>, or are poorly localized along an edge. For doing this, a contrast thresholding is applied on  $D(x, y, \sigma)$  to eliminate all the candidate keypoints below a chosen<sup>5</sup> threshold value  $\tau$ . To eliminate the candidate keypoints that are poorly localized along an edge, Lowe [5] uses a thresholding method based on the ratio of the eigenvalues of the Hessian matrix  $\mathbf{H}$  of the DoG function, because for poorly defined extrema in the DoG function the principal curvature across the edge would be much larger than the principal curvature along it. More precisely, if the ratio  $Tr(\mathbf{H})^2/Det(\mathbf{H}) > (r_{th}+1)^2/r_{th}$  then the candidate keypoint is rejected. Here,  $r_{th}$  is a chosen threshold value of the ratio between the largest magnitude eigenvalue of  $\mathbf{H}$  and the smaller one<sup>6</sup>.

Once all the keypoints are determined, one must assign a consistent orientation based on local image properties, from which the keypoint descriptor can be represented, hence achieving invariance to image rotation. For this, the scale of the keypoint is used to choose the Gaussian-blurred image  $L$  with the closest scale. The keypoint descriptor is created by computing at first the gradient magnitude  $m(x, y)$  and its

<sup>3</sup>The choice for  $k = 2^{1/s}$  is justified by Lowe in [4], where  $s$  is an integer number of intervals

<sup>4</sup>because they are sensitive to noise.

<sup>5</sup>We have chosen  $\tau = 0.02$  in our simulations.

<sup>6</sup>In [5], Lowe takes  $r_{th} = 10$ .

orientation  $\theta(x, y)$  at each pixel  $(x, y)$  in the region around the keypoint in this Gaussian-blurred image  $L$  as follows [5]

$$\begin{cases} m(x, y) = \sqrt{L_x^2 + L_y^2}, \\ \theta(x, y) = \tan^{-1}\left(\frac{L_y}{L_x}\right), \end{cases} \quad (3)$$

with  $L_x \triangleq L(x+1, y) - L(x-1, y)$  and  $L_y \triangleq L(x, y+1) - L(x, y-1)$ . In [5], a set of orientation histograms is created on  $4 \times 4$  pixel neighborhoods with 8 directions (bins) each. These histograms are computed from magnitude and orientation values of samples in a  $16 \times 16$  region around the keypoint such that each histogram contains samples from a  $4 \times 4$  subregion of the original neighborhood region. The magnitudes are weighted by a Gaussian function with  $\sigma$  equal to one half the width of the descriptor window. The descriptor then becomes a 128-dimensional feature vector because there are  $4 \times 4 = 16$  histograms each with 8 directions. This vector is then normalized to unit length in order to enhance invariance to affine changes in illumination. Also a threshold of 0.2 is applied to reduce the effects of non-linear illumination, and the vector is again normalized. The figure 1 shows an example of  $4 \times 4$  keypoint descriptor, where the space delimited by the purple ellipse is the neighborhood under consideration.

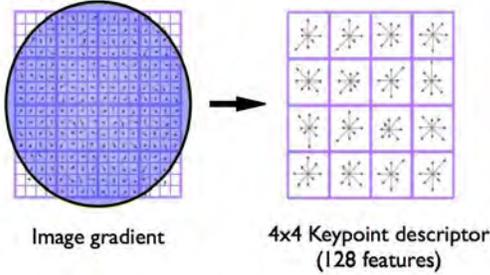

Fig. 1: A  $4 \times 4$  Keypoint descriptor (Credit: J. Hurrelmann).

The simplest method to find the best candidate match for each keypoint would consist in identifying its nearest<sup>7</sup> neighbor in the database of key points from training images. Unfortunately, SIFT-based keypoint matching requires more sophisticated methods because many features from an image will not have any correct match in the training database because of background clutter in observed scene and because of possible missing features in training images, see [5] for details. SIFT method is patented by the University of British Columbia (US Patent 6,711,293 – March 23, 2004) and a demo is available in [20]. Open SIFT codes can be found on the web, for example in [21].

### – 3D SIFT descriptor

The previous 2D SIFT descriptor working with pixels has been extended to 3D using volumes in different manners by different authors [3], [6]–[10]. In this paper, we adapt the 3D SIFT for point cloud inspired by [6], [13]. But all the methods require same functional steps as for 2D SIFT, that

<sup>7</sup>based on Euclidean distance metric.

is 1) Keypoints detection; 2) Key points orientation; and 3) Descriptor representation. We present these steps in detail in the next subsections.

#### 1) Keypoint detection

The scale space of a 3D input point cloud is defined as a 4D function  $L(x, y, z, \sigma) = G(x, y, z, k\sigma) * P(x, y, z)$  obtained by the convolution of a 3D variable-scale centered Gaussian kernel  $G(x, y, z, \sigma)$ , with the input point  $P(x, y, z)$ , where

$$G(x, y, z, \sigma) = \frac{1}{(\sqrt{2\pi}\sigma)^3} e^{-(x^2+y^2+z^2)/2\sigma^2}, \quad (4)$$

Extending Lowe's approach [5], scale-space  $\sigma$  is separated by a constant multiplicative factor  $k$ , and the candidate keypoints in 4D scale space are taken as the local extrema (maxima or minima) of the multi-scale DoG defined for  $i \in [0, s+2]$  by

$$D(x, y, z, k^i\sigma) = L(x, y, z, k^{i+1}\sigma) - L(x, y, z, k^i\sigma). \quad (5)$$

To find extrema of the multi-scale DoG function, each sample point is compared to its  $27 + 26 + 27 = 80$  neighbors, where 26 neighbors belong to the current scale, and each 27 neighbors in the scale above and below. A keypoint is chosen only if it is larger than all of its neighbors or smaller than all of them. To eliminate the bad candidate keypoints having low contrast, one uses a thresholding method to remove the erroneous points. A contrast threshold is applied on  $D(x, y, z, k^i\sigma)$  to eliminate all the candidate keypoints below a chosen<sup>8</sup> threshold value  $\tau$ .

#### 2) Keypoint orientations

Similarly to 2D SIFT, once all the keypoints are determined in 3D, one must assign a consistent orientation based on local points properties, from which the keypoint descriptor can be represented, hence achieving invariance to object rotation. For this, The two-dimensional histogram is calculated by gathering statistics of the angles between the neighboring points and their center. The keypoint descriptor is created by computing at first the vector magnitude  $m(x, y, z)$  and its orientations  $\theta(x, y, z)$  (azimuth angle) and  $\phi(x, y, z)$  (elevation angle) between each point  $(x, y, z)$  in the region around the keypoint and their center  $(x_c, y_c, z_c)$  as follows<sup>9</sup>

$$\begin{cases} m(x, y, z) &= \sqrt{(x - x_c)^2 + (y - y_c)^2 + (z - z_c)^2}, \\ \theta(x, y, z) &= \tan^{-1}((y - y_c)/(x - x_c)), \\ \phi(x, y, z) &= \sin^{-1}((z - z_c)/m(x, y, z)). \end{cases} \quad (6)$$

In 3D point cloud, each point has two values which represent the direction of the region, whereas in 2D case each pixel had only one direction of the gradient.

Extending Lowe's approach in 3D case, in order to find the keypoint orientations we construct a weighted histogram for

<sup>8</sup>We have chosen  $\tau = 0.5$  in our simulations.

<sup>9</sup>In Eq.(6),  $\theta$  and  $\phi$  refer to the original coordinate system. In the paragraph "Descriptor representation" on p. 4, they refer to the rotated coordinate system.  $(x_c, y_c, z_c)$  is not same as  $(x_p, y_p, z_p)$ . The former refers to the center of the keypoint's r-points neighborhood. The latter refers to the keypoint.

the 3D neighborhood around each candidate keypoint. There are different ways for doing this. In this work, a 2D-histogram is produced by grouping the angles in bins which divide  $\theta$  and  $\phi$  into 10 deg angular bins. A regional Gaussian weighting of  $e^{-(2d/R_{\max})^2}$  for the points whose magnitude is  $d$  is applied to the histogram, where  $R_{\max}$  represents the max distance from the center. The sample points at a distance greater than  $R_{\max}$  are ignored. The histogram is smoothed using a Gaussian filter to limit the effect of noise. The dominant azimuth  $\alpha$  and elevation  $\beta$  of the keypoint are determined by the peaks of the 2D-histogram. In order to enhance robustness, peaks in the histogram within 80% of the largest peak are also retained as possible secondary orientations.

### 3) Descriptor representation

Each keypoint  $p$  is described by its location  $\mathbf{p} \triangleq [x_p, y_p, z_p]^t$ , scale  $\sigma_p$ , and orientation angles  $\alpha_p$  and  $\beta_p$ . The descriptor representation associated with a keypoint  $p$  is based on the local spatial characteristics around it to describe its features. To ensure rotation invariance of the descriptor, the  $r$ -points  $p_i$  ( $i = 1, \dots, r$ ) of coordinates  $\mathbf{p}_i \triangleq [x_i, y_i, z_i]^t$  around the keypoint of interest  $p$  are at first transformed (rotated) in the dominant orientation of  $p$  by the following transformation

$$\mathbf{p}'_i = \begin{bmatrix} \cos \alpha_p \cos \beta_p & -\sin \alpha_p & -\cos \alpha_p \sin \beta_p \\ \sin \alpha_p \cos \beta_p & \cos \alpha_p & -\sin \alpha_p \sin \beta_p \\ \sin \beta_p & 0 & \cos \beta_p \end{bmatrix} \cdot \mathbf{p}_i. \quad (7)$$

Then the vector  $\mathbf{n}$  at the key point which is normal to the surface of the  $r$ -points neighborhood is calculated according to the routine available in the open Point Cloud Library (PCL) [22]. For each (rotated) point  $\mathbf{p}'_i$  ( $i = 1, \dots, r$ ) in the  $r$ -points neighborhood of the (rotated) keypoint  $p'$ , we calculate the vector  $\mathbf{p}'\mathbf{p}'_i$  and the magnitude  $m$  and angles  $\theta$  and  $\phi$  according to Eq. (6). The angle  $\delta$  between  $\mathbf{n}$  and  $\mathbf{p}'\mathbf{p}'_i$  is given by

$$\delta = \cos^{-1} \left( \frac{\mathbf{p}'\mathbf{p}'_i \cdot \mathbf{n}}{|\mathbf{p}'\mathbf{p}'_i| \cdot |\mathbf{n}|} \right). \quad (8)$$

Therefore, a keypoint  $p'$  with its neighbor  $p'_i$  is represented by the 4-tuple  $(m, \theta, \phi, \delta)$ . To reduce the computational time, instead of dividing the neighborhood into  $n \times n \times n$  subregions (with  $n = 4$  as in Lowe's 2D SIFT descriptor), we take directly the entire neighborhood, which means that we have  $n = 1$ . The histogram used to generate the 3D descriptor at the keypoint  $p'$  is derived by splitting  $(\theta, \phi, \delta)$  space into 45 deg bins, and adding up the number of points with the Gaussian weighting of  $e^{-(2m/R_{\max})^2}$ . So the dimension of our 3D SIFT descriptor is  $n \times n \times n \times 4 \times 4 \times 8 = 128$  (as for the 2D SIFT descriptor described previously), because  $n = 1$ ; the azimuth angle  $\theta \in [0, 360]$  deg which is split into 8 bins of 45 deg; the elevation angle  $\phi \in [-90, 90]$  deg which is split into 4 bins of 45 deg; and  $\delta \in [0, 180]$  deg which is also split into 4 bins of 45 deg. Each 3D SIFT descriptor is normalized to unity.

The 2D and 3D SIFT descriptors summarize efficiently the useful information contained in 2D and 3D images. Instead of working directly with whole images, it is usually more interesting (in terms of computational burden reduction) to

work directly with 2D and 3D SIFT descriptors, specially if real-time object recognition is necessary. Generally, the objects characterized by 2D and 3D SIFT descriptors have different number of keypoints which makes the feature fusion (FF) problem for object recognition very challenging. For example, for a simple object like an apple, we can get 45 keypoints using 3D SIFT descriptor, and 38 keypoints using 2D SIFT descriptor. To overcome this problem, we adopt the Bag of Words (BoW) model [18] to gather the statistics of the 2D and 3D SIFT descriptors to describe the objects.

### – BoW model for features vector

In the BoW feature model, the feature descriptors of all the interest points are quantized by clustering them into a pre-specified<sup>10</sup> number of clusters. Instead of using  $k$ -means algorithm as in [2], we use the  $k$ -means++ method [23] which selects more effectively the initial cluster centers to complete this step. The resultant cluster centers are now called *visual words*, while the collection of these cluster centers is referred to as the *visual word vocabulary*. Once our vocabulary is computed, the descriptors are matched to each *visual word* based on the Euclidean distance and the frequency of the visual words in image and in point cloud is accumulated into a histogram, which is the BoW feature vector of the image and of the point cloud. So each object in 2D image and in 3D point cloud is described by a  $1 \times 300$  BoW-based feature vector denoted respectively  $\mathbf{BoW}_{2D}$  and  $\mathbf{BoW}_{3D}$ . These two BoW-based feature vectors will be used for feeding the trained SVM classifiers to get the final object recognition.

### Step 2: Classifier design

Once the object description is completed, SVMs are trained to learn objects categories and to perform the object classification. SVM is a supervised and discriminative machine learning method providing usually good performance. Through offline training of pre-limited samples, we seek a compromise between model complexity and learning ability, to get a good discriminant function [19]. Linear SVM classifier is applied for its efficiency and it is a typical classifier for two categories problems. In many real-life applications, we are face to multi-category classification problems and we use trained 1V1 SVMs between classes to set up a multi-category classifier. The training process is done as follows: for training samples belonging to the  $i$ th category, we make a pairwise SVM training with respect to all the other classes. So, we get  $C_n^2 = n(n-1)/2$  1V1 SVM classifiers for training samples of  $n$  categories.

### Step 3: Features fusion strategies

When the two BoW-based features vectors of the object to recognize have been computed from 2D and 3D SIFT descriptors, we have to use them to achieve the object recognition thanks to the trained SVMs from the BoW-based features vectors of known objects of our data base. In this paper, we

<sup>10</sup>In our simulations, we took  $K = 300$ .

present briefly the following different strategies that we have tested:

- 1) *The direct feature-level fusion strategy*: this feature-level fusion is for feeding SVM classifiers in training phase and then making object recognition. With this strategy we combine (fuse) directly the two BoW-based feature vectors  $\mathbf{BoW}_{2D}$  and  $\mathbf{BoW}_{3D}$ , and we feed the trained (global) SVM classifiers with the fused vector to get the final recognition. The principle of our method based on this strategy is summarized in Fig 2.

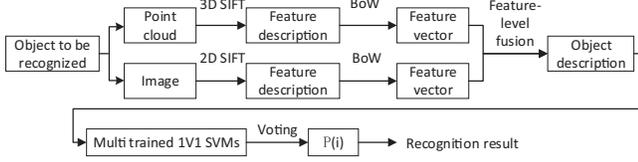

Fig. 2: Direct feature-level fusion strategy.

- 2) *The decision-level fusion strategy*: each BoW-based feature vector  $\mathbf{BoW}_{2D}$  and  $\mathbf{BoW}_{3D}$  feeds a specific trained SVM to get separately the corresponding recognition result. Then we test different fusion rules to combine these two recognition results to get the final fusioned recognition result. In this work we have evaluated the performances of the following rules:

- Average weighted fusion rule,
- PCR6 fusion rule of DSMT [24],
- Murphy's rule of combination [26].

The principle of our method based on this strategy is summarized in Fig 3.

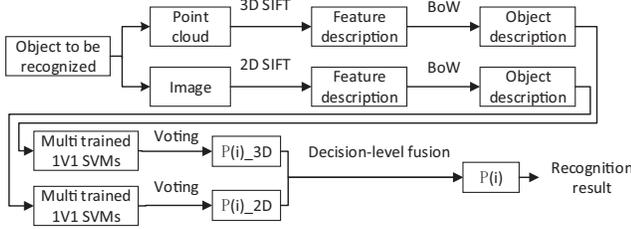

Fig. 3: Decision-level fusion strategy.

### 1) The direct feature-level fusion strategy

This strategy consists of the following steps:

- 1-a) For any object to classify, we extract its 2D and 3D SIFT descriptors associated with each keypoint. So we get  $N_{2D}$  2D SIFT descriptors of size  $1 \times 128$  if one has extracted  $N_{2D}$  keypoints from the 2D image under test, and we get  $N_{3D}$  3D SIFT descriptors of size  $1 \times 128$  if one has extracted  $N_{3D}$  keypoints from the 3D point cloud under test.
- 1-b) From the  $N_{2D}$  2D SIFT descriptors of size  $1 \times 128$ , we compute  $1 \times 300$  BoW feature vectors  $\mathbf{BoW}_{2D}$ , and from the  $N_{3D}$  3D SIFT descriptors of size  $1 \times 128$ , we

compute  $1 \times 300$  BoW feature vectors  $\mathbf{BoW}_{3D}$  thanks to the BoW model representation [18].

- 1-c) The direct feature-level fusion is done by stacking the BoW-based feature vectors  $\mathbf{BoW}_{2D}$  and  $\mathbf{BoW}_{3D}$  to get a  $1 \times 600$  vector  $\mathbf{BoW}_{2D,3D} \triangleq [\mathbf{BoW}_{2D}, \mathbf{BoW}_{3D}]$ .
- 1-d) The feature-level fused vector  $\mathbf{BoW}_{2D,3D}$  is fed in all 1v1 trained SVMs to get the corresponding discriminant results. The probability  $P(i)$  of the object to belong to the category  $c_i$  ( $i = 1, 2, \dots, n$ ) is estimated by voting.
- 1-e) The object is associated to the category (or class) having the largest probability, that is:

$$\text{Class}(\text{Object}) = \arg \max_{1 \leq i \leq n} \{P(i)\}. \quad (9)$$

### 2) The decision-level fusion strategy

As stated before, with this strategy each BoW-based feature vector  $\mathbf{BoW}_{2D}$  and  $\mathbf{BoW}_{3D}$  feeds a specific trained SVM to get separately the corresponding recognition result. Then different fusion rules can be used to combine these two recognition results to get the final fusioned recognition result.

- 2-a) **The average weighted fusion rule**: This very simple rule consists of a voting procedure. The  $\mathbf{BoW}_{2D}$  and  $\mathbf{BoW}_{3D}$  vectors feed separately all corresponding 1v1 trained SVMs to get the discriminant results, and we compute the corresponding number of votes  $vote[i]$  for each class  $c_i$ ,  $i = 1, 2, \dots, n$ . We will denote  $vote_{2D}[i]$  the distribution of votes drawn from 2D SIFT, and  $vote_{3D}[i]$  the distribution of votes drawn from 3D SIFT. The probability  $P_{2D}(i)$  of the object to belong to the class  $c_i$  based on 2D SIFT descriptors is estimated by  $P_{2D}(i) = vote_{2D}[i] / \sum_{i=1}^n vote_{2D}[i]$ , similarly we have  $P_{3D}(i) = vote_{3D}[i] / \sum_{i=1}^n vote_{3D}[i]$ . Then the voting results drawn from SVMs feeded with 2D and 3D SIFT are averaged to obtain the fusion result.
- 2-b) **PCR6 combination rule**: The BBA (Basic Belief Assignment)  $m_1(\cdot)$  and  $m_2(\cdot)$  are built from the empirical probability obtained by voting procedure described in 2-a). The elements of the frame of discernment  $\Theta$  are the  $n$  different classes  $c_1, c_2, \dots, c_n$ . To get the final result, the BBA's  $m_1(\cdot)$  and  $m_2(\cdot)$  are fused using the PCR6 combination rule<sup>11</sup> [24], defined by  $m_{PCR6}(\emptyset) = 0$  and for all  $X \neq \emptyset$  in  $2^\Theta$ ,

$$m_{PCR6}(X) \triangleq \sum_{\substack{x_1, x_2 \in 2^\Theta \\ x_1 \cap x_2 = X}} m_1(x_1)m_2(x_2) + \sum_{\substack{Y \in 2^\Theta \setminus \{X\} \\ X \cap Y = \emptyset}} \left[ \frac{m_1(X)^2 m_2(Y)}{m_1(X) + m_2(Y)} + \frac{m_2(X)^2 m_1(Y)}{m_2(X) + m_1(Y)} \right]. \quad (10)$$

<sup>11</sup>PCR6 formula coincides with the formula of PCR5 fusion rule here because one considers only two BBA's to combine. If more than two BBA's have to be fused altogether, we advise to use PCR6 rather than PCR5 - see [25] for a theoretical justification.

where all denominators in Eq.(10) are different from zero. If a denominator is zero, that fraction is discarded. All propositions/sets are in a canonical form.

- 2-c) **Murphy's rule:** Taking the feature-level fusion of 2D and 3D SIFT as a separate feature, together with the 2D and 3D SIFT, there are three features. Then the BBA  $m_1(\cdot)$ ,  $m_2(\cdot)$  and  $m_3(\cdot)$  are built from the empirical probability obtained by the voting procedure. The vote results of the features are combined based on the Murphy rule<sup>12</sup> [26].

### III. SIMULATION RESULTS

#### A. The experimental setup

We evaluate the recognition algorithm on a large-scale multi-view object dataset collected using an RGB-D camera [27]. This dataset contains color, depth images and point clouds of 300 physically distinct everyday objects taken from different viewpoints. The objects belong to one of 51 categories and contain three viewpoints. To test the recognition ability of our features, we test category recognition on objects that were not present in the training set. At each trial, we randomly choose one test object from each category and train classifiers on the remaining objects. We randomly choose 100 training samples and 60 test samples for each category. The object recognition rate (ORR) is calculated by

$$ORR = n_r / N. \quad (11)$$

where  $n_r$  is the number of objects correctly recognized, and  $N$  is the total number of test samples.

#### B. Experiment results and analysis

##### B.1 Accuracy of our 3D SIFT descriptor

In this simulation, we choose six categories with significant intra-class variations and high inter-class similarities. The objects to recognize are *apple*, *tomato*, *banana*, *pitcher*, *cereal\_box*, and *kleenex*. The Point Feature Histogram (PFH) [11] and PFHRGB methods in open PCL [22] outperform the existed 3D features based on point clouds [28]. In order to verify the advantages of the proposed 3D SIFT for GOR, we compare these tree feature descriptors under the same conditions. Keypoints are detected using SIFTKeypoint module in open PCL [22] for each feature descriptors. Then the vectors of different feature descriptors of the keypoints are calculated. The object recognition rates (ORR) that we get are shown in Table I.

Type of feature descriptor	ORR (in %)
PFH based on [11]	81.39
PFHRGB based on [22]	84.17
3D SIFT based on this paper	91.11

TABLE I: Object recognition rates (ORR) of three descriptors.

The PFHRGB descriptor is an improved PFH feature descriptor enriched with color information which allows to improve object recognition rate. As shown in Table 1, compared

<sup>12</sup>Because results of the fusion with Dempster's rule are very close to results with Murphy's rule in our applications, we do not report them in our analysis.

with PFH and PFHRGB, the object recognition rate we get with our 3D SIFT descriptor adapted for point cloud gains 6.94% w.r.t. PFHRGB and 9.72% w.r.t. PFH.

#### B.2 Performances of feature fusion strategies

Here, we evaluate the performance (i.e. the ORR) of the different features fusion strategies presented in Section II (Step 3). We have chosen 10 categories (*apple*, *tomato*, *banana*, *pitcher*, *cereal\_box*, *kleenex*, *camera*, *coffee\_mug*, *calculator*, *cell\_phone*) having significant intra-class variations and high inter-class similarities. We compare our four fusion approaches: the direct feature-level fusion and the three decision-level fusions (by average weighted fusion, PCR6, and Murphy's rule). The results are shown in Fig. 4.

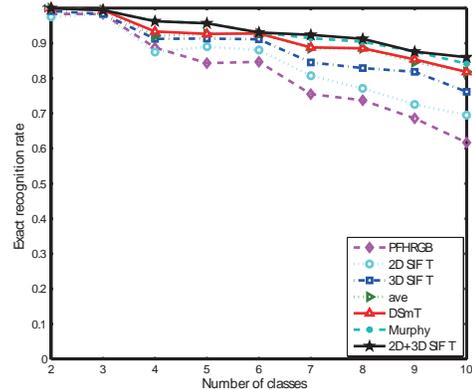

Fig. 4: Performances of the four feature fusion strategies.

where the legend of curves of Fig.4 must be read as follows: DSMT means PCR6 rule in fact, 2D+3D SIFT means the direct feature-level fusion of 2D and 3D SIFT, and *ave* means the average weighted feature fusion rule. The horizontal axis represents the total number of categories that we have tested. Due to the variability of the objects, the information provided by a single feature is too imprecise, uncertain and incomplete for getting good ORR. As shown in Fig.4, ORR obtained with the different feature fusion strategies are better than the ORR obtained with the best single descriptor. The results of average weighted fusion and PCR6 are close, but are lower than the other two fusion methods. Feature-level fusion of 2D and 3D SIFT is taken as the third feature for Murphy's rule. However, compared with the feature-level fusion, the performances of Murphy's rule do not improve. So, the direct feature-level fusion performs best among these fusion strategies, and the following experiments are completed based on the direct feature-level fusion. One clearly sees that 3D SIFT proposed in this work significantly outperforms 2D SIFT and PFHRGB descriptors for GOR. As shown in Fig.4, ORR decreases with the increasing of the number of categories because of the design of the multi-category classifier which consists of many 1V1 SVM classifiers. Each classification error will be accumulated to the final voting results, leading to an increasing of recognition errors.

### B.3 Robustness to intra-class variation and inter-class similarities

In this study, we compare the ORR performances in different classes having high similarity (e.g., apple and tomato), and in the same class but having strong variation (e.g., pitcher object) as in Figs. 5 and 6 below. We evaluate the accuracy

Fig. 5: Apple and Tomato.

Fig. 6: Pitchers.

of PFHRGB, 2D SIFT, 3D SIFT and the feature-level fusion of 2D and 3D SIFT under the same conditions. Training and testing samples are the same as in the first experiment. Our simulation results are shown in Table II.

Feature descriptor	PFHRGB	2D SIFT	3D SIFT	2D+3D SIFT
ORR(apple)	61.67	53.33	71.67	65.00
ORR(tomato)	100	98.33	91.67	100
ORR(banana)	91.67	93.33	93.33	100
ORR(pitcher)	70.00	95.00	96.67	98.33
ORR(cereal_box)	91.67	98.33	95.00	95.00
ORR(kleenex)	90.00	90.00	100	100
Averaged ORR	84.17	88.06	91.11	93.06

TABLE II: ORR (in %) of different classes.

As we see from Table II, using 3D SIFT increases the ORR of 3.05% w.r.t. 2D SIFT. This shows that the introduction of the depth information improve the quality of object recognition. Three different objects of the pitcher class are shown in Figure 6. As we see, there are great differences within such class. 3D SIFT achieves ORR with 96.67% accuracy, much superior to the 70% obtained with PFHRGB. Apple and tomato displayed in Figure 5 look highly similar even if they belong to two distinct classes. 3D SIFT provides much better ORR than the other descriptors. As shown in Table II, our GOR method based on feature-level fusion of 2D and 3D SIFT offer better robustness to intra-class variations and inter-class similarities, and 3D SIFT gives higher accuracy than the other single descriptors.

### B.4 Robustness to changes of the angle of view

In this experiment, we evaluate the performance of our GOR method when applied under different observation conditions, more precisely when the objects are observed under three very distinct angles of view (30 deg, 45 deg and 60 deg). Training samples are the same as the Experiment 1. Randomly select 60 objects from each view to be as the test samples. So for each view, there are 360 test samples from 6 categories. The experimental results are shown in Fig. 7.

From Fig. 7, one sees that ORR with 3D SIFT is relatively accurate and stable compared with PFHRGB descriptor. The direct feature-level fusion strategy (with  $ORR > 90\%$ ) offers much better ORR than using the best single descriptor, which indicates that the combination of 2D and 3D SIFT is effective

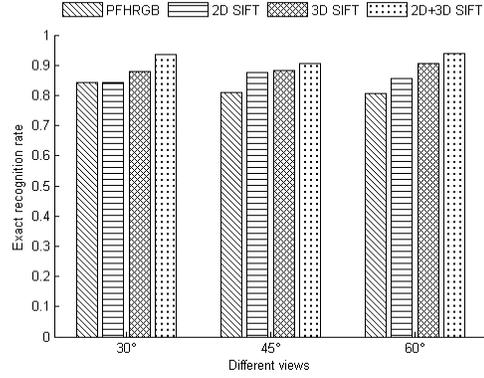

Fig. 7: ORR Performances under 3 angles of view.

and robust for category recognition even under very distinct angles of view.

### B.5 Robustness to size scaling

The training samples are the same as in the first experiment. To evaluate the robustness of our method to size scaling (zooming), the test samples are zoomed out to 1/2, 1/3 and 1/4. As shown in Table III.

Feature descriptor	PFHRGB	2D SIFT	3D SIFT	2D+3D SIFT
ORR (no Zoom)	84.17	88.06	91.11	93.06
ORR (Zoom=1/2)	74.44	77.50	76.67	82.78
ORR (Zoom=1/3)	63.33	64.17	65.28	68.89
ORR (Zoom=1/4)	61.39	46.94	61.67	63.05

TABLE III: Averaged ORR (in %) for different zoomings.

As one sees in Table III, our GOR method with fusion is superior to the algorithm based on single descriptor. However, the ORR of each feature descriptor has decreased. Especially when zoomed to 1/4, the accuracy of ORR with 2D SIFT is only 46.94%. The main reason is that part of the images, such as apple (whose original size is only  $84 \times 82$ ) after scaling, reduces the number of useful keypoints. The feature-level fusion algorithm still provides an averaged ORR of 63.05%.

### B.6 Computational time evaluation

The computational times (CT) of the different feature descriptors have been evaluated with an i7-3770@3.4GHz CPU, under x64 Win7 operating system and are shown in Table IV. The training and test samples are the same as in the first experiment. Because the Point cloud model contains a larger amount of data and richer information than image, therefore CT using point cloud is relatively long, which is normal. The largest proportion of CT in the whole recognition process is the feature extraction and description. 3D SIFT includes keypoints detection and description. If the points' number of the object is  $n$ , the time complexity of keypoints detection is  $O(octaves \cdot scale \cdot k \cdot n)$ . Because the pyramid layers  $octaves$ , scale of each layer  $scale$  and neighborhood of key points  $k$  are constant, the time complexity is  $O(n)$ . For the detected  $m$  keypoints, the time complexity of calculating the descriptors

of the key points is  $O(mn)$ . So the time complexity of 3D SIFT is  $O(mn + n)$ , ignoring lower-order item, the time complexity is  $O(mn)$ . As seen in Table IV, the CT of 3D SIFT has diminished of 34.75% w.r.t. PFHRGB, and the CT performance with fusion of 2D and 3D SIFT turns out to be faster (22.07%) than PFHRGB, and the ORR performance is substantially improved.

Feature descriptors	CT of 360 test samples (in s)	CT of each test sample (in s)
PFHRGB	3404.628	9.4573
3D SIFT	2221.608	6.1711
2D+3D SIFT	2653.272	7.3702

TABLE IV: Computational times for feature descriptors.

#### IV. CONCLUSIONS

Because there are many complex objects in the real scenes we observe in the nature and because of possible large intra-class variations and high inter-class similarities, the generic object recognition (GOR) task is very hard to achieve in general. In this paper we have proposed a new GOR method based on 2D and 3D SIFT descriptors that allows to calculate multiple feature vectors which are combined with different strategies, and feed SVM classifier for making object recognition. The evaluation of the performances based on real open-datasets has shown the superiority of our new 3D SIFT descriptor adapted for point cloud with respect to the existing 3D features such as PFHRGB. Our GOR method based on feature fusion of 2D and 3D SIFT works better than the one using best single feature. For now, if the environment substantially changes, we have to retrain the system. To overcome this problem we will also consider background segmentation within GOR in future works. Also, we would like to reduce the computational time needed for feature extraction and description in maintaining good recognition rate, and we want to explore more feature fusion strategies to improve (if possible) the recognition performances.

**Abstract**—In this paper, we present a method to estimate the quality (trustfulness) of the solutions of the classical optimal data association (DA) problem associated with a given source of information (also called a criterion). We also present a method to solve the multi-criteria DA problem and to estimate the quality of its solution. Our approach is new and mixes classical algorithms (typically Murty’s approach coupled with Auction) for the search of the best and the second best DA solutions, and belief functions (BF) with PCR6 (Proportional Conflict Redistribution rule # 6) combination rule drawn from DSMT (Dezert-Smarandache Theory) to establish the quality matrix of the global optimal DA solution. In order to take into account the importances of criteria in the fusion process, we use weighting factors which can be derived by different manners (ad-hoc choice, quality of each local DA solution, or inspired by Saaty’s Analytic Hierarchy Process (AHP)). A simple complete example is provided to show how our method works and for helping the reader to verify by him or herself the validity of our results.

**Keywords:** Data association, Multi-criteria analysis, belief functions, PCR6, DSMT.

## I. INTRODUCTION

Efficient algorithms for modern multisensor-multitarget tracking (MS-MTT) systems [1], [2] require to estimate and predict the states (position, velocity, etc) of the targets evolving in the surveillance area covered by a set of sensors. These estimation and prediction are based on sensors measurements and dynamical models assumptions. In the monosensor context, MTT requires classically to solve the data association (DA) problem to associate the available measurements at a given time with the predicted states of the targets to update their tracks using filtering techniques (Kalman filter, Particle filter, etc). In the multisensor MTT context, we need to solve more difficult multi-dimensional assignment problems under constraints. Fortunately, efficient algorithms have been developed in the operational research and tracking communities for formalizing and solving these optimal assignments problems (see the related references detailed in the sequel).

Before going further, it is necessary to recall briefly the basis of DA problem and the methods to solve it. This problem can be formulated as follows: We have  $m > 1$  targets  $T_i$

( $i = 1, \dots, m$ ), and  $n > 1$  measurements<sup>1</sup>  $z_j$  ( $j = 1, \dots, n$ ) at a given time  $k$ , and a  $m \times n$  rewards (gain/payoff) matrix  $\Omega = [\omega(i, j)]$  whose elements  $\omega(i, j) \geq 0$  represent the payoff (usually homogeneous to the likelihood) of the association of target  $T_i$  with measurement  $z_j$ , denoted  $(T_i, z_j)$ . The data association problem consists in finding the global optimal assignment of the targets with some measurements by maximizing<sup>2</sup> the overall gain in such a way that no more than one target is assigned to a measurement, and reciprocally.

Without loss of generality, we can assume  $\omega(i, j) \geq 0$  because if some elements  $\omega(i, j)$  of  $\Omega$  were negative, we can always add the constant value<sup>3</sup> to all elements of  $\Omega$  to work with a new payoff matrix  $\Omega' = [\omega'(i, j)]$  having all elements  $\omega'(i, j) \geq 0$ , and we get same optimal assignment solution with  $\Omega$  and with  $\Omega'$ . Moreover, we can also assume without loss of generality  $m \leq n$  because otherwise we can always swap the roles of targets and measurements in the mathematical problem definition by working directly with  $\Omega^t$  instead, where the superscript  $t$  denotes the transposition of the matrix. The optimal assignment problem consists of finding the  $m \times n$  binary association matrix  $\mathbf{A} = [a(i, j)]$  which maximizes the global rewards

$$R(\Omega, \mathbf{A}) \triangleq \sum_{i=1}^m \sum_{j=1}^n \omega(i, j) a(i, j), \quad (1)$$

$$\text{subject to } \begin{cases} \sum_{j=1}^n a(i, j) = 1 & (i = 1, \dots, m), \\ \sum_{i=1}^m a(i, j) \leq 1 & (j = 1, \dots, n), \\ a(i, j) \in \{0, 1\}. \end{cases} \quad (2)$$

The association indicator value  $a(i, j) = 1$  means that the corresponding target  $T_i$  and measurement  $z_j$  are associated, and  $a(i, j) = 0$  means that they are not associated ( $i = 1, \dots, m$  and  $j = 1, \dots, n$ ).

<sup>1</sup>In a multi-sensor context targets can be replaced by tracks provided by a given tracker associated with a type of sensor, and measurements can be replaced by another tracks set. In different contexts, possible equivalents are assigning personnel to jobs or assigning delivery trucks to locations.

<sup>2</sup>In some problems, the matrix  $\Omega = [\omega(i, j)]$  represents a cost matrix whose elements are the negative log-likelihood of association hypotheses. In this case, the data association problems consists in finding the best assignment that minimizes the overall cost.

<sup>3</sup>equals to the absolute value of the minimum of  $\Omega$ .

The solution of the optimal assignment problem stated in (1)–(2) is well reported in the literature and several efficient methods have been developed in the operational research and tracking communities to solve it. The most well-known algorithms are Kuhn-Munkres (or Hungarian) algorithm [3], [4] and its extension to rectangular matrices proposed by Bourgeois and Lassalle in [5], Jonker-Volgenant method [6], and Auction [7]. More sophisticated methods using Murty’s method [8], and some variants [9], [10], [11], [12], [13], [14], [15], are also able to provide not only the best assignment, but also the  $m$ -best assignments. We will not present in details all these classical methods because they have been already well reported in the literature [16], [17].

The purpose of this paper is to propose a solution for two important problems related with the aforementioned Data Association issue:

• **Problem 1 (mono-criterion):** Suppose that the DA reward  $\Omega_1$  has been established based on a unique criterion  $C_1$  then we want to evaluate the quality<sup>4</sup> of each association (pairing) provided in the optimal solution by one of the aforementioned algorithms. The choice of the algorithm does not matter as soon as they are able to provide the optimal DA solution represented by a binary matrix  $\mathbf{A}_1$  (assumed to be unique here for convenience). So based on  $\Omega_1$  and  $\mathbf{A}_1$ , we want to estimate the quality matrix  $\mathbf{Q}_1$  of the optimal pairing solutions given in  $\mathbf{A}_1$ . This quality matrix will be useful to select optimal association pairings that have sufficient quality to be used to update the tracking filters, and not to use the optimal data associations that have a poor quality, which will save computational time and avoid to potentially degrade tracking performances.

• **Problem 2 (multi-criteria):** We assume that we have different Rewards matrices  $\Omega_1, \dots, \Omega_K$  ( $K > 1$ ), established from different criteria from which we can draw optimal DA solutions  $\mathbf{A}_1, \dots, \mathbf{A}_K$  with their corresponding quality matrices  $\mathbf{Q}_1, \dots, \mathbf{Q}_K$  (obtained by the method used for solving Problem 1). We assume that each criterion  $C_k$ ,  $k = 1, \dots, K$  has its own importance with respect to the others which is expressed either by a given relative importance  $K \times K$  matrix  $\mathbf{M}$ , or directly by a weighting  $M \times 1$  vector  $\mathbf{w}$ . The problem 2 consists in finding the optimal (i.e. the one generating the best global quality) DA solution based on all information drawn from the independent multiple criteria we have, that is from  $\mathbf{Q}_1, \dots, \mathbf{Q}_K$  and  $\mathbf{M}$  (or  $\mathbf{w}$ ) in a well-justified and comprehensive manner.

This paper is organized as follows: in section 2 we present a method for solving problem 1 which uses both 1st-best and 2nd-best DA solutions provided by Murty’s algorithm. Our method is based on Belief Functions (BF), the Proportional Conflict Redistribution fusion rule #6 (PCR6) developed in Dezert-Smarandache Theory (DSMT) framework [19], and the pignistic probability transform. Section 3, proposes a solution

<sup>4</sup>In this paper, the quality of a pairing of the optimal DA solution refers to a confidence score which corresponds to a degree of trustfulness one grants to this pairing for taking the decision to use it, or not.

for Problem 2 exploiting Saaty’s AHP method, BF and also Murty’s algorithm. Section 4 presents a full simple detailed example to show how the method works for readers who want to check by themselves our results. Section 5 will conclude this paper with perspectives.

## II. SOLUTION OF PROBLEM 1 (MONO-CRITERION)

This solution has already been addressed in details in [21] and we will just briefly present here the main ideas for making this paper self containing. In problem 1, we want to establish a confidence level (i.e. a quality indicator) of the pairings of the optimal data association solution. More precisely, we are searching for an answer to the question: how to measure the quality of the pairings  $a(i, j) = 1$  provided in the optimal assignment solution  $\mathbf{A}$ ? The necessity to establish a quality indicator is motivated by the following three main practical reasons:

- 1) In some practical tracking environment with the presence of clutter, some association decisions ( $a(i, j) = 1$ ) are doubtful. For these unreliable associations, it is better to wait for new information (measurements) instead of applying the hard data association decision, and making potentially serious association mistakes.
- 2) In some multisensor systems, it can be also important to save energy consumption for preserving a high autonomy of the system. For this goal, only the most trustful specific associations provided in the optimal assignment have to be used instead of all of them.
- 3) The best optimal assignment solution is not necessarily unique. In such situation, the establishment of quality indicators may help in selecting one particular optimal assignment solution among multiple possible choices.

It is worth noting that the 1st-best, as well as the 2nd-best, optimal assignment solutions are unfortunately not necessarily unique. Therefore, we need to take into account the possible multiplicity of assignments in the analysis of the problem. The multiplicity index of the best optimal assignment solution is denoted  $\beta_1 \geq 1$ , and the multiplicity index of the 2nd-best optimal assignment solution is denoted  $\beta_2 \geq 1$ , and we will denote the sets of corresponding assignment matrices by  $\mathcal{A}_1 = \{\mathbf{A}_1^{(k_1)}, k_1 = 1 \dots, \beta_1\}$  and by  $\mathcal{A}_2 = \{\mathbf{A}_2^{(k_2)}, k_2 = 1 \dots, \beta_2\}$ . Here are three simple examples with different multiplicities in solutions:

**Example 1:** If we take  $\Omega = \begin{bmatrix} 8 & 1 & 2 \\ 5 & 3 & 3 \end{bmatrix}$ , then  $\beta_1 = 2$  and  $\beta_2 = 1$  because the 1st best and 2nd best DA solutions are

$$\mathbf{A}_1^{k_1=1} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix}, \mathbf{A}_1^{k_1=2} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \mathbf{A}_2 = \begin{bmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \end{bmatrix}.$$

**Example 2:** If we take  $\Omega = \begin{bmatrix} 6 & 3 & 9 \\ 1 & 4 & 1 \end{bmatrix}$ , then  $\beta_1 = 1$  and  $\beta_2 = 2$  because the 1st best and 2nd best DA solutions are

$$\mathbf{A}_1 = \begin{bmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \end{bmatrix}, \mathbf{A}_2^{k_2=1} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix}, \mathbf{A}_2^{k_2=2} = \begin{bmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \end{bmatrix}.$$

**Example 3:** If we take  $\Omega = \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \end{bmatrix}$ , then  $\beta_1 = 2$  and  $\beta_2 = 2$  because the 1st best and 2nd best DA solutions are

$$\mathbf{A}_1^{k_1=1} = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad \mathbf{A}_1^{k_1=2} = \begin{bmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \end{bmatrix}, \\ \mathbf{A}_2^{k_2=1} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad \mathbf{A}_2^{k_2=2} = \begin{bmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \end{bmatrix}.$$

To establish the quality of the specific associations (pairings)  $(i, j)$  satisfying  $a_1(i, j) = 1$  belonging to the optimal assignment matrix  $\mathbf{A}_1$ , we propose to use both  $\mathbf{A}_1$  and 2nd-best assignment solution  $\mathbf{A}_2$ . The basic idea is to use the values  $a_1(i, j) = 1$  in the best, and  $a_2(i, j)$  in the 2nd-best assignments to identify the change (if any) of the optimal pairing  $(i, j)$ . In fact, we assume<sup>5</sup> that higher quality of an entry in a quality matrix suggests that its association in an optimal solution is more stable across those good solutions. The connection between the stability of an association across the good solutions and the stability over an error in measurement is done through the components of the reward matrices (the inputs of our method) which must take into account the measurement uncertainties. Based on this assumption, our quality indicator will be defined using both the stability of the pairing and its relative impact in the global reward. This proposed method works also when the 2nd-best assignment solution  $\mathbf{A}_2$  is not unique (as shown in examples 2 and 3). Our method helps to select the best (most trustful) optimal assignment in case of multiplicity of  $\mathbf{A}_1$  matrices. We do not claim that the definition of the quality matrix proposed in this work is the best proposal. However, we propose a new comprehensive way of solving this problem from a practical standpoint.

To take into account efficiently the reward values of each specific association given in the best assignment  $\mathbf{A}_1$  and in the 2nd-best assignment  $\mathbf{A}_2^{k_2}$  for estimating the quality of DA solutions, we propose to use the following construction of quality indicators depending on the type of matching:

- When  $a_1(i, j) = a_2^{k_2}(i, j) = 0$ , one has full agreement on “non-association”  $(T_i, z_j)$  in  $\mathbf{A}_1$  and in  $\mathbf{A}_2^{k_2}$  and this non-association  $(T_i, z_j)$  has no impact on the global rewards  $R_1(\Omega, \mathbf{A}_1)$  and  $R_2(\Omega, \mathbf{A}_2^{k_2})$ , and it will be useless. Therefore, we can set its quality arbitrarily to any arbitrary value, typically we take  $q^{k_2}(i, j) = 0$  because these values are not useful at all for the application (i.e. tracking) standpoint.
- When  $a_1(i, j) = a_2^{k_2}(i, j) = 1$ , one has a full agreement on the association  $(T_i, z_j)$  in  $\mathbf{A}_1$  and in  $\mathbf{A}_2^{k_2}$ . his association  $(T_i, z_j)$  has however different impacts in the global rewards values  $R_1(\Omega, \mathbf{A}_1)$  and  $R_2(\Omega, \mathbf{A}_2^{k_2})$ . To qualify the quality

<sup>5</sup>This assumption has however not been proven formally yet and its validity is a challenging open-question left for future research works.

of this association  $(T_i, z_j)$ , we define the two basic belief assignments (BBA's) on  $X \triangleq (T_i, z_j)$  and  $X \cup \neg X$  (the ignorance), for  $s = 1, 2$  as follows:

$$\begin{cases} m_s(X) = a_s(i, j) \cdot \omega(i, j) / R_s(\Omega, \mathbf{A}_s), \\ m_s(X \cup \neg X) = 1 - m_s(X). \end{cases} \quad (3)$$

Applying the conjunctive fusion rule (here one has no conflicting mass), we get

$$\begin{cases} m(X) = m_1(X)m_2(X) + m_1(X)m_2(X \cup \neg X) \\ \quad + m_1(X \cup \neg X)m_2(X), \\ m(X \cup \neg X) = m_1(X \cup \neg X)m_2(X \cup \neg X). \end{cases} \quad (4)$$

Applying the pignistic transformation<sup>6</sup> [20], we get finally  $BetP(X) = m(X) + \frac{1}{2} \cdot m(X \cup \neg X)$  and  $BetP(\neg X) = \frac{1}{2} \cdot m(X \cup \neg X)$ . Therefore, we choose as quality indicator for the association  $(T_i, z_j)$  the value  $q^{k_2}(i, j) \triangleq BetP(X) = m(X) + \frac{1}{2} \cdot m(X \cup \neg X)$ .

- When  $a_1(i, j) = 1$  and  $a_2^{k_2}(i, j) = 0$ , one has a disagreement (conflict) on the association  $(T_i, z_j)$  in  $\mathbf{A}_1$  and in  $(T_i, z_{j_2})$  in  $\mathbf{A}_2^{k_2}$ , where  $j_2$  is the measurement index such that  $a_2(i, j_2) = 1$ . To qualify the quality of this non-matching association  $(T_i, z_j)$ , we define the two following basic belief assignments (BBA's) of the propositions  $X \triangleq (T_i, z_j)$  and  $Y \triangleq (T_i, z_{j_2})$

$$\begin{cases} m_1(X) = a_1(i, j) \cdot \frac{\omega(i, j)}{R_1(\Omega, \mathbf{A}_1)}, \\ m_1(X \cup Y) = 1 - m_1(X), \end{cases} \quad (5)$$

and

$$\begin{cases} m_2(Y) = a_2(i, j_2) \cdot \frac{\omega(i, j_2)}{R_2(\Omega, \mathbf{A}_2^{k_2})}, \\ m_2(X \cup Y) = 1 - m_2(Y). \end{cases} \quad (6)$$

Applying the conjunctive fusion rule, we get  $m(X \cap Y = \emptyset) = m_1(X)m_2(Y)$  and

$$\begin{cases} m(X) = m_1(X)m_2(X \cup Y), \\ m(Y) = m_1(X \cup Y)m_2(Y), \\ m(X \cup Y) = m_1(X \cup Y)m_2(X \cup Y). \end{cases} \quad (7)$$

Because we need to work with a normalized combined BBA, we can choose different rules of combination (say either Dempster-Shafer's rule, Dubois-Prade's rule, Yager's rule [19], etc). In this work, we propose to use the Proportional Conflict Redistribution rule no. 6 (PCR6) proposed originally in DSmt framework [19] because it has been proved very efficient in practice [28], [29]. Hence with PCR6, we get:

$$\begin{cases} m(X) = m_1(X)m_2(X \cup Y) + m_1(X) \cdot \frac{m_1(X)m_2(Y)}{m_1(X)+m_2(Y)}, \\ m(Y) = m_1(X \cup Y)m_2(Y) + m_2(X) \cdot \frac{m_1(X)m_2(Y)}{m_1(X)+m_2(Y)}, \\ m(X \cup Y) = m_1(X \cup Y)m_2(X \cup Y). \end{cases} \quad (8)$$

Applying the pignistic probability transformation, we get finally  $BetP(X) = m(X) + \frac{1}{2} \cdot m(X \cup Y)$  and

<sup>6</sup>We have chosen here BetP for its simplicity and because it is widely known, but DSmtP could be used instead for expecting better performances [19].

$BetP(Y) = m(Y) + \frac{1}{2} \cdot m(X \cup Y)$ . Therefore, we choose the quality indicators as follows:  $q^{k_2}(i, j) = BetP(X)$ , and  $q^{k_2}(i, j_2) = BetP(Y)$ .

The absolute quality factor  $Q_{abs}(\mathbf{A}_1)$  of the optimal assignment given in  $\mathbf{A}_1$  conditioned by  $\mathbf{A}_2^{k_2}$ , for any  $k_2 \in \{1, 2, \dots, \beta_2\}$  is defined as

$$Q_{abs}(\mathbf{A}_1, \mathbf{A}_2^{k_2}) \triangleq \sum_{i=1}^m \sum_{j=1}^n a_1(i, j) q^{k_2}(i, j). \quad (9)$$

The absolute average quality factor  $Q_{aver}(\mathbf{A}_1)$  per association of the optimal assignment given in  $\mathbf{A}_1$  conditioned by  $\mathbf{A}_2^{k_2}$ , for any  $k_2 \in \{1, 2, \dots, \beta_2\}$  is defined by

$$Q_{aver}(\mathbf{A}_1, \mathbf{A}_2^{k_2}) = \frac{1}{m} \cdot Q_{abs}(\mathbf{A}_1, \mathbf{A}_2^{k_2}). \quad (10)$$

where  $m$  is the number of "1" in the optimal DA matrix  $\mathbf{A}_1$  (i.e. the number of targets).

To take into account the eventual multiplicities (when  $\beta_2 > 1$ ) of the 2nd-best assignment solutions  $\mathbf{A}_2^{k_2}$ ,  $k_2 = 1, 2, \dots, \beta_2$ , we need to combine the  $Q_I(\mathbf{A}_1, \mathbf{A}_2^{k_2})$  values. Several methods can be used for this, in particular we can use either:

– **A weighted averaging approach:** The quality indicator components  $q(i, j)$  of the quality matrix  $\mathbf{Q}$  are then obtained by averaging the qualities obtained from each comparison of  $\mathbf{A}_1$  with  $\mathbf{A}_2^{k_2}$ . More precisely, one will take

$$q(i, j) \triangleq \sum_{k_2=1}^{\beta_2} w(\mathbf{A}_2^{k_2}) q^{k_2}(i, j), \quad (11)$$

where  $w(\mathbf{A}_2^{k_2})$  is a weighting factor in  $[0, 1]$ , such that  $\sum_{k_2=1}^{\beta_2} w(\mathbf{A}_2^{k_2}) = 1$ . Since all assignments  $\mathbf{A}_2^{k_2}$  have the same global reward value  $R_2$ , then we suggest to take  $w(\mathbf{A}_2^{k_2}) = 1/\beta_2$ . A more elaborate method would consist of using the quality indicator of  $\mathbf{A}_2^{k_2}$  based on the 3rd-best solution, which can be itself computed from the quality of the 3rd assignment solution based on the 4th-best solution, and so on by a similar mechanism.

– **A belief-based approach:** (see [18] for basics on belief functions): A second method would express the quality by a belief interval  $[q^{\min}(i, j), q^{\max}(i, j)]$  in  $[0, 1]$  instead of single real number  $q(i, j)$  in  $[0, 1]$ . More precisely, one can compute the belief and plausibility bounds of the quality by taking  $q^{\min}(i, j) \equiv Bel(a_1(i, j)) = \min_{k_2} q^{k_2}(i, j)$  and  $q^{\max}(i, j) \equiv Pl(a_1(i, j)) = \max_{k_2} q^{k_2}(i, j)$ . Hence for each possible pair  $(i, j)$ , one can define a basic belief assignment (BBA)  $m_{ij}(\cdot)$  on the frame of discernment  $\Theta \triangleq \{T = \text{trustful}, -T = \text{not trustful}\}$ , which characterizes the quality of the pairing  $(i, j)$  in the optimal assignment solution  $\mathbf{A}_1$ , as follows

$$\begin{cases} m_{ij}(T) = q^{\min}(i, j), \\ m_{ij}(-T) = 1 - q^{\max}(i, j), \\ m_{ij}(T \cup -T) = q^{\max}(i, j) - q^{\min}(i, j). \end{cases} \quad (12)$$

Because only the optimal associations<sup>7</sup>  $(i, j)$  such that  $a_1(i, j) = 1$  are useful in tracking algorithms to update the tracks, we do not need to pay attention (compute and store) the qualities of components  $(i, j)$  such that  $a_1(i, j) = 0$ . In fact all components  $(i, j)$  such that  $a_1(i, j) = 0$  should be set to zero by default in  $\mathbf{Q}$  matrix.

**Example 4:** Let's consider the rewards matrix

$$\mathbf{\Omega} = \begin{bmatrix} 1 & 11 & 45 & 30 \\ 17 & 8 & 38 & 27 \\ 10 & 14 & 35 & 20 \end{bmatrix}.$$

We get one 1st best ( $\beta_1 = 1$ ) and four 2nd best ( $\beta_2 = 4$ ) DA solutions with their respective qualities as follows:

$$\mathbf{A}_1 = \begin{bmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 \end{bmatrix} \Rightarrow R_1(\mathbf{\Omega}, \mathbf{A}_1) = 86,$$

$$\mathbf{A}_2^{k_2=1} = \begin{bmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \end{bmatrix} \Rightarrow R_2(\mathbf{\Omega}, \mathbf{A}_2^{k_2=1}) = 82,$$

$$\mathbf{Q}(\mathbf{A}_1, \mathbf{A}_2^{k_2=1}) \approx \begin{bmatrix} 0 & 0 & 0.59 & 0 \\ 0 & 0 & 0 & 0.41 \\ 0 & 0.65 & 0 & 0 \end{bmatrix},$$

$$\mathbf{A}_2^{k_2=2} = \begin{bmatrix} 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \Rightarrow R_2(\mathbf{\Omega}, \mathbf{A}_2^{k_2=2}) = 82,$$

$$\mathbf{Q}(\mathbf{A}_1, \mathbf{A}_2^{k_2=2}) \approx \begin{bmatrix} 0 & 0 & 0.89 & 0 \\ 0 & 0 & 0 & 0.56 \\ 0 & 0.45 & 0 & 0 \end{bmatrix},$$

$$\mathbf{A}_2^{k_2=3} = \begin{bmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \end{bmatrix} \Rightarrow R_2(\mathbf{\Omega}, \mathbf{A}_2^{k_2=3}) = 82,$$

$$\mathbf{Q}(\mathbf{A}_1, \mathbf{A}_2^{k_2=3}) \approx \begin{bmatrix} 0 & 0 & 0.89 & 0 \\ 0 & 0 & 0 & 0.76 \\ 0 & 0.52 & 0 & 0 \end{bmatrix},$$

$$\mathbf{A}_2^{k_2=4} = \begin{bmatrix} 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} \Rightarrow R_2(\mathbf{\Omega}, \mathbf{A}_2^{k_2=4}) = 82,$$

$$\mathbf{Q}(\mathbf{A}_1, \mathbf{A}_2^{k_2=4}) \approx \begin{bmatrix} 0 & 0 & 0.59 & 0 \\ 0 & 0 & 0 & 0.56 \\ 0 & 0.35 & 0 & 0 \end{bmatrix},$$

Note that the absolute quality factors are :

$$\begin{aligned} Q_{abs}(\mathbf{A}_1, \mathbf{A}_2^{k_2=1}) &\approx 1.66, & Q_{abs}(\mathbf{A}_1, \mathbf{A}_2^{k_2=2}) &\approx 1.91, \\ Q_{abs}(\mathbf{A}_1, \mathbf{A}_2^{k_2=3}) &\approx 2.19, & Q_{abs}(\mathbf{A}_1, \mathbf{A}_2^{k_2=4}) &\approx 1.51. \end{aligned}$$

Therefore, we can see that

$$\begin{aligned} Q_{abs}(\mathbf{A}_1, \mathbf{A}_2^{k_2=3}) &> Q_{abs}(\mathbf{A}_1, \mathbf{A}_2^{k_2=2}) \\ &> Q_{abs}(\mathbf{A}_1, \mathbf{A}_2^{k_2=1}) > Q_{abs}(\mathbf{A}_1, \mathbf{A}_2^{k_2=4}), \end{aligned}$$

<sup>7</sup>found using Murty's algorithm.

which makes perfectly sense because  $\mathbf{A}_1$  has more matching pairings with  $\mathbf{A}_2^{k_2=3}$  than with others 2nd-best assignments  $\mathbf{A}_2^{k_2}$  ( $k_2 \neq 3$ ). These pairings have also the strongest impact in the global reward value. Therefore, the quality matrix  $\mathbf{Q}$  differentiates the quality of each pairing in the optimal assignment  $\mathbf{A}_1$  as expected. This method provides an effective and comprehensive solution to estimate the quality of each specific association provided in the optimal assignment solution  $\mathbf{A}_1$ . The averaged qualities per association are:

$$\begin{aligned} Q_{aver}(\mathbf{A}_1, \mathbf{A}_2^{k_2=1}) &\approx 0.55, & Q_{aver}(\mathbf{A}_1, \mathbf{A}_2^{k_2=2}) &\approx 0.63, \\ Q_{aver}(\mathbf{A}_1, \mathbf{A}_2^{k_2=3}) &\approx 0.73, & Q_{aver}(\mathbf{A}_1, \mathbf{A}_2^{k_2=4}) &\approx 0.50. \end{aligned}$$

The global quality matrix is then given by (using the averaging approach)

$$\begin{aligned} \mathbf{Q}(\mathbf{A}_1, \mathcal{A}_2) &= \frac{1}{\beta_2} \sum_{k_2=1}^{\beta_2} \mathbf{Q}(\mathbf{A}_1, \mathbf{A}_2^{k_2}) \\ &\approx \begin{bmatrix} 0 & 0 & 0.74 & 0 \\ 0 & 0 & 0 & 0.57 \\ 0 & 0.49 & 0 & 0 \end{bmatrix}. \end{aligned}$$

The global quality indexes  $Q_{abs}(\mathbf{A}_1, \mathcal{A}_2)$  and  $Q_{aver}(\mathbf{A}_1, \mathcal{A}_2)$  are then approximately equal to 1.8 and 0.6 respectively.

One can also improve the estimation of the quality matrix by using the absolute quality factor of each solution  $\mathbf{Q}(\mathbf{A}_1, \mathbf{A}_2^{k_2})$ , for  $k_2 = 1, \dots, \beta_2$  to define the normalized weighting factors as follows:

$$\mathbf{w} = [w_{k_2}, k_2 = 1, \dots, \beta_2]',$$

with  $w_{k_2} \triangleq \frac{Q_{abs}(\mathbf{A}_1, \mathbf{A}_2^{k_2})}{K}$ , and where the normalization factor  $K$  is given by  $K = \sum_{k_2=1}^{\beta_2} Q_{abs}(\mathbf{A}_1, \mathbf{A}_2^{k_2})$ . In this example, we get the weights

$$\begin{aligned} \mathbf{w} &= [w_1 \ w_2 \ w_3 \ w_4]' \approx \left[ \frac{1.66}{7.27} \ \frac{1.91}{7.27} \ \frac{2.19}{7.27} \ \frac{1.51}{7.27} \right]' \\ &= [0.2283 \ 0.2627 \ 0.3012 \ 0.2077]'. \end{aligned}$$

The global quality matrix is then given by (using the averaging approach)

$$\begin{aligned} \mathbf{Q}(\mathbf{A}_1, \mathcal{A}_2) &= \sum_{k_2=1}^{\beta_2} w_{k_2} \mathbf{Q}(\mathbf{A}_1, \mathbf{A}_2^{k_2}) \\ &\approx \begin{bmatrix} 0 & 0 & 0.76 & 0 \\ 0 & 0 & 0 & 0.58 \\ 0 & 0.49 & 0 & 0 \end{bmatrix}. \end{aligned}$$

If we prefer to use the Belief Interval Measure (BIM) instead of the previous averaging approach, we will get in this example the following imprecise qualities values:

Optimal. assignments	BIM
(1, 3)	$\approx [0.59, 0.89]$
(2, 4)	$\approx [0.41, 0.76]$
(3, 2)	$\approx [0.35, 0.65]$

Based on the comparisons of (pessimistic) lower bounds, or (optimistic) upper bounds of BIM, we observe that we get

a consistent ordering of the qualities of the optimal solutions (same ordering as with the averaging method).

### III. SOLUTION OF THE 2ND PROBLEM (MULTI-CRITERIA)

In this section, we evaluate the global DA association solution, with estimation of its quality, based on the knowledge of the qualities of multiple optimal DA solutions established separately based on distinct association criteria  $C_k$ ,  $k = 1, \dots, K$ . More precisely, given the set of quality matrices  $\mathbf{Q}^k$  ( $k = 1, \dots, K$ ) defined by the components  $q^k(i, j)$  according to Eq.(11), how to establish the global optimal DA solution with its overall quality matrix  $\mathbf{Q}$ ? Moreover, we want to take into account the importance of each criteria (when defined) in the establishment of the solution.

In fact this 2nd problem is linked to the previous one and the method developed for solving our first problem will also help to solve this second problem as it will be shown in the following. Our solution is based on four distinct steps:

• **Step 1:** Estimation of the normalized weighting vector  $\mathbf{w}$  of the criteria: Two simple approaches are proposed to establish the normalized criteria ranking (weighting) vector.

- 1) **Direct method:** The weightings factors can be directly established either by an external factors or by the system designer. If these weightings factors are not available, we propose to compute them from the qualities indicators derived by the method used to solve the 1st problem (see the previous section). For example, if we consider  $K$  criteria providing quality factors  $Q_{abs}^k(\mathbf{A}_1(C_k), \mathcal{A}_2(C_k))$ ,  $k = 1, 2, \dots, K$ , then we compute the normalized  $K \times 1$  weighting vector  $\mathbf{w} = [w_1 w_2 \dots w_K]'$  with the  $k$ -th component given by

$$w_k \triangleq \frac{Q_{abs}^k(\mathbf{A}_1(C_k), \mathcal{A}_2(C_k))}{\sum_{j=1}^K Q_{abs}^j(\mathbf{A}_1(C_j), \mathcal{A}_2(C_j))}, \quad (13)$$

where  $Q_{abs}^k(\mathbf{A}_1(C_k), \mathcal{A}_2(C_k))$  is the absolute quality factor obtained from the quality matrix  $\mathbf{Q}^k(\mathbf{A}_1, \mathcal{A}_2)$  of the optimal DA for the criteria  $C_k$ .

- 2) **Saaty's method:** This method is part of Saaty's AHP method widely used for multi-criteria decision analysis in operational research [22], [23], [24], and it has been connected with information fusion and belief functions in [25], [26], [27]. The relative importance of one criterion over another must be expressed by the system designer using a pairwise  $K \times K$  comparison matrix (also called knowledge matrix)  $\mathbf{M} = [m_{pq}]$  where the element  $m_{pq}$  of the matrix defines the importance of criteria  $C_p$  with respect to the criteria  $C_q$ , with  $p, q \in \{1, 2, \dots, K\}$ . For example, see [25] for details, let's consider only  $K = 3$  criteria, if the comparison matrix is given by

$$\mathbf{M} = \begin{bmatrix} (1/1) & (1/3) & (4/1) \\ (3/1) & (1/1) & (5/1) \\ (1/4) & (1/5) & (1/1) \end{bmatrix},$$

it means that the element  $m_{13} = 4/1$  indicates that the criteria  $C_1$  is four times as important as the criteria  $C_3$  for the system designer (or decision-maker), etc. From this pairwise matrix, Saaty demonstrated that the ranking of the priorities of the criteria can be obtained from the normalized eigenvector, denoted  $\mathbf{w}$ , associated with the principal/max eigenvalue of the matrix  $\mathbf{M}$ , denoted  $\lambda$ . In our example, one gets  $\lambda = 3.0857$  and  $\mathbf{w} = [0.2797 \ 0.6267 \ 0.0936]^T$  which shows that  $C_2$  criterion is the most important criterion with the weight 0.6267, then the criterion  $C_1$  is the second most important criterion with weight 0.2797, and finally  $C_3$  criterion is the least important criterion with weight 0.0936.

- **Step 2:** Combined estimation of the qualities of each target association

Once the normalized weighting vector  $\mathbf{w}$  of the criteria has been obtained, we need at first to compute the combined/weighted estimation of the qualities of each target association with the  $n$  available measurements. This is done by building the following  $n \times K$  matrix

$$\mathbf{Q}_i \triangleq [\mathbf{q}_i(C_1) \dots \mathbf{q}_i(C_K)], \quad (14)$$

where each column  $\mathbf{q}_i(C_k)$  of the matrix  $\mathbf{Q}_i$  corresponds to the transpose of the  $i$ -th row of the quality matrix  $\mathbf{Q}^k(\mathbf{A}_1, \mathbf{A}_2)$ .

Then following AHP approach, we multiply this  $n \times K$  matrix  $\mathbf{Q}_i$  by the normalized criteria ranking  $K \times 1$  vector  $\mathbf{w}$  (obtained either from the direct method of Saaty's one) to get the combined estimation of the qualities of each target association. More precisely, for the  $i$ -th target, we obtain the following  $n \times 1$  vector

$$\mathbf{q}_i \triangleq \mathbf{Q}_i \mathbf{w}. \quad (15)$$

- **Step 3:** Search for the optimal global assignment based on combined qualities derived from the criteria.

From the set of  $m$  vectors  $\mathbf{q}_i$  ( $i=1,2,\dots,m$ ) we need to solve now a new optimal DA association problem with the (global)  $m \times n$  rewards matrix defined by

$$\mathbf{\Omega}_G \triangleq [\mathbf{q}_1 \ \mathbf{q}_2 \ \dots \ \mathbf{q}_m]^T. \quad (16)$$

Murty's algorithm is then used again here to get the optimal DA solution(s) providing the best global reward, and to generate also all the 2nd-best solutions that are necessary to estimate its quality in Step 4.

- **Step 4:** Estimation of the quality of the optimal DA solution.

We use the method described in Section 2 for solving the problem 1 to estimate the quality of the optimal DA solution. If several 1st-best DA solutions occur, we choose the solution generating the highest  $Q_{abs}$  quality index.

#### IV. A SIMPLE ILLUSTRATIVE EXAMPLE

For the sake of simplicity, let's consider the following example with  $m = 3$  targets,  $n = 5$  measurements, and 3 criteria  $C_1$ ,  $C_2$  and  $C_3$  associated with the (randomly chosen) rewards matrices:

$$\mathbf{\Omega}(C_1) = \begin{bmatrix} 100 & 20 & 33 & 5 & 27 \\ 11 & 80 & 25 & 37 & 62 \\ 38 & 2 & 24 & 78 & 46 \end{bmatrix},$$

$$\mathbf{\Omega}(C_2) = \begin{bmatrix} 87 & 35 & 43 & 20 & 95 \\ 28 & 83 & 25 & 10 & 29 \\ 10 & 7 & 72 & 41 & 29 \end{bmatrix},$$

$$\mathbf{\Omega}(C_3) = \begin{bmatrix} 25 & 78 & 49 & 60 & 9 \\ 30 & 26 & 79 & 20 & 49 \\ 20 & 20 & 3 & 47 & 81 \end{bmatrix}.$$

##### A. Qualities of optimal data associations

Applying the method described in section 1, we easily obtain the following quality matrices of optimal DA solutions:

- For criterion  $C_1$ , one gets  $\beta_1 = 1$  and  $\beta_2 = 1$ , and the following 1st best and 2nd best DA solutions

$$\mathbf{\Omega}(C_1) \Rightarrow \begin{cases} \mathbf{A}_1 = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \end{bmatrix}, \\ \mathbf{A}_2 = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 & 0 \end{bmatrix}, \end{cases}$$

providing the 1st and 2nd best global rewards  $R(\mathbf{\Omega}(C_1), \mathbf{A}_1) = 258$  and  $R(\mathbf{\Omega}(C_1), \mathbf{A}_2) = 240$ . Applying the method described in Section 2, we obtain the following quality matrix related with the optimal DA based on criterion  $C_1$ :

$$\mathbf{Q}^1 \approx \begin{bmatrix} 0.82 & 0 & 0 & 0 & 0 \\ 0 & 0.52 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0.76 & 0 \end{bmatrix}.$$

- For criterion  $C_2$ , one gets  $\beta_1 = 1$  and  $\beta_2 = 1$ , and the following 1st best and 2nd best DA solutions

$$\mathbf{\Omega}(C_2) \Rightarrow \begin{cases} \mathbf{A}_1 = \begin{bmatrix} 0 & 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \end{bmatrix}, \\ \mathbf{A}_2 = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \end{bmatrix}, \end{cases}$$

providing the 1st and 2nd best global rewards  $R(\mathbf{\Omega}(C_2), \mathbf{A}_1) = 250$  and  $R(\mathbf{\Omega}(C_2), \mathbf{A}_2) = 242$ . Applying the method described in Section 2, we obtain the following quality matrix related with the optimal DA based on criterion  $C_2$ :

$$\mathbf{Q}^2 \approx \begin{bmatrix} 0 & 0 & 0 & 0 & 0.51 \\ 0 & 0.78 & 0 & 0 & 0 \\ 0 & 0 & 0.74 & 0 & 0 \end{bmatrix}.$$

- For criterion  $C_3$ , one gets  $\beta_1 = 1$  and  $\beta_2 = 1$ , and the following 1st best and 2nd best DA solutions

$$\Omega(C_3) \Rightarrow \begin{cases} \mathbf{A}_1 = \begin{bmatrix} 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix}, \\ \mathbf{A}_2 = \begin{bmatrix} 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix}, \end{cases}$$

providing the 1st and 2nd best global rewards  $R(\Omega(C_3), \mathbf{A}_1) = 238$  and  $R(\Omega(C_3), \mathbf{A}_2) = 220$ . Applying the method described in Section 2, we obtain the following quality matrix related with the optimal DA based on criterion  $C_3$ :

$$\mathbf{Q}^3 \approx \begin{bmatrix} 0 & 0.53 & 0 & 0 & 0 \\ 0 & 0 & 0.78 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0.79 \end{bmatrix}.$$

### B. Multicriteria-based DA solution with its quality

- Case 1: If we assume that all criteria have the same weights in the search of optimal DA solution, then we take the normalized weighting vector as  $\mathbf{w} = [1/3 \ 1/3 \ 1/3]'$ . Therefore, the weighted average  $\Omega_G = \sum_{k=1}^{K=3} w_k \mathbf{Q}^k$  of the quality matrices  $\mathbf{Q}^1$ ,  $\mathbf{Q}^2$  and  $\mathbf{Q}^3$  gives us the following rewards matrix

$$\Omega_G \approx \begin{bmatrix} 0.27 & 0.17 & 0 & 0 & 0.17 \\ 0 & 0.43 & 0.26 & 0 & 0 \\ 0 & 0 & 0.25 & 0.25 & 0.26 \end{bmatrix}.$$

Now we solve the DA association problem to maximize the global quality reward using Murty's algorithm and we get the following 1st best and 2nd best DA solutions:

$$\Omega_G \Rightarrow \begin{cases} \mathbf{A}_1 = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix}, \\ \mathbf{A}_2 = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \end{bmatrix}, \end{cases}$$

with the 1st and 2nd best global rewards  $R(\Omega_G, \mathbf{A}_1) \approx 0.97$  and  $R(\Omega_G, \mathbf{A}_2) \approx 0.96$ . Applying the method described in Section II to estimate the quality of this optimal DA solution, we obtain the following quality matrix:

$$\mathbf{Q} \approx \begin{bmatrix} 0.74 & 0 & 0 & 0 & 0 \\ 0 & 0.84 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0.50 \end{bmatrix}.$$

- Case 2: If we use the prior information given by absolute quality indicators to build the normalized weighting vector, we get

$$Q_{abs}^1 = \sum_{i=1}^m \sum_{j=1}^n \mathbf{Q}^1(i, j) \approx 2.11,$$

$$Q_{abs}^2 = \sum_{i=1}^m \sum_{j=1}^n \mathbf{Q}^2(i, j) \approx 2.04,$$

$$Q_{abs}^3 = \sum_{i=1}^m \sum_{j=1}^n \mathbf{Q}^3(i, j) \approx 2.10,$$

and we have  $Q_{abs}^1 + Q_{abs}^2 + Q_{abs}^3 = 6.2672$ . So that, the normalized weights are given by

$$\mathbf{w} = [w_1 \ w_2 \ w_3]' = \left[ \frac{2.1154}{6.2672} \ \frac{2.0426}{6.2672} \ \frac{2.1091}{6.2672} \right]' \approx [0.3375 \ 0.3260 \ 0.3365]'$$

The weighted average  $\Omega_G = \sum_{k=1}^{K=3} w_k \mathbf{Q}^k$  of the quality matrices  $\mathbf{Q}^1$ ,  $\mathbf{Q}^2$  and  $\mathbf{Q}^3$  give us now the following rewards matrix

$$\Omega_G \approx \begin{bmatrix} 0.27 & 0.17 & 0 & 0 & 0.16 \\ 0 & 0.43 & 0.26 & 0 & 0 \\ 0 & 0 & 0.24 & 0.25 & 0.26 \end{bmatrix}.$$

Now we solve the DA association problem to maximize the global quality reward and we get the following 1st best and 2nd best DA solutions:

$$\Omega_G \Rightarrow \begin{cases} \mathbf{A}_1 = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix}, \\ \mathbf{A}_2 = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \end{bmatrix}, \end{cases}$$

with the 1st and 2nd best global rewards  $R(\Omega_G, \mathbf{A}_1) \approx 0.97$  and  $R(\Omega_G, \mathbf{A}_2) \approx 0.96$ . Applying the method described in Section 2 to estimate the quality of this optimal DA solution, we obtain the following quality matrix:

$$\mathbf{Q} \approx \begin{bmatrix} 0.74 & 0 & 0 & 0 & 0 \\ 0 & 0.84 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0.50 \end{bmatrix}.$$

Because the normalized weights based on the absolute quality indicators, in this example, are all close to 1/3, we obtain the result of the multicriteria-based optimal DA and its quality close to what we get when assuming equi-importance of the criteria in the fusion process, which is normal.

To qualify qualitatively the quality of the pairings in the optimal DA solution, we split the quality range [0;1] into three subintervals as follows<sup>8</sup>

$$\begin{aligned} \text{Low quality :} & \quad \text{if } q(i, j) \in [0; 1/3], \\ \text{Medium quality :} & \quad \text{if } q(i, j) \in [1/3; 2/3], \\ \text{High quality :} & \quad \text{if } q(i, j) \in [2/3; 1]. \end{aligned}$$

<sup>8</sup>Of course, other repartitions could be used instead depending on the what would prefer the system designer.

Based on this qualitative scale, we finally get for our example the final multicriteria-based DA solution

$$\mathbf{A}_1 = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix},$$

with the qualitative quality matrix

$$\mathbf{Q}^{qualitative} = \begin{bmatrix} High & - & - & - & - \\ - & High & - & - & - \\ - & - & - & - & Medium \end{bmatrix},$$

where the notation “-” means “that the quality evaluation does not apply”, or is interpreted (by default) as “the worst quality”.

**Remark:** It is worth to note that this approach provides in general not the same results as if one would combine (and weight) directly the original reward matrices of each criterion. In this example, the weighted global reward matrix  $\mathbf{\Omega}_{direct} = \sum_{k=1}^K w_k \mathbf{\Omega}(C_k)$  would be equal to

$$\mathbf{\Omega}_{direct} \approx \begin{bmatrix} 69.07 & 45.39 & 41.75 & 29.31 & 40.85 \\ 22.93 & 61.43 & 44.46 & 22.79 & 47.44 \\ 23.13 & 9.98 & 30.78 & 55.75 & 53.53 \end{bmatrix},$$

corresponding to the quality matrix of optimal DA solution

$$\mathbf{Q}_{direct} \approx \begin{bmatrix} 0.73 & 0 & 0 & 0 & 0 \\ 0 & 0.84 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0.47 & 0 \end{bmatrix}.$$

One sees that these high quality solutions are fully consistent with the high quality solutions of our method. However, the medium quality solution (we get (3,4) pairing from the direct optimal assignment versus (3,5) assignment obtained by our method) mismatch. This reflects an ambiguity in the choice of the assignment of target  $T_3$ . Therefore, such assignment is unreliable because of its low quality, and should not be used to update the track of this target.

## V. CONCLUSION

In this paper, we have proposed two methods based on belief functions for establishing: 1) the quality of pairings given by optimal data association (or assignment) solution using a chosen algorithm (typically Murty’s algorithm coupled with Auction algorithm) with respect to a given criterion, and 2) the quality of the multicriteria-based optimal data association solution. Our methods are independent of the choice of the algorithm used in finding the optimal assignment solution, and, in case of multiple optimal solutions, they provide also a way to select the best optimal assignment solution (the one having the highest absolute quality factor). The methods developed in this paper are general in the sense that they can be applied to different types of association problems corresponding to different sets of constraints. This method can be extended to SD-assignment problems as well. As perspectives, we would like to extend our approach to the n-D assignment context, and then evaluate its performances in a realistic multi-target tracking scenario.

**Abstract**—Grid map offers a useful representation of the perceived world for mobile robotics navigation. It will play a major role for the security (obstacle avoidance) of next generations of terrestrial vehicles, as well as for future autonomous navigation systems. In a grid map, the occupancy of each cell representing a small piece of the surrounding area of the vehicle must be estimated at first from sensors measurements, and then it must also be classified into different classes in order to get a complete and precise perception of the dynamic environment where the vehicle moves. So far, the estimation and the grid map updating have been done using fusion techniques based on the probabilistic framework, or on the classical belief function framework thanks to an inverse model of the sensors and Dempster-Shafer rule of combination. Recently we have shown that PCR6 rule (Proportional Conflict Redistribution rule #6) proposed in DSMT (Dezert-Smarandache) Theory did improve substantially the quality of grid map with respect to other techniques, specially when the quality of available information is low, and when the sources of information appear as conflicting. In this paper, we go further and we analyze the performance of the improved version of PCR6 with Zhang’s degree of intersection. We will show through different realistic scenarios (based on a 4-layers LIDAR sensor) the benefit of using this new rule of combination in a practical application.

**Keywords:** Information fusion, grid map, cell occupancy, perception, belief functions, DSMT, PCR6, ZPCR6.

## I. INTRODUCTION

Occupancy Grids (OG) are often used for intelligent vehicle environment perception and navigation, which requires techniques for data fusion, localization and obstacle avoidance. As OGs manage a representation of the environment that does not make any assumption on the geometrical shape of the detected elements, they provide a general framework to deal with complex perception conditions. In our previous works, we did focus on the use of a multi-echo and multi-layer LIDAR system in order to characterize the dynamic surrounding environment of a vehicle driving in common traffic conditions. The perception strategy involved map estimation and scan grids [1], [2] based either on the classical bayesian framework, or on classical evidential framework based on Dempster-Shafer theory (DST) [3] of belief functions. The map grid acts as a filter that accumulate information and allows to detect moving objects. A comparative analysis of performances of these approaches has already been published recently in [4].

In dynamic environments, it is crucial to have a good modeling of the information flow in the data fusion process

in order to avoid adding wrong implicit prior knowledge that will need time to be forgotten. In this context, evidential OG are particularly interesting to make a good management of the information since it is possible to explicitly make the distinction between non explored and moving cells.

The idea of using the probabilistic framework to estimate the grid occupancy has been popularized by Elfes in his pioneered works in 1990’s [8]. Later, the idea has been extended with the fuzzy logic theory framework by Oriolo et al. [10], and in parallel with the belief function (evidential) framework as well [11]–[15]. Most of the aforementioned research works dealt only with acoustic sensors (i.e SONAR). Recently, DSMT has also been applied for the perception of the environment with acoustic sensors as reported in [16]–[18].

The aim of this paper is to analyze the performance of the improved version of PCR6 taking into account Zhang’s degree of intersection of focal elements (called ZPCR6 rule) which has been presented in details in the companion paper [7] in a realistic perception problem using a 4-layers LIDAR sensor. We show how the environment perception with non acoustic sensors can be done, and compare the performances of different fusion rules (Bayesian, Dempster-Shafer, PCR6 and ZPCR6) in terms of accuracy of grid map estimation.

This paper is organized as follows. After a short presentation of the basics of belief functions and rules of their combination based on DST and DSMT in the next section, we will present the inverse sensor models in section III with the construction of the basic belief assignments (BBA). In section IV, we present an illustrating scenario for environment perception including a mobile object with a platform equipped with a LIDAR, and we compare our new realistic simulation results with those obtained by the probabilistic and the classical belief-based approaches. We will show how static and mobile objects are extracted from the occupancy grid map using digital image processing. Finally, conclusion and outline perspectives are given in section V.

## II. BASICS OF BELIEF FUNCTIONS AND THEIR FUSION

Dempster-Shafer’s theory (DST) of evidence has been developed by Shafer in 1976 from Dempster’s works [3]. DST is known also as the theory of belief functions and it is mainly characterized by a frame of discernment (FoD), sources of evidence represented by basic belief assignment (BBA), belief

(Bel) and plausibility (Pl) functions, and Dempster's rule and denoted DS rule in the sequel<sup>1</sup> of combination. DST has been modified and extended into Dezert-Smarandache theory [6] (DSmT) to work with quantitative or qualitative BBA and to combine the sources of evidence in a more efficient way thanks to new proportional conflict redistribution (PCR) fusion rules – see [19]–[22] for discussion and examples. We briefly recall in the next subsections the basics of the theory of belief functions

### A. Belief functions

Let consider a finite discrete FoD  $\Omega = \{\omega_1, \omega_2, \dots, \omega_n\}$ , with  $n > 1$ , of the fusion problem under consideration and its fusion space  $G^\Omega$  which can be chosen either as the power-set  $2^\Omega$ , the hyper-power set<sup>2</sup>  $D^\Omega$ , or the super-power set  $S^\Omega$  depending on the model that fits with the problem [6]. A BBA associated with a given source of evidence is defined as the mapping  $m(\cdot) : G^\Omega \rightarrow [0, 1]$  satisfying  $m(\emptyset) = 0$  and  $\sum_{A \in G^\Omega} m(A) = 1$ . The quantity  $m(A)$  is called mass of belief of  $A$  committed by the source of evidence. Belief and plausibility functions are defined by

$$\text{Bel}(A) = \sum_{\substack{B \subseteq A \\ B \in G^\Omega}} m(B) \quad \text{and} \quad \text{Pl}(A) = \sum_{\substack{B \cap A \neq \emptyset \\ B \in G^\Omega}} m(B) \quad (1)$$

The degree of belief  $\text{Bel}(A)$  given to a subset  $A$  quantifies the amount of justified specific support to be given to  $A$ , and the degree of plausibility  $\text{Pl}(A)$  quantifies the maximum amount of potential specific support that could be given to  $A$ . If for some  $A \in G^\Omega$ ,  $m(A) > 0$  then  $A$  is called a focal element of the BBA  $m(\cdot)$ . When all focal elements are singletons and  $G^\Omega = 2^\Omega$  then the BBA  $m(\cdot)$  is called a Bayesian BBA [3] and its corresponding belief function  $\text{Bel}(\cdot)$  is homogeneous to a (possibly subjective) probability measure, and one has  $\text{Bel}(A) = P(A) = \text{Pl}(A)$ , otherwise in general one has  $\text{Bel}(A) \leq P(A) \leq \text{Pl}(A)$ ,  $\forall A \in G^\Omega$ . The vacuous BBA representing a totally ignorant source is defined as  $m_v(\Omega) = 1$ .

### B. Fusion rules

Many rules have been proposed in the literature in the past decades (see [6], Vol. 2 for a detailed list of fusion rules) to combine efficiently several distinct sources of evidence represented by the BBA's  $m_1(\cdot)$ ,  $m_2(\cdot)$ ,  $\dots$ ,  $m_s(\cdot)$  ( $s \geq 2$ ) defined on same fusion space  $G^\Omega$ . In this paper, we focus only on DS rule because it has been historically proposed in DST and it is still widely used in applications, and on the PCR rule no. 6 (i.e. PCR6) proposed in DSmT because it provides a very interesting alternative of DS rule, even if PCR6 is more complex to implement in general than DS rule.

In DST framework, the fusion space  $G^\Omega$  equals the power-set  $2^\Omega$  because Shafer's model of the frame  $\Omega$  is assumed, which means that all elements of the FoD are exhaustive and

exclusive. The combination of the BBA's  $m_1(\cdot)$  and  $m_2(\cdot)$ , is done by :  $m_{1,2}^{DS}(\emptyset) = 0$  and for all  $X \neq \emptyset$  in  $2^\Omega$

$$m_{1,2}^{DS}(X) \triangleq \frac{1}{1 - m_{1,2}(\emptyset)} \sum_{\substack{X_1, X_2 \in 2^\Omega \\ X_1 \cap X_2 = X}} \prod_{i=1}^2 m_i(X_i) \quad (2)$$

where the numerator of (2) is the mass of belief on the conjunctive consensus on  $X$ . The denominator  $1 - m_{1,2}(\emptyset)$  is a normalization constant. The total degree of conflict between the two sources of evidences is classically defined by

$$m_{1,2}(\emptyset) \triangleq \sum_{\substack{X_1, X_2 \in 2^\Omega \\ X_1 \cap X_2 = \emptyset}} \prod_{i=1}^2 m_i(X_i) \quad (3)$$

According to Shafer [3], the two sources are said in total conflict if  $m_{1,2}(\emptyset) = 1$ . In this case the combination of the sources by DS rule cannot be done because of the mathematical 0/0 indeterminacy. The vacuous BBA  $m_v(\Omega) = 1$  is a neutral element for DS rule. This rule is commutative and associative, and the formula (2) can be easily generalized for the combination of  $s > 2$  sources of evidences. DS rule remains the milestone fusion rule of DST.

The doubts of the validity of DS rule has been discussed by Zadeh in 1979 [28]–[30] based on a very simple example with two highly conflicting sources of evidences. Since 1980's, many criticisms have been done about the behavior and the justification of such DS rule. More recently, Dezert et al. in [19], [20] have put in light other problematic behaviors of DS rule even in low conflicting cases and showed serious flaws in logical foundations of DST [21]. To overcome the limitations and problems of DS rule of combination, a new family of PCR rules have been developed in DSmT framework. We present the most elaborate one, i.e. the PCR6 fusion rule, which has been used in our perception application for grid occupancy estimation.

In PCR rules, instead of following the DS normalization (the division by  $1 - m_{1,2}(\emptyset)$ ), we transfer the conflicting mass only to the elements involved in the conflict and proportionally to their individual masses, so that the specificity of the information is entirely preserved. The general principle of PCR consists: 1) to apply the conjunctive rule, 2) to calculate the total or partial conflicting masses; 3) then redistribute the (total or partial) conflicting mass proportionally on non-empty sets according to the integrity constraints one has for the frame  $\Omega$ . Because the proportional transfer can be done in different ways, there exist several versions of PCR rules of combination. PCR6 fusion rule has been proposed by Martin and Osswald in [6] Vol. 2, Chap. 2, as a serious alternative to PCR5 fusion rule proposed originally by Smarandache and Dezert in [6] Vol. 2, Chap. 1. Martin and Osswald had proposed PCR6 based on intuitive considerations and they had shown through different simulations that PCR6 was more stable than PCR5 in term of decision for combining  $s > 2$  sources of evidence. When only two sources are combined, PCR6 and PCR5 fusion rules coincide, but they differ as soon as more than two sources

<sup>1</sup>DS acronym standing for *Dempster-Shafer* since Dempster's rule has been widely promoted by Shafer in the development of his mathematical theory of evidence [3].

<sup>2</sup>which corresponds to a Dedekind's lattice, see [6] Vol. 1.

have to be combined altogether. Recently, it has been proved in [22] that only PCR6 rule is consistent with the averaging fusion rule which allows to estimate the empirical (frequentist) probabilities involved in a discrete random experiment. For Shafer's model of FoD<sup>3</sup>, PCR6 fusion of two BBA's  $m_1(\cdot)$  and  $m_2(\cdot)$  is defined by  $m_{1,2}^{PCR6}(\emptyset) = 0$  and for all  $X \neq \emptyset$  in  $2^\Omega$

$$m_{1,2}^{PCR6}(X) = \sum_{\substack{X_1, X_2 \in 2^\Omega \\ X_1 \cap X_2 = X}} m_1(X_1)m_2(X_2) + \sum_{\substack{Y \in 2^\Omega \setminus \{X\} \\ X \cap Y = \emptyset}} \left[ \frac{m_1(X)^2 m_2(Y)}{m_1(X) + m_2(Y)} + \frac{m_2(X)^2 m_1(Y)}{m_2(X) + m_1(Y)} \right] \quad (4)$$

where all denominators in (4) are different from zero. If a denominator is zero, that fraction is discarded. All propositions/sets are in a canonical form [6]. Very basic Matlab codes of PCR rules can be found in [6], [23] and from the toolboxes repository on the web [27]. Like the averaging fusion rule, the PCR6 fusion rule is commutative but not associative. The vacuous belief assignment is a neutral element for this rule.

The PCR6 rule of combination (as well as DS rule) use only part of the whole information available (i.e. the values of the masses of belief only), and they don't exploit the cardinalities of focal elements entering in the fusion process. Because the cardinalities of focal elements are fully taken into account in the computation of the measure of degree of intersection between sets, we have recently proposed to improve PCR6 rules using this measure in the companion paper [7]. The basic idea is to replace any conjunctive product by its discounted version thanks to the measure of degree of intersection  $D$  when the intersection of focal elements is not empty. The product of partial (or total) conflicting masses are not discounted by the measure of degree of intersection because the degree of intersection between two (or more) conflicting focal elements always equals zero, that is if  $X \cap Y = \emptyset$ , then  $D(X, Y) = 0$ . In [7], we have shown in different examples why Zhang's *degree of intersection* [31], denoted  $D^Z(X_1, \dots, X_s)$ , is more interesting than classical Jaccard's degree.  $D^Z(X_1, \dots, X_s)$  is mathematically defined by

$$D^Z(X_1, \dots, X_s) \triangleq \frac{|X_1 \cap X_2 \cap \dots \cap X_s|}{|X_1| \cdot |X_2| \cdot \dots \cdot |X_s|} \quad (5)$$

where  $|X_1 \cap X_2 \cap \dots \cap X_s|$  is the cardinality of the intersection of the focal elements  $X_1, X_2, \dots, X_s$ , and  $|X_1|, |X_2|, \dots, |X_s|$  their cardinalities. The improved version of PCR6 with Zhang's degree of intersection (called ZPCR6 rule) is easy to get and it corresponds to the following formula<sup>4</sup>

<sup>3</sup>that is when  $G^\Omega = 2^\Omega$ , and assuming all elements exhaustive and exclusive.

<sup>4</sup>The general ZPCR6 formula for  $s > 2$  sources is detailed in [7].

$$m_{1,2}^{ZPCR6}(X) = \frac{1}{K_{1,2}^{ZPCR6}} \left[ \sum_{\substack{X_1, X_2 \in 2^\Omega \\ X_1 \cap X_2 = X}} D^Z(X_1, X_2) m_1(X_1) m_2(X_2) + \sum_{\substack{Y \in 2^\Omega \setminus \{X\} \\ X \cap Y = \emptyset}} \left[ \frac{m_1(X)^2 m_2(Y)}{m_1(X) + m_2(Y)} + \frac{m_2(X)^2 m_1(Y)}{m_2(X) + m_1(Y)} \right] \right] \quad (6)$$

where  $K_{1,2}^{ZPCR6}$  is a normalization constant such that  $\sum_{X \in 2^\Omega} m_{1,2}^{ZPCR6}(X) = 1$ . As for PCR6, one has  $m_{1,2}^{ZPCR6}(\emptyset) = 0$  and ZPCR6 is commutative but not associative. The advantage of ZPCR6 over PCR6 and DS rules is its ability to respond to the inputs in a more effective way has clearly shown in very interesting examples detailed in [7]. Due to space limitation, these examples will not be presented and discussed here again.

### C. Discounting

A discounting effect can be applied on a mass function  $m(\cdot)$  if a piece of information has its reliability lowered. In this case, a new mass function  $m_\alpha(\cdot)$  (with  $\alpha \in [0, 1]$ ) is computed from  $m(\cdot)$  and a part of the mass of each element of the FoD is transferred to the whole FoD  $\Omega$  which represents the total ignorance.

$$m_\alpha(A) = \begin{cases} (1 - \alpha) \cdot m(A) & \text{if } A \neq \Omega \\ (1 - \alpha) \cdot m(A) + \alpha & \text{if } A = \Omega \end{cases} \quad (7)$$

### III. EVIDENTIAL OCCUPANCY GRID

The basic idea of an Occupancy Grid (OG) is to divide the surrounding environment (the ground plane of 2D world) into a set of cells (denoted  $C^i$ ,  $i \in [0, n]$ ) in order to estimate their occupancy state. In a probabilistic framework, the aim is to estimate the probabilities  $P(O^i | z_{1:t})$  and  $P(F^i | z_{1:t})$  given a set of measures  $z_{1:t}$  from the beginning up to the current time  $t$ .  $O^i$  (resp.  $F^i$ ) denotes the occupied (resp. free) state of the cell  $C^i$ . Finally, a decision rule is applied in order to select the most likely state for each cell.

For Evidential approach, occupancy grid represents the information using a mass function over the frame of discernment (FoD)  $\Omega = \{F, O\}$ . So the mass functions used in grid have the structure

$$m_t = [ m_t(\emptyset) \quad m_t(F) \quad m_t(O) \quad m_t(\Omega) ] \quad (8)$$

The occupancy mass function can be used during the fusion process, then the decision can be taken using pignistic transform [26] to get a probability measure and use the same decision rule. An interesting part of evidential occupancy grid is that the FoD can be more complex, and as the fusion is done cell by cell the fusion scheme will be still valid.

Occupancy grids can be classified into two categories depending on the use of a forward or inverse sensor model. The forward model relies on Bayes inference. Since this approach takes into account the conditional dependency of the cells of

the map, it is well adapted to a sensor that observes a large domain of cells with only one reading measurement (e.g. an ultrasonic sonar). However, it requires heavy processing that can be handled by optimized approximation.

The inverse model approach is well adapted to narrow fields of measure by sensors (e.g. LIDAR). It is composed of two separate steps. First, a snapshot map of the sensor reading is built using an inverse sensor model  $P(O^i|z_t)$ . This model can take into account the conditional dependency between the sensor reading and the occupancy of the seen cells. Then, a fusion process (denoted  $\odot$ ) is done with the previous map  $P(O^i|z_{1:t-1})$  as an independent opinion poll fusion:

$$P(O^i|z_{1:t}) = P(O^i|z_t) \odot P(O^i|z_{1:t-1}) \quad (9)$$

In the probabilistic framework, the usual fusion operation between states  $A$  and  $B$  coming from independent measurement, use independent opinion poll [34] :

$$P(A) \odot P(B) = \frac{P(A)P(B)}{P(A)P(B) + (1 - P(A))(1 - P(B))} \quad (10)$$

Inverse approaches have very efficient implementations (e.g. log-odd) that make them popular in mobile robotics [8], [9], [25]. Maps built using inverse models are usually less accurate, since they just take into account the dependency of the cells observed in one reading, but it is a good approximation with accurate and high resolution sensors observing a limited number of cells at a time. Moreover, when the sensor is multi-echo and multi-layer, the conditional dependency of the seen cells can be modeled in an efficient way.

#### A. Fusion strategy with the inverse model

When dealing with the inverse model approach, an estimate of the pose of the robot has to be available, and a map grid  $G^M$  has to be handled. This grid is defined in a world-referenced frame (so it does not move with the robot) and it is updated when a new sensor reading is available. Because of the likely evolution of the world in a dynamic environment, the OG update has to be completed by a remanence strategy. The fusion architecture is based on a prediction-correction paradigm to fuse one or several sensors observations.

*a) Prediction step:* The prediction step computes the predicted map grid at time  $t$  from the map grid estimated at time  $t - 1$ . Depending on the available information, this step can be very refined as done in [24]. Because we don't have specific information on the velocity of the objects (or cells), the prediction step is done by the classical discounting technique. The confidence in past data is controlled by a remanence factor  $\alpha \in [0; 1]$ . The prediction stage is therefore governed by

$$G_t^M = \text{discount}(\hat{G}_{t-1}^M, \alpha) \quad (11)$$

*b) Correction step:* The correction step consists in the combination of the previously estimated map grid with the grid built from the current measures thanks to the inverse model sensor (see more details in [1], [2]). This one is called ScanGrid  $G_t^S$ . As this information is referenced in the sensor frame, a 2D warping is applied to reshape this grid into the

fusion frame. To perform this operation, the current pose  $q_t$  is estimated using a GPS sensor and the rigid homogeneous transformation matrix  $H_t$  is computed. When GPS becomes unavailable, the CAN (Controller Area Network) bus is used to get the robot odometric data. The motion matrix  $H_t$  and the extrinsic calibration matrix  $C$  are used to compute a remapping function  $f(x, y)$  according to Eq. (12) below

$$f(x, y) = C \cdot H_t \cdot \begin{bmatrix} x \\ y \\ 1 \end{bmatrix} \quad (12)$$

Finally, the ScanGrid is remapped with  $f$  and fused with the previous map grid according to the general formula

$$G_t^M(i, j) = \hat{G}_t^M(i, j) \odot G_t^S(f(i, j)) \quad (13)$$

where the grid  $G_t^S$  represents the BBA produced by the sensor model. This BBA is created in respect to sensor data (e.g. LIDAR point here) and a sensor model to infer an instant occupancy grid. With the probabilistic approach, it refers to the occupancy probability  $P_t^S(O)$ . With the evidential approach it refers to the occupancy mass function  $m_t^S = [m_t^S(\emptyset) \ m_t^S(F) \ m_t^S(O) \ m_t^S(\Omega)]$ . The grid  $\hat{G}_t^M$  refers to the previous MapGrid  $G_{t-1}^M$  predicted at current time using Eq. (11). In the next parts, for each approach considered, the fusion rule  $\odot$  used in Eq. (13) is different. Bayesian approach uses Eq. (10), DS approach uses Eq. 2, PCR6 approach uses Eq. (4), and ZPCR6 approach Eq. (6).

#### B. Discounting in Occupancy Grids

The main advantage of using discounting is to provide a simple way to model the presence of dynamic object in the scene. This model allows to make a prediction without information on the dynamic at the cell level (or at the object level) which is generally not directly available from sensors, and merely difficult to estimate without greedy time-computing algorithms [24] (especially when the evidential framework is adopted). The main issue with the discounting effect is that it makes impossible to build persistent static map. Indeed, cells not viewed by the sensor will quickly converge to the ignorance state, so this strategy cannot be used to build the map of a building for instance. If we are interested to build static map in presence of moving objects, the discounting function is then not recommended. We will see why in the next part of the paper where in this case Bayesian and DS fusion rules will not be very efficient. To handle this case, it is recommended to use either PCR6 or ZPCR6 rules.

## IV. SIMULATION RESULTS

In this section, we present simulation results of grid occupancy estimation in a realistic scenario based on different rules of combination (Bayesian fusion, Dempster-Shafer rule, PCR6 and ZPCR6 fusion rules).

A. Basic simulation

**Setup:** In order to present the basic behavior of the different combination rules studied, we have realized at first some simple 1D-simulations, where we consider a grid cell crossed by a moving object. In this case, the state of the cell changes from free-state to occupied-state at time  $t_1$  and from occupied-state to free-state at time  $t_2$ . The figures 1–4 show the results of these simulations under different conditions.

On each subfigure, we show on the top raw the real state of the cell (i.e. the ground-truth). The second raw shows the sensor data simulated that correspond to the BBA of the state of the cell. This mass function is built according to the state of the cell, the level of confidence of the sensor and can be

eventually perturbed with additional noises. FA indicates the rate of False Alarms and ND the rate of Non Detections. We will consider different level of confidence for  $m_{SG}(O)$  when the cell is occupied and  $m_{SG}(F)$  when the cell is free. The subfigures at the bottom represent the level of belief of the cell state obtained with Bayesian fusion, Dempster-Shafer (DS) fusion, PCR6 and ZPCR6 fusion rules.

**Effect of discounting:** Fig.1 shows the results of the classical chain using a discounting factor  $\alpha = 0.05$  while Fig. 2 is the same case without discounting ( $\alpha = 0$ ). With discounting, all the fusion rules behave similarly. Without discounting, a lag appears with Bayesian and DS fusion rules. The lag is seriously reduced with PCR6 and ZPCR6.

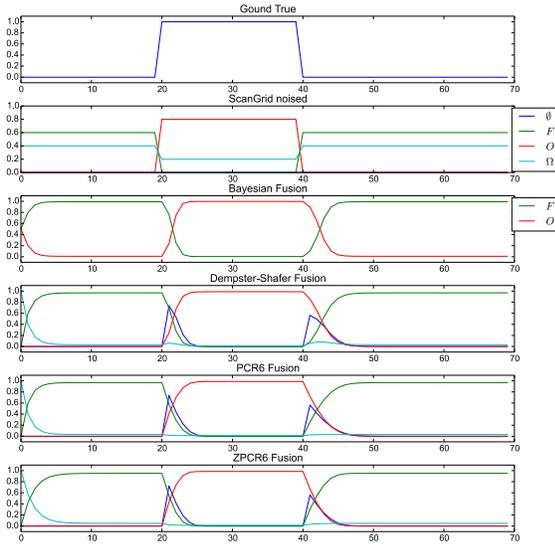

Fig. 1. Case with discounting ( $\alpha = 0.05$ ).

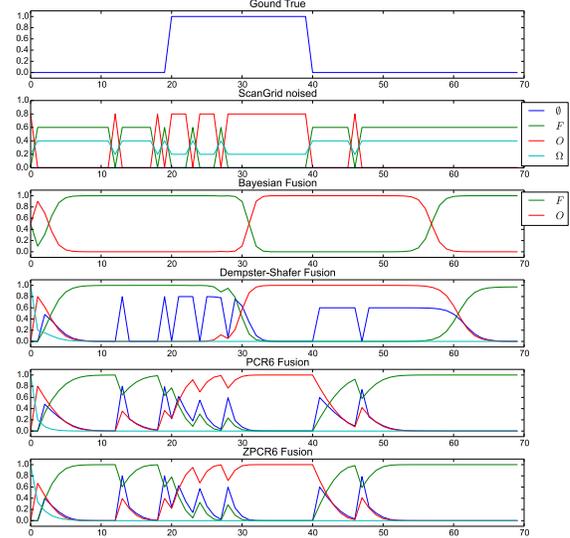

Fig. 3. Case with noise (FA=10%, ND=10%) and  $\alpha = 0$ .

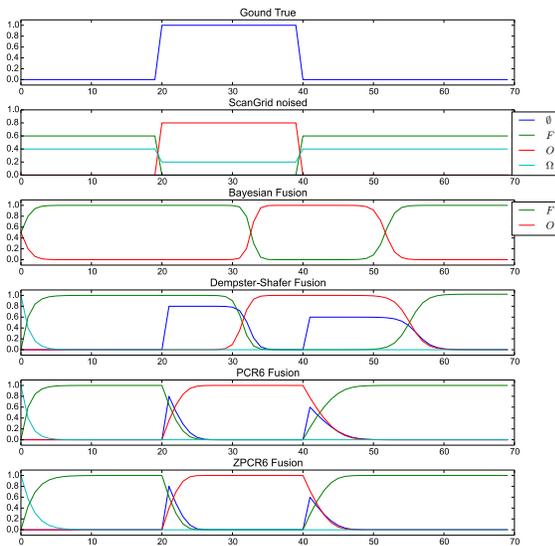

Fig. 2. Case without discounting ( $\alpha = 0$ ).

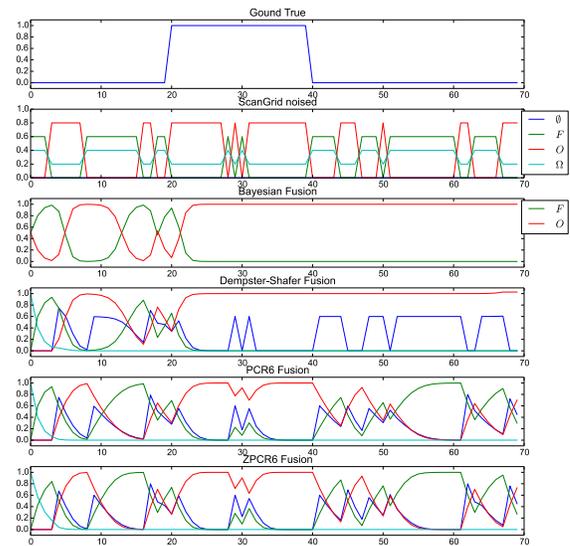

Fig. 4. Case with noise (FA=30%, ND=15%) and  $\alpha = 0$ .

**Performances analyses:** To evaluate the performance of our method, we did perform 10000 Monte Carlo runs for each simulation in order to estimate the false alarm and non detection rates. In order to make the decision, the pignistic probability has been computed and a MAP estimator has been used. Each simulation (from No 0 to No 8) correspond to different conditions (the discounting level, the rate of noise impacting sensor observations) reported in Table I.

Simu N°	discounting $\alpha$	sensor noise $ND/FA$	sensor belief $m_{SG}(O)/m_{SG}(F)$
0	0.05	0	0.8/0.6
1	0	0	0.8/0.6

TABLE I  
PARAMETERS OF SIMULATIONS.

For each simulation presented in the Table I, we obtain the performances (rates of FA and ND in %) shown in Table II.

Simu #	Bayesian		DS		PCR6		ZPCR6	
	ND	FA	ND	FA	ND	FA	ND	FA
0	10.0	6.0	10.0	6.0	10.0	6.0	10.0	4.0
1	65.0	24.0	60.0	32.0	10.0	6.0	10.0	4.0
2	11.2	9.2	10.5	10.0	10.0	9.6	11.1	7.8
3	77.7	15.2	73.5	18.9	11.5	6.7	11.3	7.5
4	9.2	28.0	8.2	31.5	8.4	28.9	9.8	25.8
5	33.0	62.7	26.9	65.8	8.4	28.8	10.1	24.7
6	31.3	63.9	26.0	67.3	9.3	38.7	8.8	32.3
7	15.1	76.9	11.5	79.4	5.7	64.0	7.5	55.2
8	7.1	83.9	5.1	85.1	1.9	87.3	3.0	76.2

TABLE II  
RATES OF FALSE ALARM AND NON DETECTION (IN %).

Simulations 0 and 1 illustrated by Figures 1 and 2, correspond to the noise-free situation. By removing the discounting operator, Bayesian and DS approach have a lag in the detection of the change of state that impacts clearly their performances. The PCR6 and ZPCR6 approach are not concerned by this effect because of PCR of conflict. Simulations 2 and 3 (see Fig. 3) include 10% of wrong measurement caused by noises. The fusion rules behave similarly as for simulations 0 and 1, but the performances are a bit lower which shows the effect of noisy measurements in the estimation process. For simulations 4, 5 and 6, the noise reaches 15% for ND and 30% for FA which is important. As we see in Fig. 4, the Bayesian and DS fusion rules are not able to detect the second state change, during the simulation time. This induces the bad false alarm rates. In the last simulations 7 and 8 the noise is very important (about 25% of ND and 50% of FA). In these conditions, all the methods have poor false alarm rates but the PCR6 and ZPCR6 keep good non detection rates. Globally, we see an improvement of the performances when using ZPCR6, specially for the reduction of the FA rates.

## B. LIDAR simulation

In this simulation, the DS and PCR6 fusion rules are compared on a 2D occupancy grid problem close to real application for robot perception. The simulation was realized using the Robot Operating System (ROS) [32] environment and the Gazebo [33] simulator is used here to simulate a Hokuyo LIDAR and a moving object as shown on Figure 5. The simulated sensor has a FoV (Field of View) about  $270^\circ$  and a max range about 10m. The rate of the scan is 20Hz and the ranges of the LIDAR point is corrupted with a Gaussian noise  $\mathcal{N}(0, 0.1)$ .

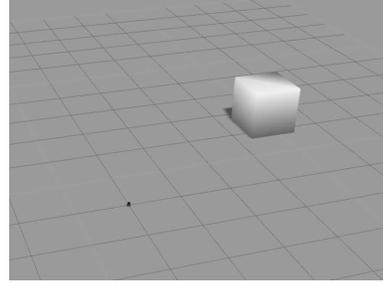

Fig. 5. Gazebo simulation: the box turns around the LIDAR sensor.

Figure 6 shows a simulated scan. The beams that do not hit obstacle within the range are considered as max range (as done in the real Hokuyo sensor). The moving object is a box which has a circular trajectory and moves at 6 rpm around the LIDAR. A *ground true* grid is computed according the real position of the box and its geometry at each scan time. The grid used is a square of 10 m by 10 m with a resolution of 0.1 m and the ScanGrid BBA are set to  $m_{SG}(O) = 0.8$ ,  $m_{SG}(\Omega) = 0.2$  for occupied cells and  $m_{SG}(F) = 0.6$ ,  $m_{SG}(\Omega) = 0.4$  for free cells.

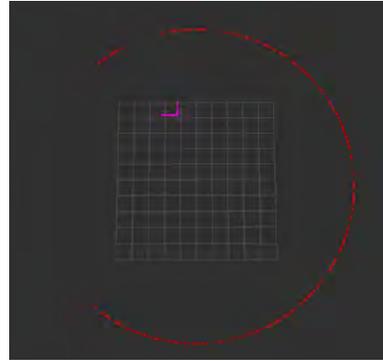

Fig. 6. Bird view of one LIDAR scan.

In order to quantify the results, we compute some metrics. However, because of occlusion, only the cells located on the edges of the box can be considered, that is why we don't consider global metrics. We consider here the two following metrics: 1) the number of correct occupied cell (proportional to recall in our case), and 2) the number of conflicting cells close to the box. The first describes the ability of the method to add

objects into the map, and also by analogy to remove object from the map. The second describes the ability of the method to detect moving objects by generating conflict, this ability is important and is one of the improvement of the evidential grid with respect to the classical Bayesian grid.

Figures 7 shows the result over one turn. The number of cells detected for both metrics depends a lot on the position around the sensor. This can be explained because, in some place, the LIDAR sensor is able to see two edges of the box, in other situations the LIDAR sensor detects just one edge, and when the box is behind (on the back of) the sensor it is out of the field of view of the LIDAR. On figure 7, we can see that the number of occupied cell with the ZPCR6 is more than those with PCR6 and DS fusion rules. Contrarily to the ZPCR6 and PCR6, the DS fusion without discounting can not handle well the quick change of states in the map. The x-axis of Figures 7 is the time stamp of the LIDAR scans, and the y-axis is the number of occupied cells.

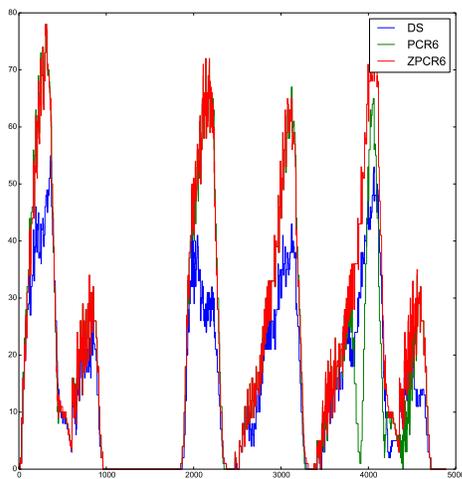

Fig. 7. 2D LIDAR Simulation: Number of correct occupied cells (blue=DS rule, green=PCR6 rule, red=ZPCR6 rule).

### C. Real data processing

A real experimentation was realized using an Hokuyo UTM-30LX sensor. This experimentation takes place in an office in which a person was walking into. The evidential occupancy grid fusion node was implemented within the ROS environment. The grid has the same size and resolution as in the previous example. The BBA used in the sensor model has been set to  $m_{SG}(O) = 0.8$ ,  $m_{SG}(\Omega) = 0.2$  for occupied cells and  $m_{SG}(F) = 0.8$ ,  $m_{SG}(\Omega) = 0.2$  for free cells. No discounting was applied.

Figures 8–10 present the occupancy grid estimation using DS, PCR6 and ZPCR6 rules for a typical snapshot of the sequence. The color of cells denotes the state having the highest mass value: green for  $F$  (free state), red for  $O$  (occupied state), and black for  $\Omega$  (full uncertainty). For convenience, we have also displayed in blue all the cells that carry a conflicting mass  $m(\emptyset) > 0$  before applying the normalization step of DS rule,

or before applying the proportional conflict redistribution with PCR6, or both with ZPCR6.

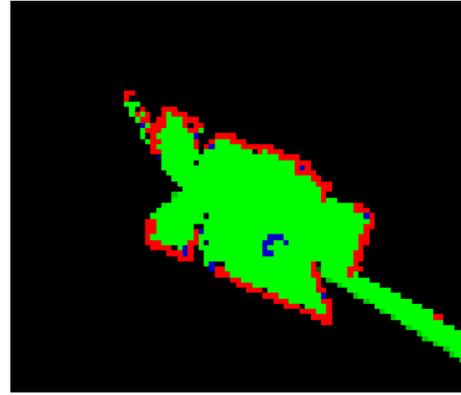

Fig. 8. Snapshot 1 - with DS fusion.

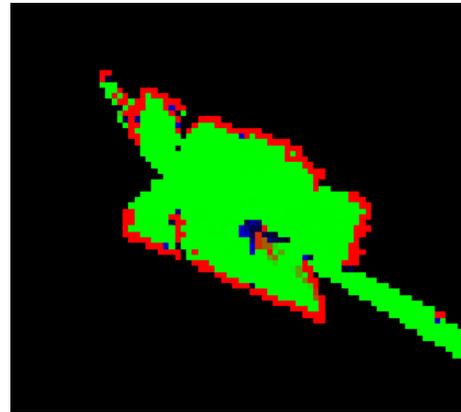

Fig. 9. Snapshot 1 - with PCR6 fusion.

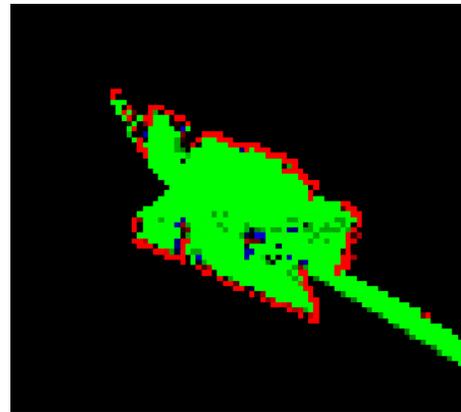

Fig. 10. Snapshot 1 - with ZPCR6 fusion.

Figure 8 shows the result using DS rule. The room scanned by the sensor is correctly mapped and its bounds (mainly walls and doors) are clearly identified by the red pixels. The free space (green pixels) is correctly detected in the room except near the people that is labeled as free (with conflicting cell

shown in blue for convenience). The people moving around the desk in the office room is only detected from conflicting cells when he stops to walk several times. Figure 9 shows the PCR6 result at the same time stamps. In this case, the people is rightly detected as shown by the red pixels (occupied cells) inside the green area (the office room). A conflict cell is created when he starts walking in the room. The static part of the room is also detected (as with DS fusion rule). Figure 10 shows the ZPCR6 result at the same time stamps. The results of this rule are close to the PCR6 rule but the level of ignorance (the mass on  $\Omega$ ) is higher on the cells behind the person. This can be understood because the mass  $m(\Omega)$  is weighed by a factor 0.5 during the transition.

## V. CONCLUSIONS AND PERSPECTIVES

In this work we have presented a novel application of the belief functions which significantly improves the map building process for intelligent vehicles environment perception and grid map estimation. This work shows the importance of defining an accurate sensor model. We have considered the uncertainties of the LIDAR measurements and used the ZPCR6 rule of DSMT to model and combine sensor information. Our new method differs of Bayesian approach by allowing support for more than one proposition at a time, rather than a single hypothesis. It is an interval-based approach, as defined by the lower and upper probability bounds  $[Bel, Pl]$  allowing the lack of measurement to be modeled adequately. This new method based on ZPCR6 rule differs from the classical evidential approach based on DS rule and improves in theory the results based PCR6, and more substantially the results of DS rule. Our experimental results with the LIDAR confirm the improvement of the accuracy of this new grid estimation method w.r.t previous methods, but the improvement obtained with ZPCR6 over PCR6 is not so important because of the too simplistic structure of the chosen frame of discernment. As research perspectives, we will try to implement these fusion rules in 3D occupancy grid (Octomap based) and use a stereo camera with dense disparity map computation as sensor source. Also we would like to deal with refined frames of discernment to ameliorate the precision of the perception and to emphasize the advantages of ZPCR6 rule.

**Abstract**—In this contribution, we propose to improve the grid map occupancy estimation method developed so far based on belief function modeling and the classical Dempster’s rule of combination. Grid map offers a useful representation of the perceived world for mobile robotics navigation. It will play a major role for the security (obstacle avoidance) of next generations of terrestrial vehicles, as well as for future autonomous navigation systems. In a grid map, the occupancy of each cell representing a small piece of the surrounding area of the robot must be estimated at first from sensors measurements (typically LIDAR, or camera), and then it must also be classified into different classes in order to get a complete and precise perception of the dynamic environment where the robot moves. So far, the estimation and the grid map updating have been done using fusion techniques based on the probabilistic framework, or on the classical belief function framework thanks to an inverse model of the sensors. Mainly because the latter offers an interesting management of uncertainties when the quality of available information is low, and when the sources of information appear as conflicting. To improve the performances of the grid map estimation, we propose in this paper to replace Dempster’s rule of combination by the PCR6 rule (Proportional Conflict Redistribution rule #6) proposed in DSMT (Dezert-Smarandache) Theory. As an illustrating scenario, we consider a platform moving in dynamic area and we compare our new realistic simulation results (based on a LIDAR sensor) with those obtained by the probabilistic and the classical belief-based approaches.

**Keywords:** Grid map, cell occupancy, perception, belief functions, DSMT, PCR6, robotics.

## I. INTRODUCTION

Occupancy Grids (OG) are often used for robot environment perception and navigation, which requires techniques for data fusion [1], localization [2] and obstacle avoidance [3]. As OGs manage a representation of the environment that does not make any assumption on the geometrical shape of the detected elements, they provide a general framework to deal with complex perception conditions. In our previous works, we did focus on the use of a multi-echo and multi-layer LIDAR system in order to characterize the dynamic surrounding environment of a robot navigating in an unrestricted area. The perception strategy involved map estimation and scan grids [4], [5] based either on the classical Bayesian framework, or on classical evidential framework based on Dempster-Shafer theory (DST) [6] of belief functions. The map grid acts as a filter that accumulate information and allows to detect moving objects.

A comparative analysis of performances of these approaches has already been published recently in [7].

In dynamic environments, it is crucial to have a good modeling of the information flow in the data fusion process in order to avoid adding wrong implicit prior knowledge that will need time to be forgotten. In this context, evidential OG are particularly interesting to make a good management of the information since it is possible to explicitly make the distinction between non explored and moving cells. In this paper, we explore the use of Dezert-Smarandache Theory [8] (DSMT) as an alternative approach of the classical DST to provide better accurate estimation of the grid map occupancy for robot perception.

The idea of using the probabilistic framework to estimate the grid occupancy has been popularized by Elfes in his pioneered works in 1990’s [9]–[13]. Later, the idea has been extended with the fuzzy logic theory framework by Oriolo et al. [15]–[21], and in parallel with the belief function (evidential) framework as well [22]–[29]. Most of the aforementioned research works dealt only with acoustic sensors only (i.e SONAR). Recently, DSMT has also been applied for the perception of the environment with acoustic sensors as reported in [30]–[32], [34]–[36].

Our main contribution is to propose a new method to make the perception with non acoustic sensors, and to compare the performances of the Proportional Conflict Redistribution rule no. 6 (PCR6) of DSMT with respect to Dempster-Shafer’s (DS) rule of combination in terms of accuracy of grid map estimation. In our application, we work with a LIDAR sensor on board on a robot moving in dynamic environment.

This paper is organized as follows. After a short presentation of the basics of belief functions and rules of their combination based on DST and DSMT in the next section, we will present the inverse sensor models in section III with the construction of the basic belief assignments (BBA). In section IV, we present an illustrating scenario for environment perception including a mobile object with a platform equipped with a LIDAR, and we compare our new realistic simulation results with those obtained by the probabilistic and the classical belief-based approaches. We will show how static and mobile objects are extracted from the occupancy grid map using digital image processing. Finally, conclusion and outline perspectives are given in section V.

## II. EVIDENTIAL FRAMEWORK

Dempster-Shafer's theory (DST) of evidence has been developed by Shafer in 1976 from Dempster's works [6]. DST is known also as the theory of belief functions and it is mainly characterized by a frame of discernment (FoD), sources of evidence represented by basic belief assignment (BBA), belief (Bel) and plausibility (Pl) functions, and the Dempster's rule, denoted as DS rule of combination in the sequel<sup>1</sup>. DST has been modified and extended into Dezert-Smarandache theory [8] (DSMT) to work with quantitative or qualitative BBA and to combine the sources of evidence in a more efficient way thanks to new proportional conflict redistribution (PCR) fusion rules – see [37]–[40] for discussion and examples. We briefly recall in the next subsections the basics of the theory of belief functions.

### A. Belief functions

Let's consider a finite discrete FoD  $\Omega = \{\omega_1, \omega_2, \dots, \omega_n\}$ , with  $n > 1$ , of the fusion problem under consideration and its fusion space  $G^\Omega$  which can be chosen either as the power-set  $2^\Omega$ , the hyper-power set<sup>2</sup>  $D^\Omega$ , or the super-power set  $S^\Omega$  depending on the model that fits with the problem [8]. A BBA associated with a given source of evidence is defined as the mapping  $m(\cdot) : G^\Omega \rightarrow [0, 1]$  satisfying  $m(\emptyset) = 0$  and  $\sum_{A \in G^\Omega} m(A) = 1$ . The quantity  $m(A)$  is called mass of belief of  $A$  committed by the source of evidence. Belief and plausibility functions are defined by

$$\text{Bel}(A) = \sum_{\substack{B \subseteq A \\ B \in G^\Omega}} m(B) \quad \text{and} \quad \text{Pl}(A) = \sum_{\substack{B \cap A \neq \emptyset \\ B \in G^\Omega}} m(B) \quad (1)$$

The degree of belief  $\text{Bel}(A)$  given to a subset  $A$  quantifies the amount of justified specific support to be given to  $A$ , and the degree of plausibility  $\text{Pl}(A)$  quantifies the maximum amount of potential specific support that could be given to  $A$ . If for some  $A \in G^\Omega$ ,  $m(A) > 0$  then  $A$  is called a focal element of the BBA  $m(\cdot)$ . When all focal elements are singletons and  $G^\Omega = 2^\Omega$  then the BBA  $m(\cdot)$  is called a Bayesian BBA [6] and its corresponding belief function  $\text{Bel}(\cdot)$  is homogeneous to a (possibly subjective) probability measure, and one has  $\text{Bel}(A) = P(A) = \text{Pl}(A)$ , otherwise in general one has  $\text{Bel}(A) \leq P(A) \leq \text{Pl}(A)$ ,  $\forall A \in G^\Omega$ . The vacuous BBA representing a totally ignorant source is defined as  $m_v(\Omega) = 1$ .

### B. Fusion rules

Many mathematical rules have been proposed in the literature over the decades (see [8], Vol. 2 for a detailed list of fusion rules) to combine efficiently several distinct sources of evidence represented by the BBA's  $m_1(\cdot)$ ,  $m_2(\cdot)$ ,  $\dots$ ,  $m_s(\cdot)$  ( $s \geq 2$ ) defined on same fusion space  $G^\Omega$ . In this paper, we focus only on DS rule because it has been historically proposed

in DST and it is still widely used in applications, and on the PCR rule no. 6 (i.e. PCR6) proposed in DSMT because it provides a very interesting alternative of DS rule, even if PCR6 is more complex to implement in general than DS rule.

In DST framework, the fusion space  $G^\Omega$  equals the power-set  $2^\Omega$  because Shafer's model of the frame  $\Omega$  is assumed, which means that all elements of the FoD are exhaustive and exclusive. The combination of the BBA's  $m_1(\cdot)$  and  $m_2(\cdot)$ , is done by :  $m_{1,2}^{DS}(\emptyset) = 0$  and for all  $X \neq \emptyset$  in  $2^\Omega$

$$m_{1,2}^{DS}(X) \triangleq \frac{1}{1 - m_{1,2}(\emptyset)} \sum_{\substack{X_1, X_2 \in 2^\Omega \\ X_1 \cap X_2 = X}} \prod_{i=1}^2 m_i(X_i) \quad (2)$$

where the numerator of (2) is the mass of belief on the conjunctive consensus on  $X$ . The denominator  $1 - m_{1,2}(\emptyset)$  is a normalization constant, where the total degree of conflict denoted  $m_{1,2}(\emptyset)$  between the two sources of evidences is defined by

$$m_{1,2}(\emptyset) \triangleq \sum_{\substack{X_1, X_2 \in 2^\Omega \\ X_1 \cap X_2 = \emptyset}} \prod_{i=1}^2 m_i(X_i) \quad (3)$$

According to Shafer [6], the two sources are said in total conflict if  $m_{1,2}(\emptyset) = 1$ . In this case the combination of the sources by DS rule cannot be done because of the mathematical 0/0 indeterminacy. The vacuous BBA  $m_v(\Omega) = 1$  is a neutral element for DS rule. This rule is commutative and associative, and the formula (2) can be easily generalized for the combination of  $s > 2$  sources of evidences. DS rule remains the milestone fusion rule of DST.

The doubts of the validity of DS rule has been discussed by Zadeh in 1979 [47]–[49] based on a very simple example with two highly conflicting sources of evidences. Since 1980's, many criticisms have been done about the behavior and the justification of such DS rule. More recently, Dezert et al. in [37], [38] have put in light other counter-intuitive behaviors of DS rule even in low conflicting cases and showed serious flaws in logical foundations of DST [39]. To overcome the limitations and problems of DS rule of combination, a new family of PCR rules have been developed in DSMT framework. We present the most elaborate one, i.e. the PCR6 fusion rule, which has been used in our perception application for grid occupancy estimation.

In PCR rules, instead of following the DS normalization (the division by  $1 - m_{1,2}(\emptyset)$ ), we transfer the conflicting mass only to the elements involved in the conflict and proportionally to their individual masses, so that the specificity of the information is entirely preserved. The general principle of PCR consists: 1) to apply the conjunctive rule, 2) to calculate the total or partial conflicting masses; 3) then redistribute the (total or partial) conflicting mass proportionally on non-empty sets according to the integrity constraints one has for the frame  $\Omega$ . Because the proportional transfer can be done in different ways, there exist several versions of PCR rules of combination. PCR6 fusion rule has been proposed by Martin and Osswald in

<sup>1</sup>DS acronym standing for *Dempster-Shafer* since Dempster's rule has been widely promoted by Shafer in the development of his mathematical theory of evidence [6].

<sup>2</sup>which corresponds to a Dedekind's lattice, see [8] Vol. 1.

[8] Vol. 2, Chap. 2, as a serious alternative to PCR5 fusion rule proposed originally by Smarandache and Dezert in [8] Vol. 2, Chap. 1. Martin and Osswald had proposed PCR6 based on intuitive considerations and they had shown through different simulations that PCR6 was more stable than PCR5 in term of decision for combining  $s > 2$  sources of evidence. When only two sources are combined, PCR6 and PCR5 fusion rules coincide, but they differ as soon as more than two sources have to be combined altogether. Recently, it has been proved in [40] that only PCR6 rule is consistent with the averaging fusion rule which allows to estimate the empirical (frequentist) probabilities involved in a discrete random experiment.

For Shafer's model of FoD<sup>3</sup>, the PCR6 combination of two BBA's  $m_1(\cdot)$  and  $m_2(\cdot)$  is defined by  $m_{1,2}^{PCR6}(\emptyset) = 0$  and for all  $X \neq \emptyset$  in  $2^\Omega$

$$m_{1,2}^{PCR6}(X) = \sum_{\substack{X_1, X_2 \in 2^\Omega \\ X_1 \cap X_2 = X}} m_1(X_1)m_2(X_2) + \sum_{\substack{Y \in 2^\Omega \setminus \{X\} \\ X \cap Y = \emptyset}} \left[ \frac{m_1(X)^2 m_2(Y)}{m_1(X) + m_2(Y)} + \frac{m_2(X)^2 m_1(Y)}{m_2(X) + m_1(Y)} \right] \quad (4)$$

where all denominators in (4) are different from zero. If a denominator is zero, that fraction is discarded. All propositions/sets are in a canonical form [8]. Very basic Matlab codes of PCR rules can be found in [8], [41] and from the toolboxes repository on the web [46]. Like the averaging fusion rule, the PCR6 fusion rule is commutative but not associative. The vacuous belief assignment is a neutral element for this rule.

### C. Discounting

A discounting effect can be applied on a mass function  $m(\cdot)$  if a piece of information has its reliability lowered. In this case, a new mass function  $m_\alpha(\cdot)$ , (with  $\alpha \in [0, 1]$ ) is computed from  $m(\cdot)$  and a part of the mass of each element of the FoD is transferred to the whole FoD  $\Omega$  which represents the total ignorance.

$$m_\alpha(A) = \begin{cases} (1 - \alpha) \cdot m(A) & \text{if } A \neq \Omega \\ (1 - \alpha) \cdot m(A) + \alpha & \text{if } A = \Omega \end{cases} \quad (5)$$

### D. Pignistic transformation

Finally, the pignistic transformation *BetP* [45] allows to compute a probability measure from a mass function by distributing proportionally the mass of the subsets on their focal elements:

$$\forall A \in \Omega, \text{BetP}(A) \triangleq \sum_{B \in 2^\Omega} \frac{|A \cap B|}{|B|} \cdot m(B) \quad (6)$$

where  $|A \cap B|$  is the cardinal of the subset  $A \cap B$ , and  $|B|$  is the cardinal of subset the  $B$ .

However, this transformation is not bijective (a part of the information is lost). So, one can find an infinity of mass functions with the same pignistic probability. This issue is inherent in the nature of probabilities which are not able to distinguish randomness from (epistemic) uncertainty.

<sup>3</sup>i.e. when  $G^\Omega = 2^\Omega$ , and assuming all elements exhaustive and exclusive.

## III. EVIDENTIAL OCCUPANCY GRID

The basic idea of an Occupancy Grid (OG) is to divide the surrounding environment (the ground plane of 2D world) into a set of cells (denoted  $C^i$ ,  $i \in [0, n]$ ) in order to estimate their occupancy state. In a probabilistic framework, the aim is to estimate the probabilities  $P(O^i|z_{1:t})$  and  $P(F^i|z_{1:t})$  given a set of measures  $z_{1:t}$  from the beginning up to the current time  $t$ .  $O^i$  (resp.  $F^i$ ) denotes the occupied (resp. free) state of the cell  $C^i$ . Finally, a decision rule is applied in order to select the most likely state for each cell.

For Evidential approach, occupancy grid represents the information using a mass function over the frame of discernment (FoD)  $\Omega = \{F, O\}$ . So the mass functions used in grid have the structure

$$m_t = [ m_t(\emptyset) \quad m_t(F) \quad m_t(O) \quad m_t(\Omega) ] \quad (7)$$

The occupancy mass function can be used during the fusion process, then the decision can be taken using pignistic transform to get a probability measure and use the same decision rule. An interesting part of evidential occupancy grid is that the FoD can be more complex, and as the fusion is done cell by cell the fusion scheme will be still valid .

Occupancy grids can be classified into two categories depending on the use of a forward, or inverse, sensor model. The forward model relies on Bayes inference. Since this approach takes into account the conditional dependency of the cells of the map, it is well adapted to a sensor that observes a large domain of cells with only one reading measurement (e.g. a ultrasonic SONAR). However, it requires heavy processing that can be handled by optimized approximation [42] or GPU computing [43].

The inverse model approach is well adapted to narrow fields of measures sensors (e.g. LIDAR). It is composed of two separate steps. First, a snapshot map of the sensor reading is built using an inverse sensor model  $P(O^i|z_t)$ . This model can take into account the conditional dependency between the sensor reading and the occupancy of the seen cells. Then, a fusion process (denoted  $\odot$ ) is done with the previous map  $P(O^i|z_{1:t-1})$  as an independent opinion poll fusion:

$$P(O^i|z_{1:t}) = P(O^i|z_t) \odot P(O^i|z_{1:t-1}) \quad (8)$$

In the probabilistic framework, the usual fusion operation between states  $A$  and  $B$  coming from independent measurement, use independent opinion poll [52] :

$$P(A) \odot P(B) = \frac{P(A) \cdot P(B)}{P(A) \cdot P(B) + (1 - P(A)) \cdot (1 - P(B))} \quad (9)$$

Inverse approaches have very efficient implementations (e.g. log-odd) that make them popular in mobile robotics [10], [14], [44]. Maps built using inverse models are usually less accurate, since they just take into account the dependency of the cells observed in one reading, but it is a good approximation with accurate and high resolution sensors observing a limited number of cells at a time. Moreover, when the sensor is multi-echo and multi-layer, the conditional dependency of the seen cells can be modeled in an efficient way.

### A. Fusion strategy with the inverse model

When dealing with the inverse model approach, an estimate of the pose of the robot has to be available and map grid  $G^M$  has to be handled. This grid is defined in a world-referenced frame (so it does not move with the robot) and is updated when a new sensor reading is available. Because of the likely evolution of the world in a dynamic environment, the OG update has to be completed by a remanence strategy. The fusion architecture follows then a prediction-correction paradigm and can be used to fuse one or several sensors observations.

*a) Prediction step:* The prediction step computes the predicted map grid at time  $t$  from the map grid estimated at time  $t - 1$ . Depending on the available information, this step can be very refined like done in [43]. As we consider here that no specific information on the velocity of the objects (or cells) is available, the prediction is done by discounting. The confidence in aged data is controlled by a remanence factor  $\alpha \in [0; 1]$ . The prediction stage is therefore governed by

$$G_t^M = \text{discount} \left( \hat{G}_{t-1}^M, \alpha \right) \quad (10)$$

*b) Correction step:* The correction step consists in the combination of the previously estimated map grid with the grid built from the current measures thanks to the inverse model sensor (see more details in [4], [5]). This one is called ScanGrid  $G_t^S$ . As this information is referenced in the sensor frame, a 2D warping is applied to reshape this grid into the fusion frame. To perform this operation, the current pose  $q_t$  is estimated using a GPS sensor and the rigid homogeneous transformation matrix  $H_t$  is computed. When GPS becomes unavailable, the CAN (Controller Area Network) bus is used to get the robot odometric data. The motion matrix  $H_t$  and the extrinsic calibration matrix  $C$  are used to compute a remapping function  $f(x,y)$  according to Eq.(11) below

$$f(x, y) = C \cdot H_t \cdot \begin{bmatrix} x \\ y \\ 1 \end{bmatrix} \quad (11)$$

Finally, the ScanGrid is remapped with  $f$  and fused with the previous map grid.

$$G_t^M(i, j) = \hat{G}_t^M(i, j) \odot G_t^S(f(i, j)) \quad (12)$$

The grid  $G_t^S$  represents the BBA produced by the sensor model. This BBA is created in respect to sensor data (e.g. LIDAR point here) and a sensor model to infer an instant occupancy grid. For probabilistic approach, it refers to the occupancy probability  $P_t^S(O)$ , for evidential approach it refers for a occupancy mass function  $m_t^S = [m_t^S(\emptyset) \ m_t^S(F) \ m_t^S(O) \ m_t^S(\Omega)]$ . The grid  $\hat{G}_t^M$  refers to the previous MapGrid  $G_{t-1}^M$  predicted at current time using Eq.(10). In the following parts, for each approach considered, the rule  $\odot$  used in Eq.(12) is different. Bayesian approach uses Eq.(9), DS approach uses Eq.(2) and PCR6 approach uses Eq.(4).

### B. Discounting in Occupancy Grids

The main advantage of using discounting is to provide a simple way to model the presence of dynamic object in the scene. This model allows to make a prediction without information on the dynamic at the cell level (or at the object level) which is generally not directly available from sensors and merely difficult to estimate without greedy time-computing algorithms [43] (especially when the evidential framework is adopted). The main issue with the discounting effect is that it makes impossible to build persistent static map. Indeed, cells not viewed by the sensor will quickly converge to the ignorance state. Therefore, this strategy cannot be used to build the map of a building for instance. If we are interested to build static map in presence of moving objects, the discounting function is then not recommended. We will see why in the next part of the paper where in this case Bayesian and DS fusion rules will not be very efficient. To handle this case, we will show why it is recommended to use the PCR6 rule.

## IV. RESULTS

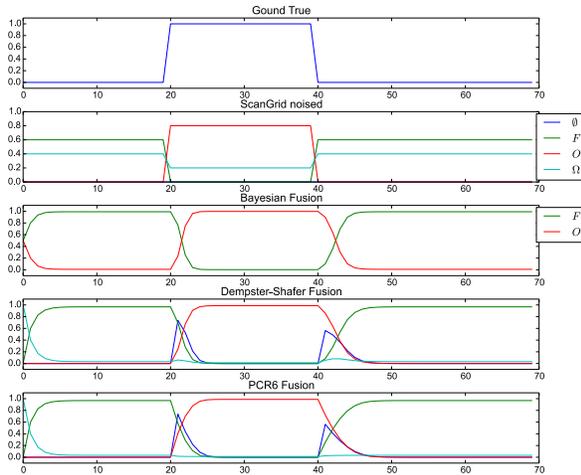

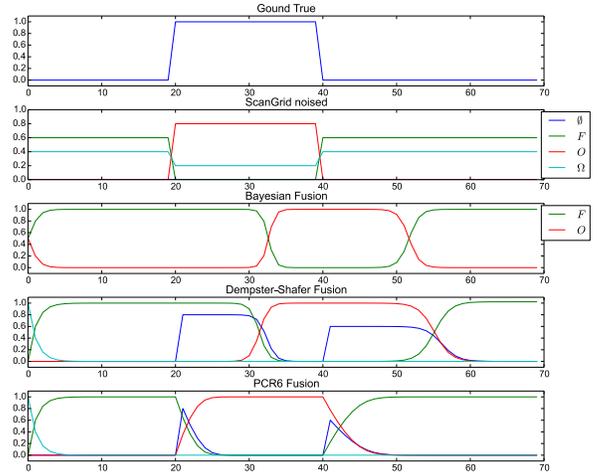

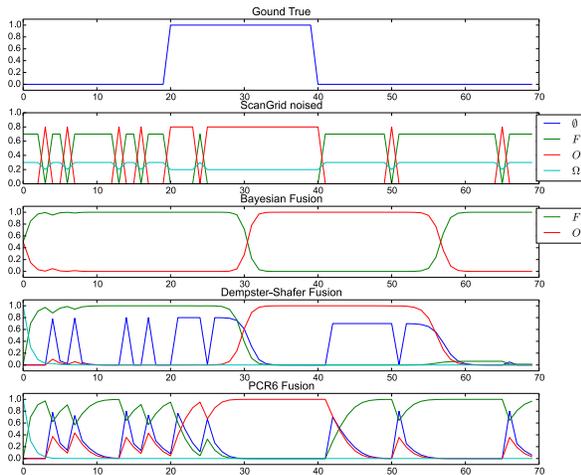

In this section, we present simulation results of grid occupancy estimation in a realistic scenario based on different rules of combination (Bayesian fusion, Dempster-Shafer rule, and PCR6 fusion rule).

### A. Basic simulation

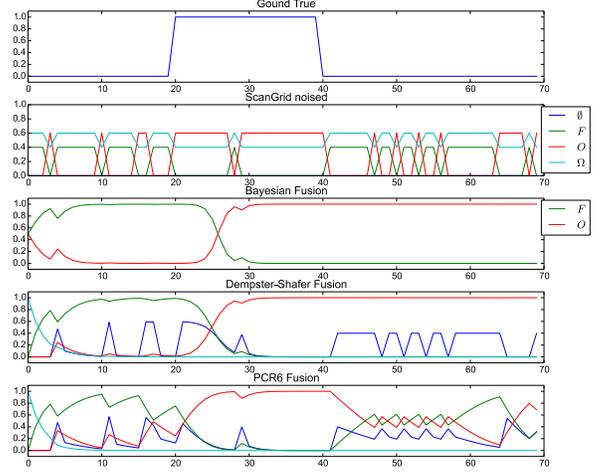

*a) Setup:* In order to present the basic behavior of the different combination rules studied, we have realized at first some simple 1D-simulations, where we consider a grid cell crossed by a moving object. In this case, the state of the cell changes from free-state to occupied-state at time  $t_1$  and from occupied-state to free-state at time  $t_2$ . Figure 1 shows the results of these simulations under different conditions. On each subfigure, we show on the top plot the real state of the cell (i.e. the groundtruth). The second row of each subplot shows the sensor data simulated that corresponds to the BBA of the state of the cell. This mass function is built according to the state of the cell, the level of confidence of the sensor and can be eventually perturbed with additional noises. FA indicates the rate of False Alarms, and ND the rate of Non Detections. We will consider different levels of confidence for  $m_{SG}(O)$  when the cell is occupied, and  $m_{SG}(F)$  when the cell is free. The bottom plot of each subplot represents the level of belief of the cell state obtained with Bayesian fusion, Dempster-Shafer (DS) fusion and the PCR6 fusion rules respectively.

*Effect of discounting:* Figure 1a presents the results of the classical chain using a discounting factor  $\alpha = 0.05$  while figure 1b presents the same case without discounting ( $\alpha = 0$ ). If the discounting is applied, all the fusion rules behave similarly, but if the discounting is not used, a lag appears with Bayesian and DS fusion rules. The lag effect is seriously reduced with PCR6 rule.

*Performances analyses:* The performance of our method is summarized in Table I. For each simulation, 10000 Monte Carlo runs have been performed, in order to estimate the false alarm and non detection rates. In order to make the

 (a) Case with discounting ( $\alpha = 0.05$ ).

 (b) Case without discounting ( $\alpha = 0$ ).

(c) Case with noise (FA=10%, ND=10%) and no discounting.

(d) Case with noise (FA=30%, ND=15%) and no discounting.

Figure 1: Evolution of the belief in a cell crossed by an obstacle observed by a sensor.

decision, the pignistic probability has been computed and a MAP estimator has been used. For each simulation presented in the Table I, we also mention the discounting level, the rate of noise impacting sensor observations.

Simulations 0 and 1, illustrated by the figure 1a and the figure 1b, correspond to the noise-free situation. By removing the discounting operator, Bayesian and DS approach have a lag in the detection of the change of state that impacts clearly their performances. The PCR6 approach is much less concerned by this effect because of the proportional conflict redistribution process. Simulations 2 and 3 (see figure 1c) include 10% of wrong measurement caused by noises. The fusion rules behave similarly as for simulation 0 and 1, but the performances are

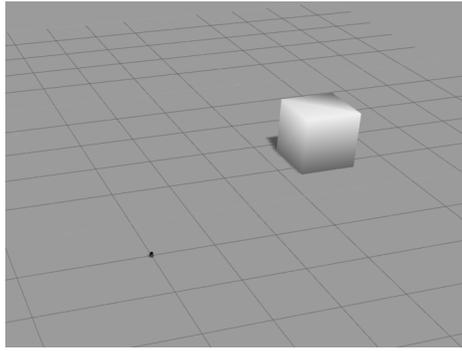

a bit lower which reflects the effect of noisy measurements in the grid estimation process. For simulations 4, 5 and 6, the noise reaches 15% for ND and 30% for FA which is quite strong. As we see in figure 1d, the Bayesian and DS fusion rules are not able to detect the second state change, during the simulation time. This induces bad False alarm rates. In the last simulations 7 and 8, the noise is about 25% of ND and 50% of FA. In these conditions, all the methods have poor false alarm rates but the PCR6 keeps good (low) non detection rates.

### B. LIDAR simulation

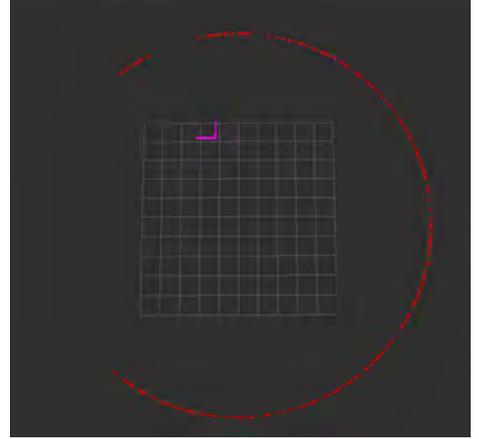

In this simulation, the DS and PCR6 fusion rules are compared on a 2D occupancy grid problem close to real

N°	discounting	key time	sensor noise	sensor belief	Bayesian		DS		PCR6

(b) Bird view of one LIDAR scan.

Figure 2: Simulation setup.

application for robot perception. The simulation was realized using the Robot Operating System (ROS) [50] environment and the Gazebo [51] simulator is used here to simulate a Hokuyo LIDAR and a moving object as shown on Figure 2a. The simulated sensor has a FoV (Field of View) about  $270^\circ$  and a max range about 10m. The rate of the scan is 20Hz and the ranges of the LIDAR point are corrupted with a Gaussian noise  $\mathcal{N}(0, 0.1)$ .

Figure 2b shows a simulated LIDAR scan. The beams that do not hit obstacle within the range are considered as max range (as done in the real Hokuyo sensor). The moving object is a box which has a circular trajectory and moves at 6 rpm around the LIDAR. A *ground true* grid is computed according the real position of the box and its geometry at each scan time. The grid used is a square of 10 m by 10 m with a resolution of 0.1 m, and the ScanGrid BBA are set to  $m_{SG}(O) = 0.8$ ,  $m_{SG}(\Omega) = 0.2$  for occupied cells and  $m_{SG}(F) = 0.6$ ,  $m_{SG}(\Omega) = 0.4$  for free cells.

In order to quantify the results, we compute some metrics. However, because of occlusion, only the cells located on the edges of the box can be considered, that is why we don't consider global metrics. We consider here the two following metrics: 1) the number of correct occupied cell (proportional to recall in our case), and 2) the number of conflicting cells

close to the box. The first describes the ability of the method to add objects into the map and also by analogy to remove object from the map. The second describes the ability of the method to detect moving objects by generating conflict. This ability is important and is one of the improvement of evidential grid against classical Bayesian grid estimation.

Figures 3 & 4 show the result over one turn. The number of cells detected for both metrics depends a lot on the position around the sensor. This can be explained because, in some place, the LIDAR sensor is able to see two edges of the box. In other situations, the LIDAR sensor detects just one edge, and when the box is behind (on the back of) the sensor it is out of the field of view of the LIDAR. On Fig. 3, we can see that the number of occupied cells with the PCR6 fusion is greater than with the DS fusion. Contrarily to the PCR6, the DS fusion without discounting cannot estimate well the quick changes of states in the map. From the motion standpoint, Fig. 4 shows that the PCR6 approach keeps the same level to generate conflict in presence of moving object (similar to DS fusion). The x-axis of Figures 3 & 4 is the time stamp of the LIDAR scans, and the y-axis is the number of cells in different states (occupied for Fig. 3, or with conflict for Fig. 4).

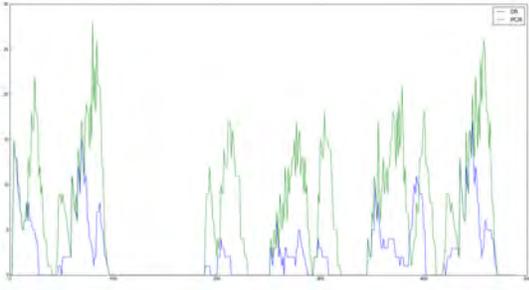

Figure 3: 2D LIDAR simulation: Number of correct occupied cells (green=PCR6,blue=DS).

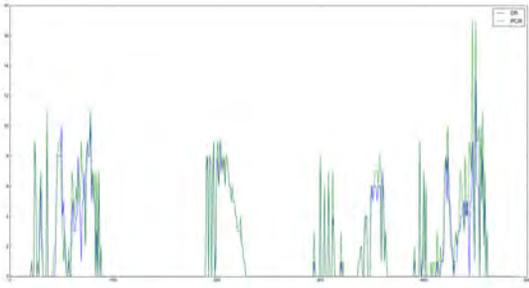

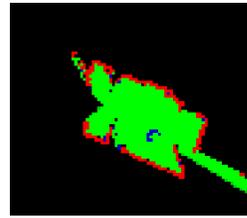

Figure 4: 2D LIDAR simulation: Number of conflicted cells into the box shape (green=PCR6,blue=DS).

### C. Real data processing

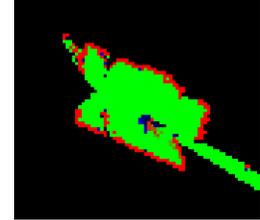

A real experimentation was realized using an Hokuyo UTM-30LX sensor. This experimentation takes place in an office in which a person was walking into. The evidential occupancy grid fusion node was implemented within the ROS environment. The grid has the same size and resolution as in the previous example. The BBA used in the sensor model has been set to  $m_{SG}(O) = 0.8$ ,  $m_{SG}(\Omega) = 0.2$  for occupied cells and  $m_{SG}(F) = 0.86$ ,  $m_{SG}(\Omega) = 0.2$  for free cells. No discounting was applied.

Figure 5 presents the occupancy grid estimation using DS and PCR6 rules of combination and for two typical snapshots of the sequence. The color of cells denotes the state having the highest mass value: green for  $F$  (free state), red for  $O$  (occupied state), and black for  $\Omega$  (full uncertainty). For convenience, we have also displayed in blue all the cells that carry a conflicting mass  $m(\emptyset) > 0.1$  before applying the normalization step of DS rule, or before applying the proportional conflict redistribution with PCR6. Figure 5a and 5c show the result using DS rule. The room scanned by the sensor is correctly mapped and its bounds (mainly walls and doors) are clearly identified by the red pixels. The free space (green pixels) is correctly detected in the room except near the people that is labeled as free (with conflicting cell shown in blue for convenience). The people moving around the desk in the office room is only detected from conflicting cells when

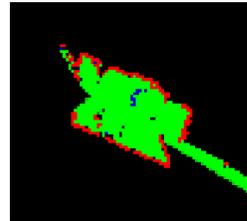

he stops to walk several times. Figure 5b and 5d show the PCR6 result at the same time stamps. In this case, the people is correctly detected as shown by the red pixels (occupied cells) inside the green area (the office room). A conflict cell is created when he starts walking in the room. The static part of the room is also detected (as with DS fusion rule).

## V. CONCLUSIONS AND PERSPECTIVES

In this work we have presented a novel application of the belief functions which significantly improves the map building process for robots environment perception and grid map estimation. This work shows the importance of defining an accurate sensor model. We have considered the uncertainties of the LIDAR measurements and used the PCR6 rule of DSmT to model and combine sensor information. Our new method differs of Bayesian approach by allowing support for more than one proposition at a time, rather than a single hypothesis. It is an interval-based approach, as defined by the lower and upper probability bounds  $[Bel, Pl]$  allowing the lack of measurement to be modeled adequately. This new method differs also from the classical evidential approach because the PCR6 rule is used instead of DS rule. Experimental results with the LIDAR confirm the improvements of the accuracy of this new grid estimation method with respect to previous methods. As perspectives, we will try to implement this fusion rule in 3D occupancy grid (Octomap based) and use a stereo camera with dense disparity map computation as sensor source. In future works, we will consider in this perception context more classes into the frame of discernment and we will also test the improved PCR6 rule of combination including Zhang's degree of intersection.

(ESREL 2015), Zurich, Switzerland, Sept. 7–10, 2015, and reprinted with permission.

**Abstract**—Civil engineering protection works mitigate natural risks in mountains, such as torrents. Analysing their effectiveness at several scales is an essential issue in the risk management. Based on expert knowledge, used methods have been developed under risky environment. However, decision is made under uncertainty because of 1) the lack of information and knowledge on natural phenomena and 2) the heterogeneity of available information and 3) the reliability of sources. In this paper, we propose to help decision-makers with advanced multicriteria decision making methods (MCDMs). Combining classical MCDM approaches, belief function, fuzzy sets and possibility theories, they make it possible decisions based on heterogeneous, imprecise and uncertain evaluation of criteria provided by more or less reliable sources in an uncertain context. COWA-ER (Cautious Ordered Weighted Averaging with Evidential Reasoning), Fuzzy-Cautious OWA or ER-MCDA (Evidential Reasoning for Multi Criteria Decision Analysis) are thus applied to several scales of effectiveness assessment.

**Keywords:** Torrent protection, belief functions, MCDM.

## I. INTRODUCTION

Mountain natural phenomena such as torrential floods put people and buildings at risk. Protection works influence both causes and effects of phenomena to limit induced risks. For instance, check-dams control material volume and flow of torrential floods. Their design allow them to reduce sediment production (Figure 1). Defining the strategy for investment and maintenance is an essential issue in the risk management process. It is based on their effectiveness assessment. Decision support tools help assessing their economic efficiency depending on their structural state and functional effects on phenomena (stopping, braking, guiding, etc.) [1].

Cost Benefit Analysis (CBA) is the most used decision-aid method in the natural hazard context. It helps assessing efficiency of potential actions comparing, for several scenarii, investment and maintenance costs with direct and indirect losses [2]. Actually, natural risk analysis is limited to a set of scenarii which can be discussed [3]. However, probability

knowledge (distribution or scenarii) is affected by the lack of information on phenomena, but also by heterogeneity and reliability of available sources (Tacnet 2009). [4].

Concepts of failure mode and effects analysis (FMEA), already used for hydraulic dams [5], are extended to assess the effectiveness of check-dams [6]. Those methodologies elicit the expert reasoning process and consider structural, functional and economic features [1]: indicators formalise information processing to make it repeatable and reproducible [7]. Nevertheless, assessment is based on heterogeneous and imprecise information provided by more or less reliable sources [4].

Methods to represent information imperfection are needed to aid decisions including check-dam effectiveness assessment. Advanced MCDMs combining classical MCDM approaches [8], [9], belief function [10], [11], fuzzy sets [12] and possibility theories [13] have been developed to help decisions under risk or uncertainty such as COWA [14], Fuzzy-Cautious OWA [15] and ER-MCDA [16].

This paper first recalls the context of information imperfection related to check-dams. We secondly introduce the principles of new belief function theory based evolutions of MCDMs. We then apply them to cases related to effectiveness of check-dams. We finally discuss remaining issues for new decision-making methods in risky and uncertain contexts.

## II. EFFECTIVENESS OF PROTECTION WORKS IN AN UNCERTAIN ENVIRONMENT

Assessing effectiveness of existing check-dams is based on their structural state, functional capacity and relative risk reduction. We describe below the decision context and information imperfection all over the decision process.

### A. Formalization of decision context

1) *Several system scales as alternatives:* Protecting exposed elements with check-dams is based on interdependent systems. A check-dam  $E^l$  belongs to a device  $D^o$ . Several

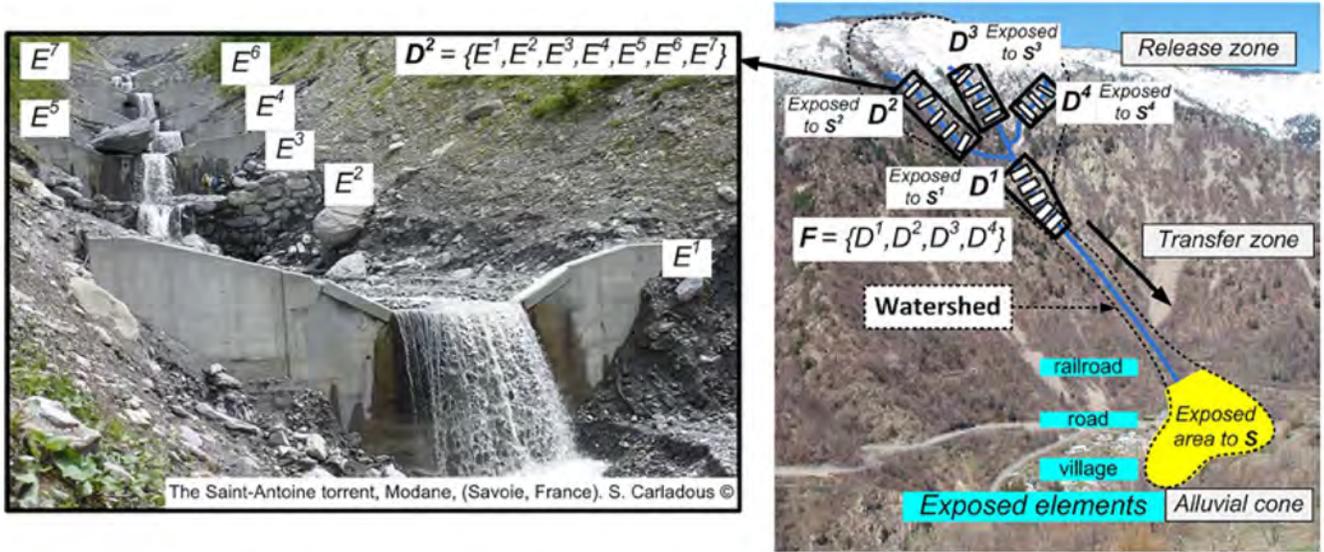

Figure 1. Multi-system formalization for check-dams in a torrential watershed.

devices protect exposed elements at the watershed scale ( $F$ ). Each  $E^l$  is considered as an alternative belonging to a set of  $m$  check dams  $D^o = \{E^1, \dots, E^l, \dots, E^m\}$ .  $D^o$  is a device alternative in the set  $F = \{D^1, \dots, D^o, \dots, D^t\}$ .  $F$  represents all  $t$  devices which protect exposed elements in the watershed (Figure 1).

2) *Possible actions on systems as alternatives*: For each system scale  $E^l$ ,  $D^o$  and  $F$ , several actions  $a_i$  can be proposed: for example, no action ( $a_1$ ), maintenance of check-dams ( $a_2$ ) or building new works ( $a_3$ ).  $E_i^l$ ,  $D_i^o$  and  $F_i$  represent all possible actions on each system scale (resp. a single check-dam, a set of check-dams, all sets in the watershed).

3) *Decision objects and linked problems*: A decision-making problem consists in choosing, ranking or sorting alternatives on the basis of quantitative or qualitative criteria  $g_j$  [9]. Effectiveness is the level of objective achievement [17]. Sorting alternatives  $E^l$ ,  $D^o$  and  $F$  in effectiveness classes (e.g., optimal, correct, partial, deficient) is a recurrent issue. Choosing between several alternatives  $a_i$ , or ranking them, are other practical issues.

#### B. Various information is needed but is imperfect

1) *The states of the nature  $S$  or  $S^o$* : Debris flows and torrential floods with bed-load transport are the two main torrential processes [18]. Choosing a specific criterion of interest for each process is needed (e.g., flow volume or deposit depth).

The states of the nature analysis depends on its location in the watershed. They can be represented by a finite or a continuous set according to available information. For torrential floods, field experts define a finite set  $S = \{S_1, \dots, S_k, \dots, S_n\}$  for  $F$  scale and another set  $S^o = \{S_1^o, \dots, S_k^o, \dots, S_n^o\}$  for  $D^o$  and  $E^l$  scales [1].

2) *The decision-maker (DM) preferences on  $g_j$* : Assessing each alternative in a MCDM context requires three elements from the DM about  $g_j$ : 1) the list of  $g_j$ , 2) weights  $w_j$ : preferences between  $g_j$ , 3)  $g_j$  assessment scale: preferences between alternative evaluations through a total or a partial pre-order [9], [19].

3) *Decision-making and imperfect information*: To compare several alternatives, decision support tools are based on several  $g_j$  evaluations of their consequences (payoffs/gains) under  $S$  (or  $S^o$ ). For example, each  $F_i$  is evaluated given the knowledge on  $S$  and the payoff matrix defined by  $C = [C_{ik}]$  where  $i = 1, \dots, q$  and  $k = 1, \dots, n$  (Eq. (1)). The decision problem consists in choosing the alternative  $F_{i^*} \in F_i$  which maximizes the payoff to the DM. We assume that  $C_{ik}$  assessment can be based on several  $g_j$ .

$$\begin{matrix}
 & S_1 & \dots & S_k & \dots & S_n \\
 F_1 & \left( \begin{array}{cccc} C_{11} & \dots & C_{1k} & \dots & C_{1n} \\ \vdots & & \vdots & & \vdots \\ F_i & C_{i1} & \dots & C_{ik} & \dots & C_{in} \\ \vdots & & \vdots & & \vdots \\ F_q & C_{q1} & \dots & C_{qk} & \dots & C_{qn} \end{array} \right) & = & C, & (1)
 \end{matrix}$$

Whatever the decision context, all decisions relate to imperfection of used information to assess  $S$ ,  $C_{ik}$  and  $g_j$  [4]: **inconsistency** (conflict between sources); **imprecision** (e.g., interval of numerical values); **incompleteness** (lack of information while data exist); **aleatory uncertainty** (aleatory events); **epistemic uncertainty** (lack of knowledge).

Depending on his knowledge about  $S$ , the DM is face on different decision-making problems [14]: **under certainty** (only one  $S_k$  is known); **under risk** (the true  $S$  is unknown but one knows all the probabilities  $p_k = P(S_k)$ ); **under**

**ignorance** (one assumes no knowledge about the true state but that it belongs to  $S$ ); **under uncertainty** (the knowledge on  $S$  is characterized by a belief structure).

### III. NEW BELIEF FUNCTION THEORY BASED EVOLUTION OF MCDMS

Comparing alternatives requires assessment of 1) DM preferences on  $w_j$  and  $g_j$ , 2) information imperfection to evaluate  $S$  and  $g_j$ , 3) MCDM choice to aggregate several  $g_j$  to define  $C$ . In this part, we introduce the principles of methods based on new MCDMs evolutions based on belief function theory.

#### A. Basics of belief functions

Shafer [10] originally proposed the basics of belief functions. One starts with a finite set  $\Theta$  (called the frame of discernment of the decision problem). Each element of  $\Theta$  is a potential answer of the decision problem and they are assumed exhaustive and exclusive. The powerset of  $\Theta$  denoted  $2^\Theta$  is the set of all subsets of  $\Theta$ , empty set included. A body of evidence is a source of information that will help the DM to identify the best element of  $\Theta$ . The interest of belief functions is their ability to model epistemic uncertainties. Each body of evidence is characterized by basic belief assignment (bba), or a mass of belief, which is a mapping  $m(\cdot) : 2^\Theta \rightarrow [0, 1]$  that satisfies  $m(\emptyset) = 0$ , and for all  $A \neq \emptyset \in 2^\Theta$  the condition  $\sum_{A \subseteq \Theta} m(A) = 1$ . The Belief function  $\text{Bel}(\cdot)$  and the plausibility function  $\text{Pl}(\cdot)$  are defined from  $m(\cdot)$  by :

$$\text{Bel}(A) = \sum_{B \subseteq A | B \in 2^\Theta} m(B), \quad (2)$$

$$\text{Pl}(A) = \sum_{B \cap A \neq \emptyset | B \in 2^\Theta} m(B). \quad (3)$$

$\text{Bel}(A)$  and the plausibility function  $\text{Pl}(A)$  are often interpreted as lower and upper bounds of the unknown probability of  $A$ . The vacuous bba defined as  $m_v(\Theta) = 1$  models the full ignorant source of evidence. Shafer [10] proposed Dempster's rule to combine distinct sources of evidence which has been subject to strong debates in fusion community starting from Zadeh's first criticism in 1979. Since the 90's many alternatives have been proposed to combine more or less efficiently belief functions, as well as an extension of belief function in the framework of Dezert-Smarandache Theory (DSMT) as shown and discussed in [11].

According to the DM attitude, credibilities, plausibilities, Smets' Pignistic probability  $BetP$  [20] or Dezert-Smarandache probability  $DSmP_{\epsilon=0}$  [11] (Vol. 3) can be computed to compare alternatives.

#### B. ER-MCDA

Tacnet [4] proposed the ER-MCDA methodology. Its originality consists in the association of different theories. It dissociates imperfect evaluations from their combination in the fusion process considering both evaluation imperfection and heterogeneity, reliability of sources. It uses developments for MCDM based on the combination of Analytic Hierarchic Process (AHP) approach developed by Saaty [8] and DSMT

[11]. AHP allows to build bbas from DM preferences on solutions which are established with respect to several  $g_j$ . DSMT allows to aggregate efficiently the (possibly highly conflicting) bbas based on each criterion. DSMT-AHP method also allows to take into account the different importances of  $g_j$  and/or of the different members of the DM group.

ER-MCDA exploits the following general principles into independent steps:

- The AHP methodology helps to analyze the decision problem through a hierarchical structure and to define the evaluation classes for decision through a common frame of discernment  $\Theta$ .
- The imprecise evaluation and mapping of  $g_j$ : qualitative or quantitative criteria are evaluated through possibility distributions representing both imprecision and uncertainty [13]. Possibility distribution can be derived into bbas [21]. We use a mapping process that projects the bbas expressed on fuzzy sets expressed on  $\Theta$  [12].
- The fusion of mapped evaluations and  $g_j$ : a first fusion process is done for all evaluations of the different sources for a same  $g_j$ . Bbas can be discounted according to the reliability level of each source. We finally get bbas for each  $g_j$  whose weights  $\omega_j$  have been defined according to the classical AHP method. Those  $\omega_j$  are derived into importance discounting factors. Bbas corresponding to each  $g_j$  are then fused a second time to get the final result which is called a decision profile. This profile shows not only the decision to take but provides also an evaluation of the distribution of knowledge on the other levels and uncertainty. It is possible to check if all sources agree about the decision and also to have an idea about the uncertainty of their evaluation. The quality of information leading to decision is linked to the decision itself. The results can be bbas or belief, plausibility values that correspond to pessimistic or optimistic choice of a decision level. With ER-MCDA, one uses PCR6 (Proportional Conflict Redistribution Rule no 6) developed in DSMT [11] (Vol. 3) to palliate disadvantages of the classical Dempster fusion rule discussed in [22]. The importance of criteria is a different concept than the classical reliability concept developed and used in the belief theory context. In order to make a difference between importance of criteria, uncertainty related to the evaluations of criteria and reliability of the different sources, specific methods such as DSMT-AHP [23], [24] have extended Saaty's AHP method.

#### C. COWA-ER and Fuzzy Cautious OWA

Tacnet and Dezert [14] proposed the COWA-ER method for decision-making under uncertainty taking into account imperfect evaluations and unknown beliefs about groups of the possible states of the world. COWA-ER mixes cautiously the principle of Ordered Weighted Averaging (OWA) approach [25] with the fusion of belief functions proposed in DSMT [11]. Fuzzy Cautious OWA [15] is an improvement of COWA-ER using fuzzy sets.

1) *The OWA approach*: To recall it, we take into account the **decision-making** problems introduced in II-B3 and Eq. (1).

**1 – under certainty**: one chooses  $F_{i^*}$  with  $i^* \triangleq \arg \max_i \{C_{ik}\}$ .

**2 – under risk**: as for the CBA (cf Sec. I), for each  $F_i$ , we compute expected payoff  $E[C_i] = \sum_k p_k \cdot C_{ik}$ , then we choose  $F_{i^*}$  with  $i^* \triangleq \arg \max_i \{E[C_i]\}$ .

**3 – under ignorance**: Yager [25] uses the OWA operator as a weighted average of ordered values of a variable. For each  $F_i$  and a given criterion of interest  $g_j$ , one chooses a weighting vector  $W_i = [w_{i1}, w_{i2}, \dots, w_{in}]$  and computes its OWA value  $V_i \triangleq \text{OWA}(C_{i1}, C_{i2}, \dots, C_{in}) = \sum_k w_{ik} \cdot b_{ik}$  where  $b_{ik}$  is the  $k$ th largest element in the collection of payoffs  $C_{i1}, C_{i2}, \dots, C_{in}$ . Then one chooses  $F_{i^*}$  with  $i^* \triangleq \arg \max_i \{V_i\}$ .  $W_i$  depends on the decision attitude of the DM (pessimistic, optimistic, normative/neutral, etc.).

**4 – under uncertainty**: one assumes that a priori knowledge on the frame  $S$  is given by a bba  $m(\cdot) : 2^S \rightarrow [0, 1]$ . This case includes all previous cases depending on the choice of  $m(\cdot)$ . Yager's OWA under uncertainty is based on the derivation of a *generalized expected value*  $C_i$  of payoff for each  $F_i$  as follows:

$$C_i = \sum_{l=1}^r m(X_l) V_{il}, \quad (4)$$

where  $r$  is the number of focal elements of the belief structure  $(S, m(\cdot))$ .  $m(X_l)$  is the mass of belief of  $X_l \in 2^S$ , and  $V_{il}$  is the payoff we get when we select  $F_i$  and the state of the nature lies in  $X_l$ .

For  $F_i$  and a focal element  $X_l$ , instead of using all payoffs  $C_{ik}$ , we consider only the payoffs in the set  $M_{il} = \{C_{ik} | S_k \in X_l\}$  and  $V_l = \text{OWA}(M_{il})$  for some decision-making attitude chosen a priori. Once generalized expected values  $C_i$ ,  $i = 1, 2, \dots, q$  are computed, we compare alternatives through these results.

The principle of this method is simple, but its implementation can be quite greedy in computational resources specially if one wants to adopt a particular attitude for a given level of optimism, specially if the dimension of the frame  $S$  is large.

2) *The COWA-ER approach*: Yager's OWA approach is based on the choice of a given attitude measured by an optimistic index in  $[0, 1]$  to get the weighting vector  $W_i$ . What should be done in practice if we don't know which attitude to adopt? An answer to this question has been proposed in Cautious OWA with Evidential Reasoning (COWA-ER) which exploits the results of the two extreme attitudes jointly (pessimistic and optimistic ones) to take a decision under uncertainty based on the imprecise valuation of alternatives. In COWA-ER, the pessimistic and optimistic OWA are used respectively to construct the intervals of expected payoffs for different alternatives. For example, for  $q$  alternatives, the expected payoffs are:

$$E[C] = \begin{bmatrix} E[C_1] \\ E[C_2] \\ \vdots \\ E[C_q] \end{bmatrix} \subset \begin{bmatrix} [C_1^{\min}, C_1^{\max}] \\ [C_2^{\min}, C_2^{\max}] \\ \vdots \\ [C_q^{\min}, C_q^{\max}] \end{bmatrix}.$$

Therefore, one has  $q$  sources of information before using the belief functions framework. Basically, the COWA-ER methodology requires four steps:

- Step 1: normalization of imprecise values in  $[0, 1]$ ;
- Step 2: conversion of each normalized imprecise value into elementary bba  $m^o(\cdot)$ ;
- Step 3: fusion of bba  $m^i(\cdot)$  with some combination rule (typically the PCR6 rule);
- Step 4: choice of the final decision based on the resulting combined bba.

With COWA-ER, we consider as  $\Theta$ , the finite set of alternatives  $\Theta = \{Z_1, Z_2, \dots, Z_q\}$  and the sources of belief associated with them obtained from the normalized imprecise expected payoff vector  $E^{Imp}[C_i]$ . The modeling for computing a bba associated to hypothesis  $F_i$  from any imprecise value  $[a; b] \subseteq [0; 1]$  is done by:

$$\begin{cases} m_i(F_i) = a, \\ m_i(\bar{F}_i) = 1 - b, \\ m_i(F_i \cup \bar{F}_i) = m_i(\Theta) = b - a, \end{cases} \quad (5)$$

where  $\bar{F}_i$  is the  $F_i$ 's complement in  $\Theta$ .

COWA-ER can help to take a decision if one wants on a group/subset of alternatives satisfying a min of credibility (or plausibility level) selected by the DM. It can also be extended directly for the fusion of several sources of informations when each source can provide a payoffs matrix. We can also discount each source easily if needed.

3) *The Fuzzy-COWA-ER approach*: Unfortunately, COWA-ER has a serious limitation because the computational time depends on the number of alternatives. In COWA-ER, each expected interval is used as an information source, however, these expected intervals are jointly obtained and thus these information sources are relatively correlated. For these reasons, a modified version of COWA-ER, called Fuzzy-COWA-ER (or FCOWA-ER for short) has been developed in [15]. With FCOWA-ER, we consider the 2 columns of the expected payoff  $E[C_i]$  as two information sources, representing pessimistic and optimistic attitudes. The column-wise normalized expected payoff is:

$$E^{Fuzzy}[C] = \begin{bmatrix} N_1^{\min}, N_1^{\max} \\ N_2^{\min}, N_2^{\max} \\ \vdots \\ N_q^{\min}, N_q^{\max} \end{bmatrix},$$

where  $N_i^{\min} \in [0, 1]$  ( $i = 1, \dots, q$ ) represents the normalized value in the column of pessimistic attitude, and  $N_i^{\max} \in [0, 1]$  represents the normalized value in the column of optimistic attitude. The vectors  $[N_1^{\min}, \dots, N_q^{\min}]$  and  $[N_1^{\max}, \dots, N_q^{\max}]$

can be seen as two fuzzy membership functions (FMFs) representing the possibilities of all the alternatives  $F_1, \dots, F_q$ . The FCOWA-ER method requires also four steps:

- Step 1: normalize each column in  $E[C]$ , respectively, to obtain  $E^{Fuzzy}[C]$ ;
- Step 2: conversion of two normalized columns, i.e., two FMFs (Fuzzy Membership Functions) into two bbas  $m_{Pess}(\cdot)$  and  $m_{Opti}(\cdot)$  using the  $\alpha$ -cut approach introduced in [26];
- Step 3: fusion of bbas  $m_{Pess}(\cdot)$  and  $m_{Opti}(\cdot)$  with some combination rule (typically the PCR6 rule);
- Step 4: choice of the final decision based on the resulting combined bba.

In FCOWA-ER, only one combination step is needed. Furthermore, the bba's obtained by using  $\alpha$ -cuts are consonant support (nested in order).

#### IV. APPLICATION TO PROBLEMS OF PROTECTION WORKS EFFECTIVENESS

##### A. Assessment of structural effectiveness of a single check-dam through ER-MCDA

1) *AHP methodology*: The problem consists in choosing the observed structural effectiveness level of a given  $E^l$ . It is assessed through 6 criteria  $g_j$  [27] (Figure 2).  $\omega_j$  in Table I are defined by experts.

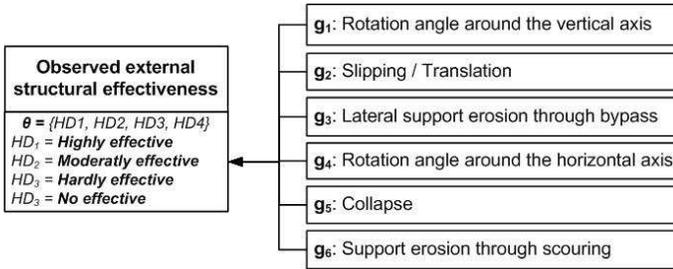

Figure 2. Hierarchical structure to assess observed structural effectiveness of  $E^l$ .

According to *DST* (Dempster-Shafer Theory) framework [10],  $\Theta$  is composed of 4 exclusive elements of effectiveness levels:  $HD_1 = \text{'High'}$ ,  $HD_2 = \text{'Medium'}$ ,  $HD_3 = \text{'Low'}$  and  $HD_4 = \text{'None'}$ .

2) *Imprecise evaluation and mapping of  $g_j$* : For  $E^l$ , we assume evaluations of  $g_j$  by two experts (sources)  $s_1$  and  $s_2$  through possibility distributions (Table I). Through expert elicitation, a set of fuzzy intervals  $L-R$  links each  $g_j$  evaluation scale and  $\Theta$ . Quotations used are extracted from [28] (Table II). Using this mapping process, bbas are established in Table III.

To take into account the reliability of each source, we discount the input masses of Table III by applying the classical Shafer's discounting method [10]. We use here discounting factors  $\alpha_{s1} = 0.7$  and  $\alpha_{s2} = 0.5$ . We obtain 12 discounted bba's (noted  $m'_1$  and  $m'_2$ ) in Table IV.

3) *Two steps of fusion*: The step 1 consists in combining the bbas  $m'_1(\cdot)$  and  $m'_2(\cdot)$  for each  $g_j$  with PCR6 fusion rule (Table V).

In step 2, we apply to each bba of Table V the importance discounting method presented in [29]. We use  $\omega_j$  (Table I) to get the Table VI. After combining its 6 bba with a variant of PCR6 to take into account positive masses on  $\emptyset$ , noted  $PCR6_\emptyset$  and a normalization procedure [29], we finally get the Table VII.

According to it,  $E^l$  is mainly medium effective because the highest belief mass is  $m(HD2)$ . Because  $m(HD3)$ , we can say that  $E^l$  effectiveness is more between low and medium, but not high, nor none.

##### B. Comparing actions on $A_i$ using (F)COWA-ER

1) *Decision problem elicitation*:  $g_j$  is the  $D^o$  effectiveness level. In a *DST* framework, one assumes 7 scenarii such as flood with bedload transport ( $S_3^o$ ) or debris flow ( $S_6^o$ ). One considers 5 possible actions such as repair of all the degraded check-dams ( $a_3$ ) or renewal of all check-dams ( $a_5$ ).

2)  *$C_{ik}$  and  $S^o$  evaluations*: One rates  $C_{ik}$  with an integer between 0 (no effective) and 10 (very high effective) [7]. As Eq. (1), one assumes  $C$  where  $q = 5$  and  $n = 7$  (Eq. (6)).

$$C = \begin{bmatrix} 5 & 3 & 4 & 2 & 3 & 1 & 1 \\ 7 & 4 & 6 & 3 & 4 & 2 & 1 \\ 8 & 5 & 7 & 4 & 5 & 3 & 1 \\ 10 & 7 & 10 & 6 & 7 & 5 & 2 \\ 10 & 9 & 10 & 9 & 10 & 10 & 4 \end{bmatrix}. \quad (6)$$

One considers 4  $X_l$ :  $X_1 = S_1^o \cup S_3^o \cup S_5^o$ ,  $X_2 = S_2^o \cup S_4^o \cup S_5^o \cup S_6^o$ ,  $X_3 = S_7^o$ ,  $X_4 = \Theta$ . One gives  $m(X_1) = 0.6$ ,  $m(X_2) = 0.2$ ,  $m(X_3) = 0.01$  and  $m(X_4) = 0.19$ . Applying the OWA pessimistic and optimistic operators, one can assess the bounds of expected effectiveness levels for each actions given by Eq. (7).

$$E[C] \subset \begin{bmatrix} [2.20; 4.56] \\ [3.00; 6.34] \\ [3.80; 7.33] \\ [5.60; 9.32] \\ [8.60; 9.94] \end{bmatrix}, \quad (7)$$

$$E^{Imp}[C] \approx \begin{bmatrix} [0.22; 0.46] \\ [0.30; 0.64] \\ [0.38; 0.74] \\ [0.56; 0.94] \\ [0.87; 1.00] \end{bmatrix}. \quad (8)$$

3) *Results through COWA-ER*: Steps 1 and 2 make it possible to assess bbas of the 5 actions in the Table VIII passing by the normalized imprecise matrix  $E^{Imp}[C]$  given in Eq. (8).

Step 3 combines the 5 bba's altogether with choice of the PCR6 fusion rule (Table IX).

Choosing the decision-making rule is needed to implement the step 4. Results are compared in the Table X. One sees that based on max of Bel, of BetP, of DSMP or of PI, the best action is always  $D_5$ .

Table I  
CRITERIA EVALUATIONS OF  $E^l$ .

$D_4$	0	0.227	0	0.611
$D_5$	0.389	0.616	1	1

### V. CONCLUSIONS AND PERSPECTIVES

In this paper, we have both formalized the decision problem and applied recent advanced MCDMs (ER-MCDA, COWA-ER, FCOWA-ER) to assess effectiveness of torrent protective check-dams in a context of imperfect information and more or less reliable sources. This application, based on expert knowledge, provides a class evaluation related to available knowledge. Others outranking methods such as the Soft-Electre Tri (SET) methodology [30] can also be applied to sort protection systems in predefined effectiveness classes. Defining uncertain states of nature and corresponding belief mass  $m(\cdot)$  remains challenging. Comparing belief functions theory with Bayesian probabilities or Choquet capacities in this actual context is a next step [31]. Effect on results of the fusion rules and order of combinations have also to be compared.

From an operational point of view, next steps will consist in DM and decision problem complete elicitation, criteria, importance, preferences on evaluation scale assessments. Afterwards, these methods will be combined in a global process taking into account all the system scales related to protection system devices.

Originally published as: J. Dezert, A. Tchamova, P. Konstantinova, *The Impact of the Quality Assessment of Optimal Assignment for Data Association in a Multitarget Tracking Context*, Cybernetics and Information Technologies, Vol. 15, No. 7, pp. 88–98, Dec. 2015, and reprinted with permission.

**Abstract**—The main purpose of this paper is to apply, and to test the performance of the new method, based on belief functions, proposed by Dezert & all to evaluate the quality of individual association pairings provided in the optimal data association solution for improving the performances of multisensor-multitarget tracking systems. The advantages of its implementation in an illustrative realistic surveillance context when some of association decisions are unreliable and doubtful and lead to potentially critical mistakes are discussed. A comparison with the results obtained on the base of Generalized Data Association is made.

**Keywords:** data association, belief functions, PCR6 fusion rule, multitarget tracking.

## I. INTRODUCTION

The problem of Data Association (DA) is a central in the modern multi-target tracking (MTT) systems' design [1,2]. It relates to the process of associating uncertain measurements (observations) to known tracks, and it is conditioned and motivated by the most important function of each surveillance system – to keep and to improve target tracks maintenance performance. In the monosensor context it corresponds to proper sensor observations partitioning (at a given scan) to the predicted states of the targets in such a way that their tracks' updates to be as precise, correct, and reasonable, as possible.

There are several approaches developed to resolve correlation ambiguities and to select the best observation-track pairings, based on different models. Some of them establish reward matrix based on Kinematic only Data Association (KDA) and on a probabilistic framework [3,4]. Some of them rely on Belief Functions (BF) [5-9] and motivate the incorporation of the advanced concepts for Generalized Data Association (GDA) [6-8], allowing the introduction of target attribute (target type, radar cross section, etc.) into the association logic, in order to improve track maintenance performance in complicated situations (closely spaced/crossing targets), when kinematics data are insufficient for coherent decision making. The main peculiarity consists in applying Dezert-Smarandache theory (DSMT) of plausible and paradoxical reasoning [8] to model and to process the utilized attribute data. In most

common case, when surveillance system provides kinematic only information (such as range, azimuth, elevation), obtained during a given scan, the most common way of dealing is to solve the optimal DA solution and to use all solutions (pairings) to update tracks, even if some of the pairings have poor quality. It could yields, in fact, to a bad/wrong track updating, and, as a result, the overall tracking performance could be degraded substantially.

The most recent method proposed by Dezert & Benameur [10] to evaluate the Quality Assessment of Data Association (QADA) encountered in multiple target tracking applications in a mono-criterion context, and recently extended in [11] for the multi-criteria context deal just with the case above. It assumes that the rewards matrix is known and has been obtained by a method chosen by the user. It is based on belief functions for establishing the quality of pairings (interpreted as a confidence score) belonging to the optimal data assignment solution based on its consistency (stability) with respect to all the second best solutions, provided by a chosen algorithm.

The main purpose of our paper is to serve as a preliminary study of MTT performance evaluation based on QADA-KDA approach, and to discuss its advantages in an illustrative multi-target tracking scenario. We will make also comparison between its performance and the results obtained on the base of GDA. The paper is organized as follows. Section II described the problem of DA in the multitarget tracking context. Section III provides the details about the new method [10] for quality assessment of optimal DA solution. In Section IV the simulation scenario and results are presented and discussed. The conclusion is given in Section V.

## II. DATA ASSOCIATION PROBLEM IN MULTITARGET TRACKING CONTEXT

Data Association is very important, and the most decisive step in the multitarget tracking surveillance process. The DA problem consists in finding the global optimal assignment of the targets  $T_i$  ( $i = 1, \dots, m$ ) to some measurements  $z_j$  ( $j = 1, \dots, n$ ) at a given time  $k$  by maximizing the overall gain

ignorance is modelled by the proposition  $X \cup Y$ . Then one obtains:

$$\begin{cases} m_1(X) = a_1(i, j)\omega(i, j)/R_1(\Omega, A_1), \\ m_1(X \cup Y) = 1 - m_1(X). \end{cases} \quad (5)$$

$$\begin{cases} m_2(Y) = a_2(i, j_2)\omega(i, j_2)/R_2(\Omega, A_2), \\ m_2(X \cup Y) = 1 - m_2(Y). \end{cases} \quad (6)$$

Different rules of combination (Dempster-Shafer's, Dubois-Prade's, Yager's [16]) could be chosen to work with a normalized combined BBA. The method [10] recommends to use the Proportional Conflict Redistribution rule no. 6 (PCR6), proposed originally in DSMT framework [8], because it has been proved very efficient in practice. With PCR6, the following fusion result  $m_{PCR6}(\cdot) = m_1(\cdot) \oplus m_2(\cdot)$  is obtained:

$$\begin{cases} m_{PCR6}(X) = m_1(X)m_2(X \cup Y) + m_1(X) \frac{m_1(X)m_2(Y)}{m_1(X)+m_2(Y)}, \\ m_{PCR6}(Y) = m_1(X \cup Y)m_2(Y) + m_2(Y) \frac{m_1(X)m_2(Y)}{m_1(X)+m_2(Y)}, \\ m_{PCR6}(X \cup Y) = m_1(X \cup Y)m_2(X \cup Y). \end{cases} \quad (7)$$

The decision is taken on the base of the pignistic transformation:

$$BetP(X) = m_{PCR6}(X) + \frac{1}{2}m_{PCR6}(X \cup Y), \quad (8)$$

$$BetP(Y) = m_{PCR6}(Y) + \frac{1}{2}m_{PCR6}(X \cup Y). \quad (9)$$

The quality indicators are chosen as:  $q(i, j) = BetP(X)$  and  $q(i, j_2) = BetP(Y)$ . The absolute quality factor becomes:

$$Q_{abs}(A_1, A_2) = \sum_{i=1}^m \sum_{j=1}^n a_1(i, j)q(i, j). \quad (10)$$

#### IV. SIMULATION SCENARIO AND RESULTS

The noise-free multitarget tracking simulation scenario (Fig.1) consists of three air targets moving in parallel from West to East with constant velocity of 100 m/sec and a distance between them 150 m. The stationary sensor is located at the origin. The sampling period is  $T_{scan} = 5$  sec, and the measurement standard deviations are 0.5 deg and 65m for azimuth and range respectively. The surveillance of moving targets is performed during 15 scans. Figure 2 shows the respective noised scenario.

The classical target tracking algorithm was run, consisting in two basic steps: (i) data association to associate proper measurements (distance, angle) with correct targets and (ii) track filtering to update the targets state vectors, once the optimal assignment was found. In our simulation the Converted Measurement Kalman Filter [1] is used.

In this work we will focus our attention on DA step, which is very important, and the most decisive one in the multitarget tracking. The Global Nearest Neighbour (GNN) [1] approach is used in order to make a decision for data association. One obtains the assignment matrix  $AMat(i, j)$ , ( $i = 1, \dots, m; j = 1, \dots, n$ ) based on normalized distances between measurement  $j$  and target  $i$ . In order to eliminate unlikely (kinematics-based) observation-to-track pairings, the classical validation

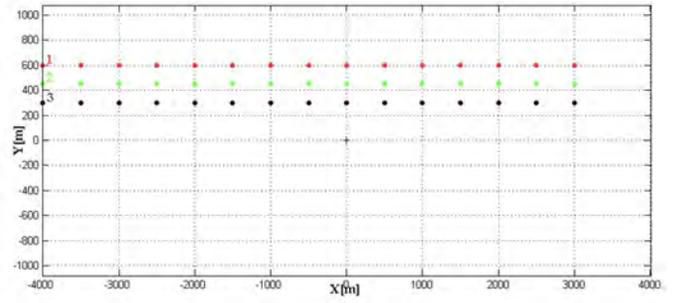

Fig. 1. Noise-free MTT scenario.

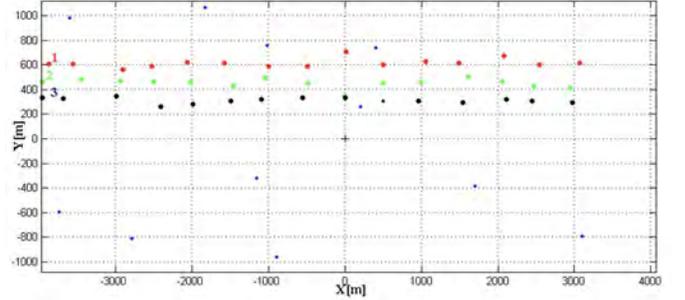

Fig. 2. Noised MTT scenario.

test  $d^2(i, j) \leq \gamma$  is carried on the Mahalanobis distance [1,2]  $d^2(i, j)$  computed from the measurement  $z_j(k)$  at a given time moment  $k$ , and its prediction  $\hat{z}_i(k|k-1)$  by

$$d^2(i, j) \triangleq (z_j(k) - \hat{z}_i(k|k-1))' S^{-1}(k) (z_j(k) - \hat{z}_i(k|k-1)). \quad (11)$$

Assuming given measurement vector's size  $M$ , the quantity  $d^2(i, j)$  could be interpreted as a sum of the squares of  $M$  independent Gaussian random variables with zero means and unit standard deviations. For that reason  $d^2(i, j)$  have  $\chi_M^2$  distribution with  $M$  degrees of freedom and allowable probability of a valid observation falling outside the gate. In our case a probability of 1% is approved, then from the table of the chi-square distribution [2] one obtains the threshold  $\gamma = 9.21$ . In fact, this value represents the biggest possible distance's value associated with observation-to-track pairings. Based on this, one assumes that if  $j$ -th measurement does not fall in the gate of target  $i$ , then the value, associated with this pairing ( $i, j$ ) in the assignment matrix could be set to be enough big (in our case equals to 100), in order to prepare the assignment matrix for the next step. The classical Munkres and Katta-Murty methods [15] are used in order to obtain the first and second best assignment solutions for measurement-to-track associations. By minimizing the sum of the chosen pairings' distances, a binary association matrix  $A = [a(i, j)]$  is obtained. Figure 3 shows the typical MTT performance, based on classical GNN approach with Kinematic only DA (KDA), when one does not utilize additional procedures to improve the quality of DA.

In case of noised measurements, it is evident that at scan number 9 tracks 2 and 3 change their directions, becoming

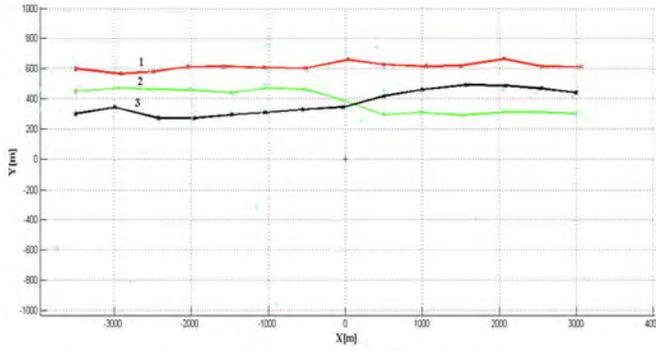

Fig. 3. Typical MTT performance with KDA.

crossing, instead of following their parallel moving behavior. It is because of incorrect determination of the incoming measurements in such a way, that they are too close and the solution of the assignment problem, which is the core of GNN, is impossible to be categorical. The problem consists also in the proximity of the targets (inter-distance of 150 m), and in the bad sensor distance resolution of  $\sigma_D = 65$  m. It leads to wrong GNN association decision.

A criterion for a minimal admissible measurements' distances is chosen here as  $d_{\min} < \sigma_D/2$ . During scan no. 9 one has:  $d_{23} < d_{\min}$ .

In such a critical case, one needs to utilize some additional information in order to avoid associations' miscorrelations. Here the method in [10] is applied. The goal is to estimate the quality of questionable pairings  $(T_2, z_2)$  and  $(T_3, z_3)$ . One obtains the corresponding reward matrix  $\Omega = [\omega(i, j)]$  with elements  $\omega(i, j)$  representing the gain of the associations of target  $T_i$  ( $i = 1, \dots, m$ ) with measurement  $z_j$  ( $j = 1, \dots, n$ ). It is achieved as:  $\omega(i, j) = 10 - AMat(i, j)$ . The reason for this expression relates to the already determined maximal normalized distance  $\gamma = 9.21$ , according to the table of chi-square distribution. The data association deals with finding the global optimal assignment of the targets to some measurements by maximizing the overall gain in such a way that no more than one target is assigned to a measurement, and reciprocally. This is an equivalent measure for optimality, as is the global minimum of the distances.

The algorithm, based on [10] was automatically applied during the scan no. 9, because the minimum distance between observations no. 2 and no. 3 is under the accepted limits  $d(2, 3) = 15.83\text{m} < \sigma_D/2$ . The quality matrix at scan no. 9, containing the quality levels associated with the chosen pairings in the first best solution

$$A_1 = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix},$$

characterizing the set  $\{(T_1, z_1), (T_2, z_2), (T_3, z_3)\}$  of associa-

tions, with respect to the second best solution

$$A_2 = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{bmatrix},$$

characterizing the set  $\{(T_1, z_1), (T_2, z_3), (T_3, z_2)\}$  of associations, is given in Table I below.

 TABLE I  
 QUALITY MATRIX AT SCAN 9.

Obs/Track	1	2	3
1	0.773	0.000	0.000
2	0.000	0.504	0.000
3	0.000	0.000	0.498

It is obvious that according to the first best assignment solution, one has:  $q(T_1, z_1) = 0.773$ ,  $q(T_2, z_2) = 0.504$ , and  $q(T_3, z_3) = 0.498$ . We accept the admissible for a correct association quality threshold to be set to  $q_T = 0.7$ .

Based on the associations quality assessment (Table I), and the accepted quality threshold  $q_T = 0.7$ , one could make the following decision: The only pairing, among those, chosen by Munkres algorithm in the first best assignment is  $(T_1, z_1)$ , because its quality level exceeds the accepted reasonable for correct association quality threshold  $q(T_1, z_1) = 0.773 > q_T$ . Following the decision logic in [10], only  $(T_1, z_1)$  pairing will be used in the updating process, while the second and third tracks will keep going under prediction mode while the next measurements will be available, because  $q(T_2, z_2) = 0.504 < q_T$ , and  $q(T_3, z_3) = 0.498 < q_T$ . The performance of the MTT algorithm, based on the QADA-KDA is shown on Fig.4. It is obvious that the reasoned/informed decision taken at scan no.9, based on QADA-KDA method leads to miscorrelation conflict resolution.

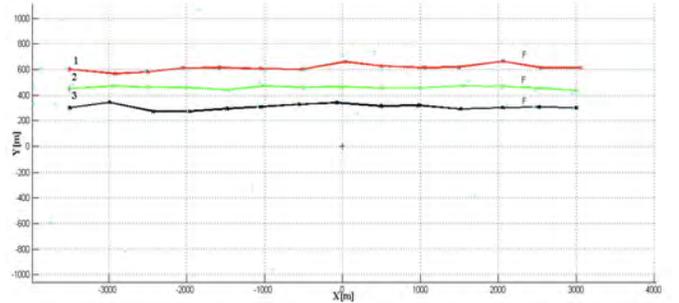

Fig. 4. MTT performance with QADA-KDA.

In order to compare the obtained by QADA result, the simulation was made by applying GDA (Fig.5), when the target attribute (target type) is introduced into the association logic, in order to improve track maintenance performance in the same MTT scenario, with an additional assumption, that targets go from West to East in a group with the following type order {Fighter, Cargo, Fighter}.

GDA-MTT improves the process of DA by utilizing target's type decision (based on confusion matrix  $C = [c_{ij}]$ ) coupled

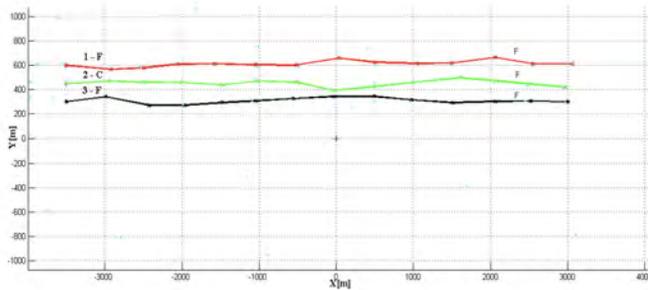

Fig. 5. MTT performance with GDA.

with the classical kinematic measurements. The way of constructing the confusion matrix is based on some underlying decision-making process based on specific attribute features measurements. Its elements represent the probability of decisions  $T_d$  ( $T_1 = \text{Fighter}$ ,  $T_2 = \text{Cargo}$ ) that the target type is  $j$  when its real type is  $i$ , more precisely

$$c_{ij} = P(T_d = T_j | \text{True Target Type} = i).$$

In our simulation we have chosen the following confusion matrix

$$C = \begin{bmatrix} 0.95 & 0.05 \\ 0.05 & 0.95 \end{bmatrix}.$$

GDA is applied at each scan during the whole surveillance process, in order to prevent observation-to-track miscorrelations.

## V. CONCLUSION

This work is a preliminary study of MTT performance evaluation based on the new Quality Assessment of optimal DA method, proposed by Dezert & al. It assures the stability of MTT performance and could be applied in all cases relating to the impossibility of DA to produce an association decision with a high quality. It might concern cases, when only kinematics measurements are available, as well the cases when attribute and kinematic data are both available, because QADA is totally independent of the applied logic to obtain the best DA solution. The work's perspective concerns Monte Carlo based evaluation of different, more critical MTT scenarios in a multi-sensor context.

**Abstract**—The main objective of this paper is to present, to apply, and to test the effectiveness of the new method, based on belief functions, proposed by Dezert et al. in order to evaluate the quality of the individual association pairings provided in the classical optimal data association solution for improving the performances of multitarget tracking systems in clutter, when some of the association decisions given in the optimal assignment solution are unreliable and doubtful and lead to potentially critical mistake. This evaluation is based on a Monte Carlo simulation for particular difficult maneuvering and non-maneuvering MTT problems in clutter. A comparison with the results obtained on the base of Kinematic only Data Association and Generalized Data Association is made.

**Keywords:** Data association, Belief Functions, PCR6 fusion rule, multitarget tracking.

## I. INTRODUCTION

Data association (DA) is a fundamental and central problem in up-to-date multitarget tracking (MTT) systems [1]-[2]. It entails selecting the most trustable associations between uncertain sensor's measurements and existing targets at a given time. In the presence of dense MTT environment, with false alarms and sensors detection probability less than unity, the problem of DA becomes more complex, because it should contend with many possibilities of pairings, some of which are in practice very doubtful, unreliable, and could lead to critical association mistakes in overall tracking process. To avoid such cases, sometimes it is better to wait for a new measurements during the next scan, instead of taking a hard DA decision, which actually is not always unique.

Several methods have been devised over the years, in order to resolve properly DA problem. They are originating from different models. Some rely on the established reward matrix based on Kinematic only Data Association (KDA) and on a probabilistic framework [3]-[4]. Some other studies are based on Belief Functions (BF) [5]-[9], motivating the incorporation of the advanced concepts for Generalized Data Association (GDA) [6]-[8], where a particular target's attribute is introduced into the association logic in order to compensate the complicated cluttered cases, when kinematics data are insufficient for adequate decision making. Dezert-Smarandache Theory (DSMT) of plausible and paradoxical reasoning [8] is used to model and to process the utilized

attribute data. Although interesting and approved, all these methods currently developed are limited to the following aspect - all of them solve the optimal DA problem and use all optimal observations-to-tracks pairings, selected in the first best DA solution to update tracks, even if some of them have poor quality. In consequence the overall tracking performance could be degraded substantially. In order to deal with this case the most recent method to evaluate the Quality Assessment of Data Association (QADA) encountered in multiple target tracking applications in a mono-criterion context is proposed by Dezert and Benameur [10]. It is extended in [11] for the multi-criteria context. This novel method assumes the reward matrix is known, regardless of the manner in which it is obtained by the user. It is based on BF for achieving the quality of pairings (interpreted as a confidence score) belonging to the optimal data assignment solution based on its consistency (stability) with respect to all the second best solutions, provided by a chosen algorithm.

This paper is an extension of our preliminary study on the effect of applying QADA method in MTT presented in [17]. The main purpose of our paper is to assess the efficiency of QADA method in a critical, conflicting MTT situation. The evaluation is based on a Monte Carlo simulation for particular difficult maneuvering and non-maneuvering MTT problems in clutter. The QADA based MTT performance is compared with the results, obtained for KDA and GDA based MTT, concerning the same scenarios. The paper is organised as follows. In order to achieve a good readability of the paper, we recall in section II the data association problem within the MTT context, and in a section III the details of the new method, proposed by Dezert et al. [10] for quality assessment of pairings, chosen in the optimal DA solution. In section IV we discuss and propose the way in which Kalman filtering could be affected in order to reflect the knowledge we have obtained on the base of QADA method. Two simulation MTT scenarios (with non-maneuvering and maneuvering targets) are presented and the results, obtained on the base of QADA-, KDA-, and GDA based MTT are discussed. Conclusions are made in Section VI.

## II. DATA ASSOCIATION PROBLEM IN MTT CONTEXT

The DA problem consists in finding the global optimal assignments of targets  $T_i, i = 1, \dots, m$  to some measurements  $\mathbf{z}_j, j = 1, \dots, n$  at a given time  $k$  by maximizing the overall gain in such a way, that no more than one target is assigned to a measurement, and reciprocally.

The  $m \times n$  reward (gain/painoff) matrix  $\Omega = [\omega(i, j)]$  is defined by its elements  $\omega(i, j) > 0$ , representing the gain of the association of target  $T_i$  with the measurement  $\mathbf{z}_j$ . These values are usually homogeneous to the likelihood ratios. In our case  $\omega(i, j)$  represents the normalized distances between the measurement  $Z_j$  and target  $T_i$ :  $d^2(i, j) \triangleq (\mathbf{z}_j(k) - \hat{\mathbf{z}}_i(k|k-1))' \mathbf{S}^{-1}(k) (\mathbf{z}_j(k) - \hat{\mathbf{z}}_i(k|k-1)) \leq \gamma$  computed from the measurement  $\mathbf{z}_j(k)$  and its prediction  $\hat{\mathbf{z}}_i(k|k-1)$  computed by the tracker of target  $i$  (see [2] for details), and the inverse of the covariance matrix  $\mathbf{S}(k)$  of the innovation computed by the tracking filter. In this case the DA problem consists in finding the best assignment, minimizing the overall cost.

The optimal DA problem consists in finding the  $m \times n$  binary association matrix  $\mathbf{A} = [a(i, j)]$  with  $a(i, j) \in \{0, 1\}$ , maximizing the global reward  $R(\Omega, \mathbf{A})$ , given by:

$$R(\Omega, \mathbf{A}) \triangleq \sum_{i=1}^m \sum_{j=1}^n \omega(i, j) a(i, j). \quad (1)$$

If  $a(i, j) = 1$ , it means that one has an association between target  $T_i$  and measurement  $\mathbf{z}_j$ . The association indicator value  $a(i, j) = 0$  means that they are not associated.

$$a(i, j) = \begin{cases} 1, & \text{if } \mathbf{z}_j \text{ is associated to track } T_i, \\ 0 & \text{otherwise.} \end{cases} \quad (2)$$

The importance of the assignment problem is quite clear and various successful solutions to its solving already exist. Among the well known are Kuhn-Munkres algorithm (known as Hungarian) [12]-[13], and its extension proposed by Bourgeois and Lassalle in [14] to rectangular matrices. More sophisticated Murty's method [15] provides not only the first best assignment, but also the  $m$ -best assignments in order of increasing cost, as it was shown in the examples in [10]-[11]. The best optimal assignment solution is not necessarily unique, as well as the second best one. Usually in MTT algorithms the first best assignment solution is taken as a hard decision for association. But in some real practical cases of dense multi-target and cluttered environment, DA problem is difficult to solve, because some of the associations decisions  $a(i, j)$  are unreliable, so they could lead to potential mistakes.

For example, in case of incorrect determination of the incoming measurements for two tracks in such a way, that they are too close, the solution of the assignment problem, that is the core of the Global Nearest Neighbour (GNN) approach, is impossible to be sufficiently explicit. In such a case, it will be more cautious not to rely on all the pairings confirmed in the first best solution, no matter than only some of them are trustable enough. Utilizing the already obtained and available  $m$ -best assignments solutions, Dezert et al. [10], [11] provided an appealing method for taking into account this knowledge.

## III. QUALITY ASSESSMENT OF PAIRINGS IN DA

In order to establish the quality of particular associations, associated with the optimal assignment matrix  $\mathbf{A}_1$ , and satisfying the condition  $a_1(i, j) = 1$ , QADA method proposes to utilize both, first and second assignment solutions  $\mathbf{A}_1$  and  $\mathbf{A}_2$ . For a self-containing purpose, this section recalls briefly the principle of QADA that has been already detailed in [10], [11] with a tracking application in [17].

The main idea behind it is to compare the values  $a_1(i, j)$  in  $\mathbf{A}_1$  with the corresponding values  $a_2(i, j)$  in  $\mathbf{A}_2$ , and to identify if there is a change of the optimal pairing  $(i, j)$ . In our MTT context  $(i, j)$  means an association between measurement  $\mathbf{z}_j$  and target  $T_i$ . One establishes a quality indicator associated with this pairing, depending on the stability of the pairing and also, on its relative impact in the global reward. The proposed method works also when the 1<sup>st</sup> and 2<sup>nd</sup> optimal assignments  $\mathbf{A}_1$  and  $\mathbf{A}_2$  are not unique, i.e., there are multiplicities available. The construction of the quality indicator is based on BF theory and Proportional Conflict Redistribution Rule no.6 (PCR6), defined within DSMT [8]. It depends on the type of the pairing matching, as it is described below:

- If  $a_1(i, j) = a_2(i, j) = 0$ , one has a full agreement on the hypothesis 'non-association' of the given pairing  $(T_i, \mathbf{z}_j)$  in  $\mathbf{A}_1$  and  $\mathbf{A}_2$ . This 'non-association' has no impact on the global reward values  $R_1(\Omega, \mathbf{A}_1)$  and  $R_2(\Omega, \mathbf{A}_2)$ , therefore it will be useless to utilize it in DA. Hence, in this case, the quality indicator will be set to zero,  $q(i, j) = 0$ .
- If  $a_1(i, j) = a_2(i, j) = 1$ , one has a full agreement on the hypothesis 'association' of the pairing  $(T_i, \mathbf{z}_j)$  in  $\mathbf{A}_1$  and  $\mathbf{A}_2$ . This 'association'  $(T_i, \mathbf{z}_j)$  has different impacts on the global reward values  $R_1(\Omega, \mathbf{A}_1)$  and  $R_2(\Omega, \mathbf{A}_2)$ . In order to estimate the quality of this matching pairing, one establishes two Basic Belief Assignments (BBAs),  $m_s(\cdot), s = 1, 2$ , according to both sources of information (1<sup>st</sup> and 2<sup>nd</sup> optimal assignments matrices  $\mathbf{A}_1$  and  $\mathbf{A}_2$ ). The frame of discernment consists of a single hypothesis  $X = (T_i, \mathbf{z}_j)$ : measurement  $\mathbf{z}_j$  belongs to the track  $T_i$ . The ignorance is modelled by the proposition  $X \cup \bar{X}$ , where  $\bar{X}$  is the negation of hypothesis  $X$ :

$$\begin{cases} m_s(X) = a_1(i, j) \cdot \omega(i, j) / R_1(\Omega, \mathbf{A}_1), \\ m_s(X \cup \bar{X}) = 1 - m_s(X). \end{cases} \quad (3)$$

Applying the conjunctive rule of combination [8] (Vol. 1), one gets:

$$\begin{cases} m_{12}(X) = m_1(X)m_2(X) + m_1(X)m_2(X \cup \bar{X}) \\ \quad + m_1(X \cup \bar{X})m_2(X), \\ m_{12}(X \cup \bar{X}) = m_1(X \cup \bar{X})m_2(X \cup \bar{X}). \end{cases} \quad (4)$$

The pignistic transformation [16] is applied in order to obtain pignistic probabilities, built on the base of combined belief assignments, such as:  $BetP(X) = m_{12}(X) + \frac{1}{2} \cdot m_{12}(X \cup \bar{X})$  and  $BetP(\bar{X}) = \frac{1}{2} \cdot m_{12}(X \cup \bar{X})$

$\bar{X}$ ). Then one chooses the quality indicator, associated with the pairing  $(i, j)$ , as  $q(i, j) = \text{BetP}(X)$ .

- If  $a_1(i, j) = 1$  and  $a_2(i, j) = 0$ , then a conflict is encountered on the association  $(T_i, \mathbf{z}_j)$  in  $\mathbf{A}_1$  and  $\mathbf{A}_2$ . Then one could find the association  $(T_i, \mathbf{z}_{j_2})$  in  $\mathbf{A}_2$ , where  $j_2$  is the index, such that  $a_2(i, j_2) = 1$ . In order to define the quality of such conflicting association, one establishes two BBAs,  $m_s(\cdot)$ ,  $s = 1, 2$  according to both sources of information ( $\mathbf{A}_1$  and  $\mathbf{A}_2$ ). The frame of discernment consists of two propositions:  $\Theta = \{X = (T_i, \mathbf{z}_j), Y = (T_i, \mathbf{z}_{j_2})\}$ , and the BBAs are defined by [10].

$$\begin{cases} m_1(X) = a_1(i, j) \cdot \frac{\omega(i, j)}{R_1(\Omega, \mathbf{A}_1)}, \\ m_1(X \cup Y) = 1 - m_1(X), \end{cases} \quad (5)$$

$$\begin{cases} m_2(Y) = a_2(i, j_2) \cdot \frac{\omega(i, j_2)}{R_2(\Omega, \mathbf{A}_2)}, \\ m_2(X \cup Y) = 1 - m_2(Y). \end{cases} \quad (6)$$

Applying PCR6 fusion rule [8] (Vol. 3), one gets:

$$\begin{cases} m(X) = m_1(X) \cdot m_2(X \cup Y) + m_1(X) \cdot \frac{m_1(X)m_2(Y)}{m_1(X)+m_2(Y)}, \\ m(Y) = m_1(X \cup Y) \cdot m_2(Y) + m_2(Y) \cdot \frac{m_1(X)m_2(Y)}{m_1(X)+m_2(Y)}, \\ m(X \cup Y) = m_1(X \cup Y)m_2(X \cup Y). \end{cases} \quad (7)$$

Applying again the pignistic transformation, one gets  $\text{BetP}(X) = m(X) + \frac{1}{2} \cdot m(X \cup Y)$  and  $\text{BetP}(Y) = m(Y) + \frac{1}{2} \cdot m(X \cup Y)$ . Hence, the quality indicators here are chosen as:  $q(i, j) = \text{BetP}(X)$  and  $q(i, j_2) = \text{BetP}(Y)$ . The absolute quality factor becomes:  $Q_{abs}(\mathbf{A}, \mathbf{A}_2) = \sum_{i=1}^m \sum_{j=1}^n .a(i, j) \cdot q(i, j)$ .

Once obtained, this quality matrix  $\mathbf{Q} = [q(i, j)]$ ,  $i = 1, \dots, m$ ;  $j = 1, \dots, n$ , where the elements  $q(i, j) \in [0, 1]$  define the quality of particular associations, chosen in the optimal assignment matrix  $\mathbf{A}_1$ . It will be utilized in the next step of the classical MTT algorithm - Kalman filtering (KF).

#### IV. KALMAN FILTERING INFLUENCED BY QADA METHOD

The classical target tracking algorithm was run, consisting of two basic steps: (i) data association to associate the proper measurements (distance, angle) with correct targets and (ii) track filtering to update the targets state vectors, once the optimal assignment is found. In our simulation the Global Nearest Neighbour (GNN) [1] approach is applied in order to make a decision for data associations. GNN approach is a DA method that provides an assignment matrix for quality assessment of data association.

The Converted Measurement Kalman Filter (CMKF) is used for track filtering. We will not recall it in details, which can be found in many standard textbooks [1]-[2], but will make an impact on the manner, in which the obtained quality assessment of pairings in the optimal assignment solution influences the target's state updating.

In order to derive KF equations, the goal is to find an equation computing an a posteriori state estimate  $\hat{\mathbf{x}}(k+1|k+1)$  at time  $(k+1)$  as a linear combination of an a priori estimate

$\hat{\mathbf{x}}(k+1|k)$ , and a weighted difference between the true measurement  $\mathbf{z}(k+1)$  and a measurement prediction:

$$\hat{\mathbf{x}}(k+1|k+1) = \hat{\mathbf{x}}(k+1|k) + \mathbf{W}(k+1)\tilde{\mathbf{z}}(k+1) \quad (8)$$

The difference  $\tilde{\mathbf{z}}(k+1) \triangleq \mathbf{z}(k+1) - \mathbf{H}\hat{\mathbf{x}}(k+1|k)$ , called a measurement innovation (or residual), reflects the discrepancy between the predicted measurement  $\hat{\mathbf{z}}(k+1|k) = \mathbf{H}(k+1)\hat{\mathbf{x}}(k+1|k)$  and the true one  $\mathbf{z}(k+1)$ , where  $\mathbf{H}(k+1)$  is the so-called observation matrix. If  $\tilde{\mathbf{z}}(k+1)$  is equal to zero, it means, that both, the true measurement and predicted one are in full agreement, which is the perfect case. The matrix  $\mathbf{W}(k+1)$  is the filter's gain matrix obtained by minimizing the a posteriori estimate error covariance. It is given by the following formulae, where  $\mathbf{R}$  is the measurement error covariance, and  $\mathbf{P}(k+1|k)$  is the predicted covariance matrix of the state estimate error:

$$\begin{aligned} \mathbf{W}(k+1) &= \mathbf{P}(k+1|k)\mathbf{H}^T(k+1)\mathbf{S}^{-1}(k+1) \\ &= \mathbf{P}(k+1|k)\mathbf{H}^T(k+1) \end{aligned} \quad (9)$$

$$\cdot [\mathbf{H}(k+1)\mathbf{P}(k+1|k)\mathbf{H}^T(k+1) + \mathbf{R}]^{-1}. \quad (10)$$

From Eqs. (8) and (10) one could conclude, that the value of measurement error covariance  $\mathbf{R}$  influences the gain's value  $\mathbf{W}(k+1)$ , and respectively the state estimate in the way below:

- If the measurement error covariance  $\mathbf{R} \rightarrow \mathbf{0}$ , the true measurement  $\mathbf{z}(k+1)$  is trusted more, and in the same time predicted measurement  $\mathbf{H}\hat{\mathbf{x}}(k+1|k)$  is trusted less.
- If the measurement error covariance  $\mathbf{R}$  increases, the true measurement  $\mathbf{z}(k+1)$  is trusted less, and in the same time predicted measurement  $\mathbf{H}\hat{\mathbf{x}}(k+1|k)$  is trusted more.

Let's now recall again what kind of information one obtains, having in hand the quality matrix, derived by QADA method [10]. It gives us a knowledge about the confidence  $q(i, j)$  in all pairings  $(T_i, \mathbf{z}_j)$ ,  $i = 1, \dots, m$ ;  $j = 1, \dots, n$ , chosen in the first best assignment solution. The smaller quality (confidence) of hypothesis " $\mathbf{z}_j$  belongs to  $T_i$ " means, that the particular measurement error covariance  $\mathbf{R}$  was increased and one should not trust fully in the actual (true) measurement  $\mathbf{z}(k+1)$ .

Having this conclusion in mind, in this work we propose, such a behaviour of the measurement error covariance to be modelled by  $\mathbf{R} = \frac{\mathbf{R}}{q(T_i, \mathbf{z}_j)}$ , for every pairing, chosen in the first best assignment and on the base of corresponding quality value obtained. Then, Kalman filter gain decreases, and as a result, the true measurement  $\mathbf{z}_j(k+1)$  is trusted less in the updated state estimate  $\hat{\mathbf{x}}(k+1|k+1)$ .

The MTT algorithm tested in this paper is based on the classical one (using Kalman Filters based on kinematics measurements) because we are only concerned with impact QADA on the performances of such type of tracking filters for now. Our aim is not to compare this QADA-MTT to other more sophisticate MTT algorithms<sup>1</sup>, but we believe that QADA approach could also be useful for improving performances of more sophisticate MTT algorithms as well. This is left for future research works.

<sup>1</sup>In fact, we will just compare QADA-MTT to KDA-MTT and GDA-MTT based on CMKF in Section V.

## V. SIMULATION SCENARIOS AND RESULTS

Two simulation MTT scenarios - non-maneuvering and maneuvering are presented and the results, obtained on the base of QADA-, KDA-, and GDA based MTT are discussed.

## A. Maneuvering targets simulation scenario

The simulation scenario (Fig. 1) consists of three air targets with two classes. The stationary sensor is located at the origin. The sampling period is  $T_{scan} = 5sec$  and the measurement standard deviations are 0.4 deg and 25m for azimuth and range respectively. The targets go from West to East with the following type order CFC (C=Cargo, F=Fighter) with constant velocity  $100m/sec$ . At the beginning the targets move from different directions. The first target moves from North-West with heading 120 degrees from North. At  $scan\ no. = 8$  the target performs a maneuver until  $scan\ no. = 15$  with transversal acceleration  $+1.495m/s^2$  and settles towards East, moving in parallel according to X axis. The second target moves during the whole scenario in parallel according to X from West to East without maneuvering. The third target at the beginning moves from South-West with heading 60 degrees from North. At  $scan\ no. = 8$  the target performs a maneuver until  $scan\ no. = 15$  with transversal acceleration  $-1.495m/s^2$  and settles towards East, moving in parallel according to X axis. The inter-distance between the targets during scans 15th - 18th (the parallel segment) is approximately 150m. At  $scan\ no. = 18$  to  $scan\ no. = 25$  the first and the third targets make new maneuvers. The first one is directed to North-East and the second - to South-East. The process noise standard deviations for the two nested models for constant velocity IMM (Interacting Multiple Models) filter [1], [3] are  $0.1m/s^2$  and  $7m/s^2$  respectively. The number of false alarms (FA) follows a Poisson distribution and FA are uniformly distributed in the surveillance region.

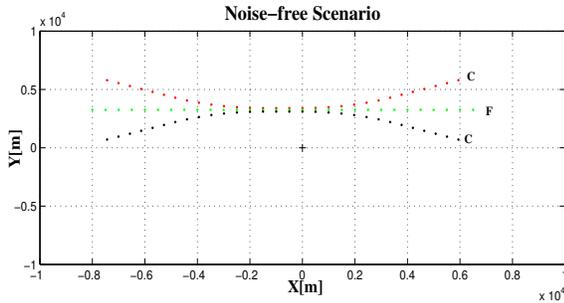

Figure 1. Noise-free maneuvering MTT Scenario.

Fig. 2 shows the respective noised scenario.

GDA-MTT [6], [7] improves DA process by utilizing target's type decision based on the confusion matrix  $\mathbf{C} = [C_{ij}]$  coupled with the classical kinematic measurements, where  $C_{ij} = P(T_d = T_j / TrueTargetType = T_i)$  represents the probability of decisions  $T_d = (T_1 \triangleq Fighter, T_2 \triangleq Cargo)$ , that the target type is  $j$  when its real type is  $i$ . In our simulation  $\mathbf{C} = \begin{bmatrix} 0.95 & 0.05 \\ 0.05 & 0.95 \end{bmatrix}$ .

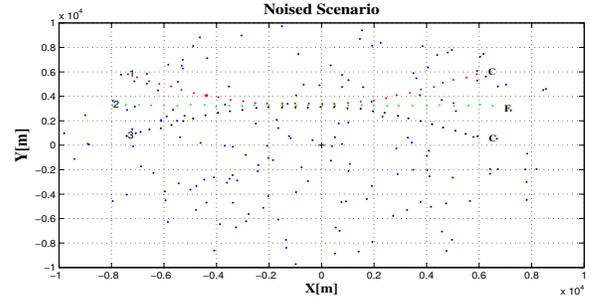

Figure 2. Noised maneuvering MTT Scenario.

Monte Carlo (MC) simulations for the considered MTT scenario are made for 200 MC runs, applying KDA, QADA, and GDA. Our goal is to evaluate, show, and to discuss the effect of Quality Assessment of Optimal Assignment for Data Association on the overall target tracking performance in comparison to results, obtained for the same scenario, by Kinematic only Data Association, and Generalized Data Association based MTT. We use an idealized track initiation in order to prevent uncontrolled impact of this stage on the statistical parameters of the tracking process during Monte Carlo tests of the new developed algorithm. The true targets positions (known in our simulations) for the first two scans are used for tracks initiation.

The evaluation of MTT performance is based on the criteria of tracks' purity, tracks' life, and percentage of miscorrelation. Track's purity criteria examines the ratio between the number of particular performed ( $j$ th observation -  $i$ th track) associations (in case of detected target) over the total number of all possible associations during the tracking scenario. Track's life is evaluated as an average number of scans before track's deletion. In our simulations, a track is cancelled and deleted from the list of tracked tracks, when during 3 consecutive scans it cannot be updated with some measurement because there is no validated measurement in the validation gate. We call this, the "cancelling/deletion condition". The status of the tracked tracks is denoted "alive".

The percentage of miscorrelation examines the relative number of incorrect (observation-to-track) associations during the scans.

The results for less noised case (with 0.2 FA in average in the filter validation gate) are given in Table 1.

Table I  
MANEUVERING SCENARIO: COMPARISON BETWEEN KDA, QADA, GDA BASED MTT PERFORMANCES FOR  $FA = 0.2$ .

	KDA-MTT	QADA-MTT	GDA-MTT
Average Track Life [%]	86.65	<b>92.82</b>	91.06
Average Miscorrelation [%]	7.27	<b>3.69</b>	3.06
Track Purity [%]	77.44	<b>88.20</b>	85.74

QADA-MTT exceeds KDA-MTT according to average track life and track purity, and shows better performance concerning the encountered average track life in comparison to GDA-MTT. Figure 3 shows the most informative knowledge - a

percentage of miscorrelations, encountered during the consecutive scans. One could see, that QADA-MTT shows almost two times better performance in comparison to KDA-MTT, and is close to GDA-MTT performance.

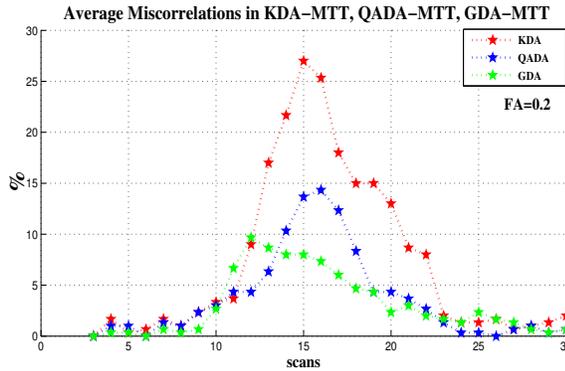

Figure 3. Maneuvering scenario: Average miscorrelations in KDA-MTT, QADA-MTT, GDA-MTT for noised case  $FA = 0.2$

The respective results for the most noised case (with 0.4 FA in average in the filter validation gate) are given in Table 2 below.

Table II  
MANEUVERING SCENARIO: COMPARISON BETWEEN KDA, QADA, GDA BASED MTT PERFORMANCES FOR  $FA = 0.4$

	KDA-MTT	QADA-MTT	GDA-MTT
Average Track Life [%]	74.27	<b>86.61</b>	86.52
Average Miscorrelation [%]	10.58	<b>7.05</b>	4.68
Track Purity [%]	60.42	<b>77.96</b>	79.35

As a whole, the results for  $FA = 0.4$  are deteriorated in comparison to the less noised case, but still QADA-MTT shows stably better performance with respect to KDA-MTT performance. The average track life keeps a little bit higher than in GDA-MTT case.

The Fig.4, showing the percentage of miscorrelations in more difficult noised case, confirms that QADA-MTT overcomes KDA-MTT performance.

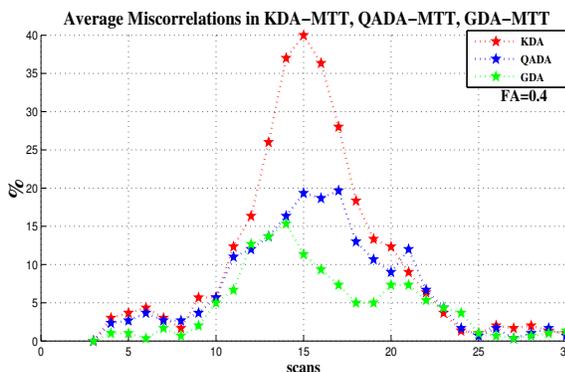

Figure 4. Maneuvering scenario: Average miscorrelations in KDA-MTT, QADA-MTT, GDA-MTT for noised case  $FA = 0.4$

The figures 5 and 6 show typical performances of QADA-MTT and KDA-MTT systems.

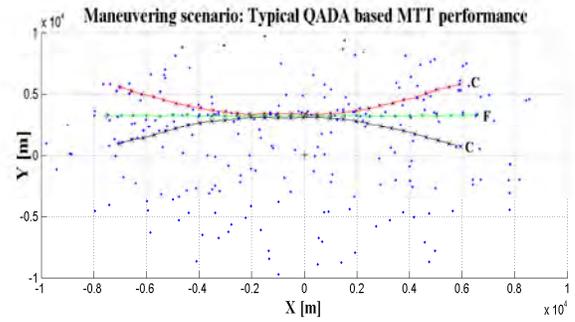

Figure 5. Maneuvering scenario: Typical performance of QADA based MTT.

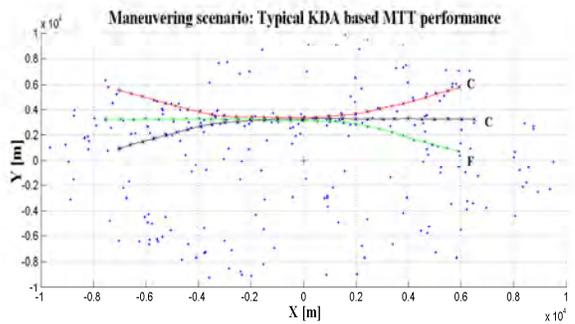

Figure 6. Maneuvering scenario: Typical performance of KDA based MTT.

The figures 7 and 8 show the averaged filtered errors along X (designated by asterisk) and Y (designated by circles) axes, and the distance error associated with the maneuvering track 1 in the considered scenario.

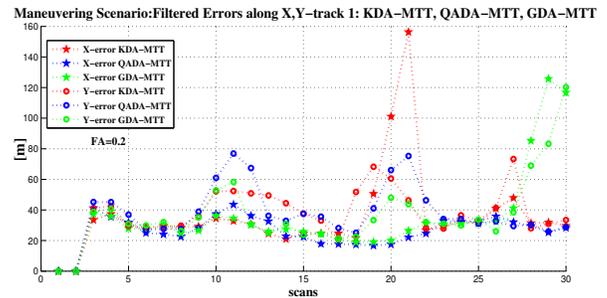

Figure 7. Filtered errors along X,Y for maneuvering track 1 - KDA-MTT, QADA-MTT, GDA-MTT.

For the maneuvering target 1, the errors, along X axis, obtained by using QADA-MTT, are definitely smaller than those, encountered with KDA-MTT. The errors along Y are a little bit bigger than respective errors along X, but as a whole the distance error, encountered by using QADA-MTT are smaller than in KDA-MTT. MC errors are evaluated on the base of the averaged errors associated with all “alive” tracks. Some of the errors occurred (for example in Fig.7 and Fig.8)

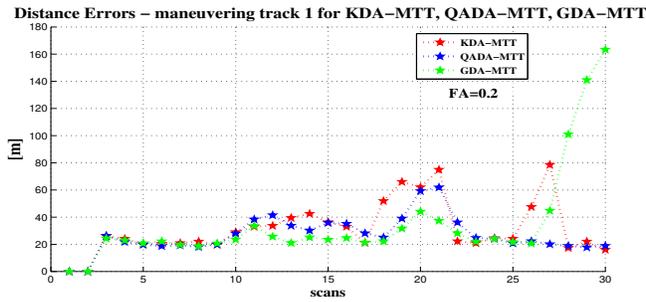

Figure 8. Maneuvering scenario: Distance errors for maneuvering track 1 - KDA-MTT, QADA-MTT, GDA-MTT.

could be explained by the unrealized canceling of tracks at the end of the scenario, when some tracks go toward canceling, but cannot satisfy the canceling condition because of lack of time. As a result they are not cancelled (and not deleted) leading that way to the increasing error.

Figures 9 and 10 show the behaviour of the same errors, but now associated with the near-by non-maneuvering target 2.

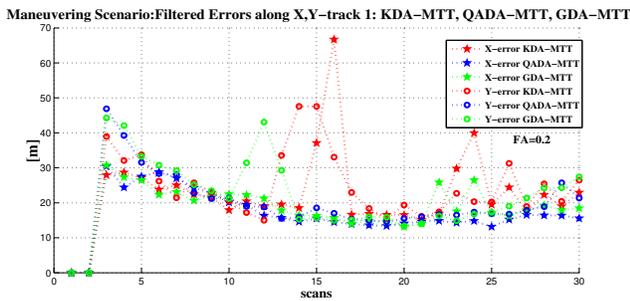

Figure 9. Maneuvering scenario: Filtered errors along X,Y for non-maneuvering track 2 - KDA-MTT, QADA-MTT, GDA-MTT.

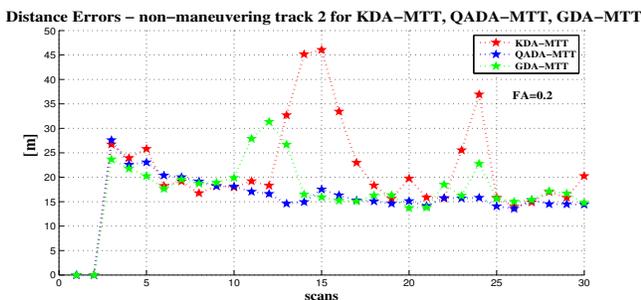

Figure 10. Maneuvering scenario: Distance errors for non-maneuvering track 2 - KDA-MTT, QADA-MTT, GDA-MTT.

For the non maneuvering target 2, the filtered errors along X and Y axes, obtained by using QADA-MTT, are smooth and definitely smaller than those, encountered with KDA-MTT. As a consequence, the associated with QADA-MTT distance error is smaller than in KDA- and GDA-MTT. The errors are calculated on the base only of the “alive” tracks.

### B. Non-maneuvering targets simulation scenario

The noise-free non-maneuvering targets simulation scenario (see Fig.11) consists of three air targets moving in parallel from West to East with the type order CFC (C=Cargo, F=Fighter) with constant velocity of 100m/sec and a distance between them 150m. The stationary sensor is located at the origin. The sampling period is  $T_{scan} = 5sec$ , and the measurement standard deviations are 0.5 deg and 65m for azimuth and range respectively. The surveillance of moving targets is performed during 15 scans. The confusion matrix, utilized by GDA is  $C = \begin{bmatrix} 0.95 & 0.05 \\ 0.05 & 0.95 \end{bmatrix}$ . Fig. 12 shows the respective noised scenario.

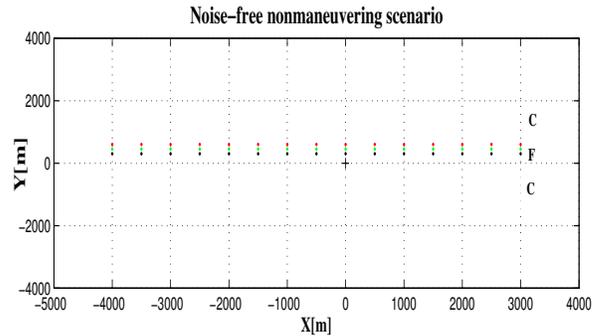

Figure 11. Noise-free non-maneuvering MTT Scenario.

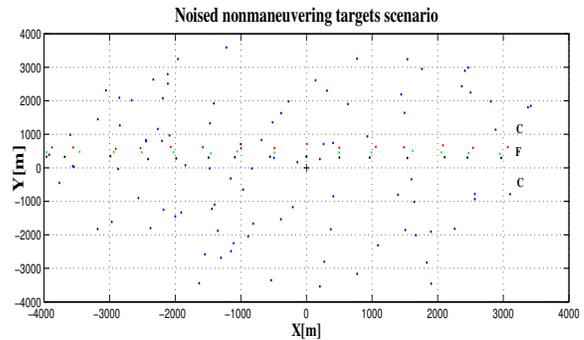

Figure 12. Noised non-maneuvering MTT Scenario.

As reported in Table 3, QADA-MTT shows again almost 2 times better performance, in comparison to KDA-MTT, according to the average miscorrelations, and also better performance regarding the average track life and track purity.

Table III  
NON-MANEUVERING SCENARIO: COMPARISON BETWEEN KDA, QADA, GDA BASED MTT PERFORMANCES FOR  $FA = 0.2$ .

	KDA-MTT	QADA-MTT	GDA-MTT
Average Track Life [%]	89.79	<b>94.21</b>	97.59
Average Miscorrelation [%]	21.36	<b>10.77</b>	5.82
Track Purity [%]	64.46	<b>81.72</b>	90.15

Fig.13 shows the percentage of miscorrelations in less noised case (with 0.2 FA in average per gate).

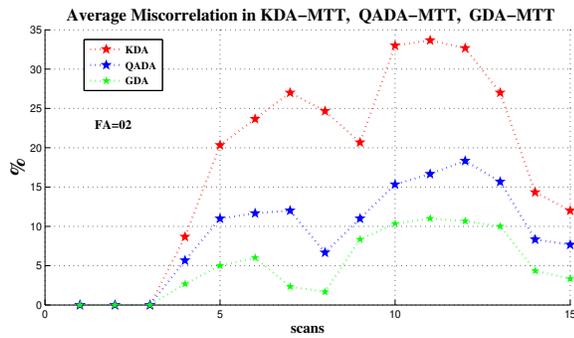

Figure 13. Non-maneuvering scenario: Average miscorrelations in KDA-MTT, QADA-MTT, GDA-MTT.

The same QADA-MTT behaviour is valid in the more dense cluttered environment with 0.4 FA in average per gate (see table 4 and fig. 14).

Table IV

NON-MANEUVERING SCENARIO: COMPARISON BETWEEN KDA, QADA, GDA BASED MTT PERFORMANCES FOR  $FA = 0.4$ .

	KDA-MTT	QADA-MTT	GDA-MTT
Average Track Life [%]	90.72	<b>92.18</b>	96.77
Average Miscorrelation [%]	20.69	<b>12.15</b>	6.26
Track Purity [%]	65.46	<b>77.38</b>	88.82

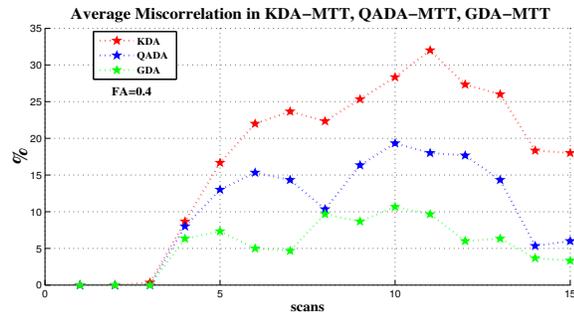

Figure 14. Non-maneuvering scenario: Average miscorrelations in KDA-MTT, QADA-MTT, GDA-MTT.

The figures 15 and 16 show typical performances of QADA-MTT and KDA-MTT systems.

The figures 17–20 show the encountered filtered errors along X and Y axes and the distance errors, associated with the intermediate track 2 for both noised cases (when the number of FA per gate is 0.2 and 0.4).

One observes (for example in Fig.9 and Fig.17) that errors associated with this simpler (non-maneuvering) scenario sometimes appear to be greater than in the previous more complicated (maneuvering) one. It is because the sensor's errors are defined deliberately greater in the non-maneuvering scenario. It provokes a complex situations, where the impact of QADA method is better demonstrated.

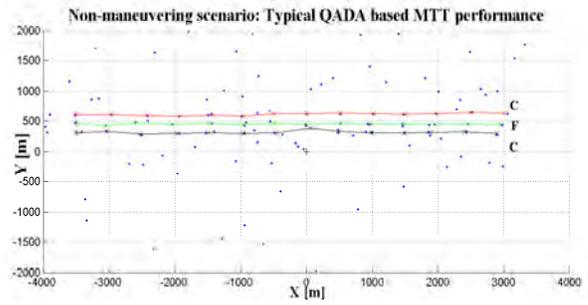

Figure 15. Non-maneuvering scenario: Typical performance of QADA based MTT.

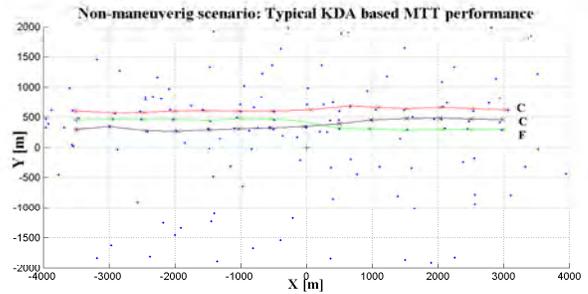

Figure 16. Non-maneuvering scenario: Typical performance of KDA based MTT.

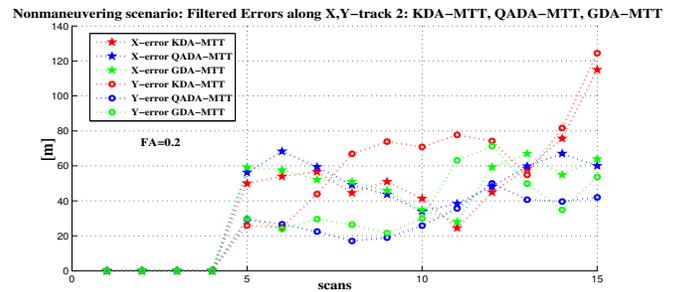

Figure 17. Non-maneuvering scenario: Filtered errors along X,Y for track 2 - KDA-MTT, QADA-MTT, GDA-MTT.

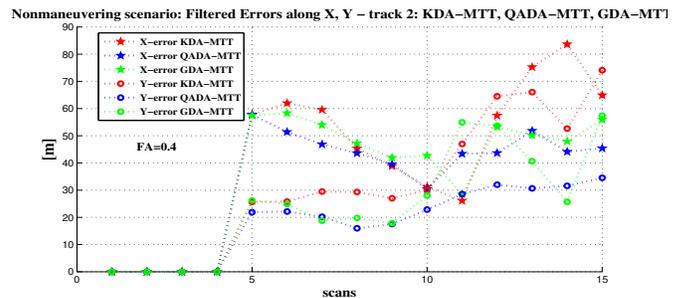

Figure 18. Non-maneuvering scenario: Filtered errors along X,Y for track 2 - KDA-MTT, QADA-MTT, GDA-MTT.

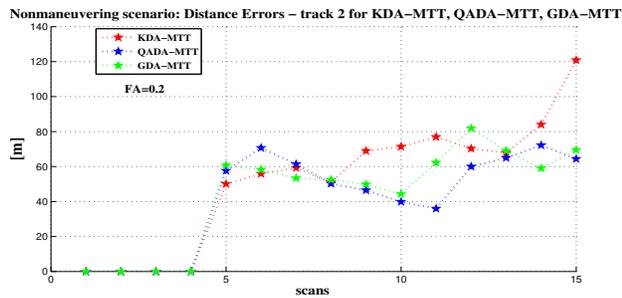

Figure 19. Non-manuevering scenario: Distance errors for non-manuevering track 2 - KDA-MTT, QADA-MTT, GDA-MTT.

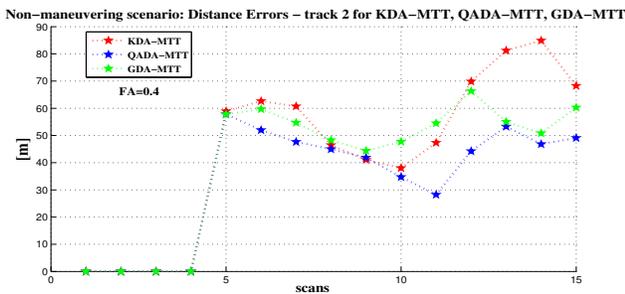

Figure 20. Non-manuevering scenario: Distance errors for non-manuevering track 2 - KDA-MTT, QADA-MTT, GDA-MTT.

## VI. CONCLUSIONS

This work assesses the efficiency of MTT performance in cluttered conflicting situations, based on the recent QADA method. The QADA based MTT performance is compared with the results, obtained for KDA and GDA based MTT, concerning two (maneuvering and non-maneuvering targets) scenarios. Our Monte Carlo simulation results show that QADA-MTT performs better than KDA-MTT for all measures of performances in all scenarios under low or heavy clutter conditions with target detection probabilities less than one, which is the main result of this paper.

Concerning the comparison of performances of QADA-MTT (using kinematics measurements only) with respect to GDA-MTT, we observe that the performances of GDA-MTT are slightly better than those of QADA-MTT. This conclusion is not very surprising because GDA-MTT uses more information (kinematics and attributes) than KDA-MTT or QADA-MTT (which are based on kinematics measurements only). Therefore, the ability of GDA-MTT to provide better tracking performances is what we naturally expect. However, we must emphasize that QADA method could also be used to improve GDA-MTT as well in a similar manner as it has been used to improve the performances of KDA-MTT. This possible improvement of GDA-MTT with QADA is under investigation and will be reported in a forthcoming publication.

Taking in mind, that MTT problems as a general do not able to utilize additional target attribute information, (i.e. when only kinematic measurements are available), applying QADA

instead of KDA leads to better MTT performance, because of its ability to estimate the quality of the individual pairings given in the optimal assignment solution. QADA is totally independent of the applied logic to obtain the best DA solution. Hence, it could be applied successfully in all cases when attribute or/and kinematic data are available.

**Abstract**—This paper presents a performance evaluation of two types of multi-target tracking algorithms: 1) classical Kalman Filter based algorithms for multi-target tracking improved with Quality Assessment of Data Association (QADA) method using optimal data association, and 2) the Joint Probabilistic Data Association Filter (JPDAF). QADA technique is improved by using new basic belief assignment (bba) modelling, and also modified by means of the new Belief interval distance applied for computing the quality indicator associated with the pairings in the optimal data association solution. The evaluation is based on Monte Carlo simulations for maneuvering multiple-target tracking (MTT) problem in clutter.

**Keywords:** Data association, JPDAF, Belief Functions, PCR6 fusion rule, QADA, Multitarget Tracking.

## I. INTRODUCTION

The main function of each radar surveillance system is to keep targets tracks maintenance. It becomes a crucial and challenging problem especially in complicated situations of closely spaced or crossing targets. The main objective of multiple-target tracking (MTT) is to estimate jointly, at each observation time moment, the number of targets continuously moving in a given region and their trajectories from the noisy sensor data.

Data Association (DA) is a central problem in MTT systems' design [1], [2]. It relates to the process of associating uncertain measurements (observations) to the tracked tracks. In the presence of a dense MTT environment, with false alarms and sensor detection probabilities less than unity, the problem of DA becomes more complex, because it should contend with many possibilities of pairings, some of which are in practice very imprecise, unreliable, and could lead to critical association mistakes in the overall tracking process.

In order to deal with these complex associations the most recent method to evaluate the Quality Assessment of Data Association (QADA) encountered in multiple target tracking applications in a mono-criterion context was proposed by Dezert and Benameur [4], and extended in [5] for the multicriteria context. It is based on belief functions (BF) for achieving the quality of pairings belonging to the optimal data assignment solution based on its consistency with respect to all the second best solutions, provided by a chosen algorithm. Recently, in

[6], [19] the authors discussed and proposed the way in which Kalman filter (KF) could be enhanced in order to reflect the knowledge obtained based on the QADA method, called QADA-KF method. QADA assumes that the reward matrix is known, regardless of the manner in which it is obtained by the user. In this paper QADA method is improved by using new BBA modelling, and also modified by means of the new Belief Interval distance (BID) [18] applied for computing the quality indicator associated with the pairing in the optimal DA solution. The results are compared with those obtained by using Pignistic Probabilities [16]. We propose and test the performance of two versions of QADA-KF. The first one utilizes the assignment matrix, provided by the Global Nearest Neighbor (GNN) method, called QADA-GNN KF approach. The second one utilizes the assignment matrix, provided by the Probabilistic Data Association (PDA) method, called QADA-PDA KF method. These two QADA-KF methods are compared with the well-known Joint Probabilistic Data Association Filter (JPDAF) [7], [8], [9] which is an extension of the Probabilistic Data Association Filter (PDAF) [1] to a fixed and known number of targets. JPDAF uses joint association events and joint association probabilities in order to avoid conflicting measurement-to-track assignments by making a soft (probabilistic) assignment of all validated measurements to multiple targets.

The main objective of this paper is to: (1) improve QADA method by using new bba modelling; (2) modify the improved QADA method by means of the new Belief interval distance for computing the quality indicator; (3) compare the performances of: (a) classical MTT algorithms based on the GNN approach for data association, utilizing Kinematic only Data (KDA) based MTT; (b) QADA-GNN KF based MTT; (c) QADA-PDA KF based MTT; (d) JPDAF based MTT.

The evaluation is based on a Monte Carlo simulation for particular difficult maneuvering MTT problem in clutter. This paper is organized as follows. Section II is devoted to the improved QADA method. Section III discusses the Kalman Filter improved by QADA. The two variants of the assignment matrix, utilized by QADA are discussed in Section IV. In Section V the JPDAF is described and discussed. A particular simulation MTT scenario and results are presented for the

KDA, QADA-GNN KF, QADA-PDA KF, and JPDAF in Section VI. Conclusions are made in Section VII.

## II. THE IMPROVED QUALITY ASSESSMENT OF OPTIMAL DATA ASSOCIATION

### A. Improvement of QADA bba modelling

DA is a decisive step in MTT systems [1], [2]. It consists in finding the global optimal assignments of targets  $T_i$ ,  $i = 1, \dots, m$  to some measurements  $z_j$ ,  $j = 1, \dots, n$  at a given time  $k$  by maximizing the overall gain in such a way, that no more than one target is assigned to a measurement, and reciprocally. The  $m \times n$  reward matrix  $\Omega = [\omega(i, j)]$  is defined by its elements  $\omega(i, j) > 0$ , representing the gain of the association of target  $T_i$  with the measurement  $z_j$ .

The first and the second best assignments matrices  $\mathbf{A}_1$  and  $\mathbf{A}_2$  are used [4], in order to establish the quality of the specific associations (pairings) satisfying the condition  $a_1(i, j) = 1$ . The main idea behind QADA method is to compare the values  $a_1(i, j)$  in  $\mathbf{A}_1$  with the corresponding ones  $a_2(i, j)$  in  $\mathbf{A}_2$ , and to identify the change (if any) of the optimal pairing  $(i, j)$ . In our MTT context,  $(i, j)$  means that measurement  $z_j$  is associated with target  $T_i$ . A quality indicator is established, depending on both the stability of the pairing and its relative impact on the global reward. The proposed method works also when the 1-st and 2-nd best optimal assignment  $\mathbf{A}_1$  and  $\mathbf{A}_2$  and are not unique, i.e. there are multiplicities available. The construction of the quality indicators is based on Belief Functions (BF) theory and Proportional Conflict Redistribution fusion rule no. 6 (PCR6), defined within DSMT theory [16]. It depends on the type of pairing matching in the way, described below:

- In case, when  $a_1(i, j) = a_2(i, j) = 0$ , one has a full agreement on “non-association” of the given pairing  $(i, j)$  in  $\mathbf{A}_1$  and  $\mathbf{A}_2$ . This “non-association” has no impact on the global reward values  $R_1(\Omega, \mathbf{A}_1)$  and  $R_2(\Omega, \mathbf{A}_2)$ , so it will be useless to utilize it in DA. Hence, the quality indicator value is set to  $q(i, j) = 1$ .
- In case, when  $a_1(i, j) = a_2(i, j) = 1$ , one has a full agreement on “association” of the given pairing  $(i, j)$  in  $\mathbf{A}_1$  and  $\mathbf{A}_2$ . This “association” has different impacts on the global reward values  $R_1(\Omega, \mathbf{A}_1)$  and  $R_2(\Omega, \mathbf{A}_2)$ . In order to estimate the quality of this matching association, one establish two basic belief assignments (BBA),  $m_s(\cdot)$  ( $s = 1, 2$ ) according to the both sources of information ( $\mathbf{A}_1$  and  $\mathbf{A}_2$ ). The Frame of Discernment (FoD), one reasons on, consists of a single hypothesis  $X = (T_i, z_j)$ : measurement  $z_j$  belongs to track  $T_i$ . The ignorance is modeled by the proposition  $X \cup \bar{X}$ , where  $\bar{X}$  is a negation of hypothesis  $X$ . The BBA  $m_s(\cdot)$  is defined by

$$\begin{cases} m_s(X) = a_s(i, j) \cdot \omega(i, j) / R_s(\Omega, \mathbf{A}_s), \\ m_s(X \cup \bar{X}) = 1 - m_s(X). \end{cases}$$

Applying the conjunctive rule of combination of  $m_1(X)$  with  $m_2(X)$  we get

$$\begin{cases} m_{12}(X) = m_1(X)m_2(X) + m_1(X)m_2(X \cup \bar{X}) \\ \quad + m_1(X \cup \bar{X})m_2(X), \\ m_{12}(X \cup \bar{X}) = m_1(X \cup \bar{X})m_2(X \cup \bar{X}). \end{cases} \quad (1)$$

In our previous works [6], [17], [19], we did propose to use the pignistic transform BetP to establish the quality indicator.

- In case, when  $a_1(i, j) = 1$  and  $a_2(i, j) = 0$ , then a disagreement (conflict) on the association  $(T_i, z_j)$  in  $\mathbf{A}_1$  and  $\mathbf{A}_2$  is detected. One could find the association  $(T_i, z_{j_2})$  in  $\mathbf{A}_2$ , where  $j_2$  is the measurement index, such that  $a_2(i, j_2) = 1$ . In order to define the quality of such conflicting association  $(T_i, z_j)$ , one establishes two basic belief assignments (BBA),  $m_s(\cdot)$  ( $s = 1, 2$ ) according to the both sources of information ( $\mathbf{A}_1$  and  $\mathbf{A}_2$ ). The FoD, one reasons on, consists of the following two propositions:  $X = (T_i, z_j)$ , and  $Y = (T_i, z_{j_2})$ . The ignorance is modeled by the proposition  $X \cup Y$ . In our previous works [4], we did define the BBAs by:

$$\begin{cases} m_1(X) = a_1(i, j) \cdot \omega(i, j) / R_1(\Omega, \mathbf{A}_1), \\ m_1(X \cup Y) = 1 - m_1(X), \end{cases} \quad (2)$$

$$\begin{cases} m_2(Y) = a_2(i, j_2) \cdot \omega(i, j_2) / R_2(\Omega, \mathbf{A}_2), \\ m_2(X \cup Y) = 1 - m_2(Y). \end{cases} \quad (3)$$

This modeling in fact does not work efficiently in some cases and that is why we need to revise it to make the QADA approach working more efficiently. For example, let's consider only one target  $T$  and two validated measurements  $z_1$  and  $z_2$  with the following payoff matrix  $\Omega = [100 \ 1]$ . The two possible associations are represented by  $\mathbf{A}_1 = [1 \ 0]$  providing a reward  $R_1(\Omega, \mathbf{A}_1) = 100$ , and  $\mathbf{A}_2 = [0 \ 1]$  providing a reward  $R_2(\Omega, \mathbf{A}_2) = 1$ . In this simple case, one has  $\Theta = \{X = (T, z_1), Y = (T, z_2)\}$ . In applying formulas (2)–(4), one gets

$$\begin{cases} m_1(X) = a_1(i, j) \cdot \omega(i, j) / R_1(\Omega, \mathbf{A}_1) = 1 \times \frac{100}{100} = 1 \\ m_1(X \cup Y) = 1 - m_1(X) = 0 \end{cases} \quad (4)$$

$$\begin{cases} m_2(Y) = a_2(i, j_2) \cdot \omega(i, j_2) / R_2(\Omega, \mathbf{A}_2) = 1 \times \frac{1}{1} = 1, \\ m_2(X \cup Y) = 1 - m_2(Y). \end{cases} \quad (5)$$

The conjunctive combination rule gives:

$$\begin{aligned} m_{12}(X) &= m_1(X)m_2(X \cup Y) = 1 \times 0 = 0, \\ m_{12}(Y) &= m_1(X \cup Y)m_2(Y) = 0 \times 1 = 0, \\ m_{12}(X \cup Y) &= m_1(X \cup Y)m_2(X \cup Y) = 0 \times 0 = 0, \\ m_{12}(\emptyset) &= m_1(X)m_2(Y) = 1 \times 1 = 1. \end{aligned}$$

Applying PCR6 fusion rule [16] (Vol.3):

$$\begin{cases} m_{12}^{PCR6}(\emptyset) = 0, \\ m_{12}^{PCR6}(X) = m_{12}(X) + m_1(X) \frac{m_1(X)m_2(Y)}{m_1(X)+m_2(Y)} = \frac{1}{2}, \\ m_{12}^{PCR6}(Y) = m_{12}(Y) + m_2(Y) \frac{m_1(X)m_2(Y)}{m_1(X)+m_2(Y)} = \frac{1}{2}, \\ m_{12}^{PCR6}(X \cup Y) = m_{12}(X \cup Y) = 0, \end{cases} \quad (6)$$

which yields (using the Pignistic transformation)  $BetP(X) = 0.5$  and  $BetP(Y) = 0.5$ . This result is counter-intuitive (not realistic) because in this very simple case one knows that  $(T, z_1)$  is obviously the best data association solution. To circumvent this serious problem, we propose to modify the bba modeling by taking a new model of bba construction as follows:

$$\begin{cases} m_1(X) = a_1(i, j) \cdot \frac{\omega(i, j)}{R_1(\Omega, A_1) + R_2(\Omega, A_2)}, \\ m_1(X \cup Y) = 1 - m_1(X), \end{cases} \quad (7)$$

$$\begin{cases} m_2(Y) = a_2(i, j_2) \cdot \frac{\omega(i, j_2)}{R_1(\Omega, A_1) + R_2(\Omega, A_2)}, \\ m_2(X \cup Y) = 1 - m_2(Y). \end{cases} \quad (8)$$

If we apply this modeling on the previous example, we obtain

$$\begin{cases} m_1(X) = a_1(i, j) \cdot \frac{\omega(i, j)}{R_1(\Omega, A_1) + R_2(\Omega, A_2)} = 1 \times \frac{100}{101} \approx 0.99, \\ m_1(X \cup Y) = 1 - m_1(X) = 0.01, \end{cases}$$

$$\begin{cases} m_2(Y) = a_2(i, j_2) \cdot \frac{\omega(i, j_2)}{R_1(\Omega, A_1) + R_2(\Omega, A_2)} = 1 \times \frac{1}{101} \approx 0.01, \\ m_2(X \cup Y) = 1 - m_2(Y) = 0.99. \end{cases}$$

Hence, one gets now

$$\begin{aligned} m_{12}(X) &= m_1(X)m_2(X \cup Y) = 0.9801, \\ m_{12}(Y) &= m_1(X \cup Y)m_2(Y) = 0.0001, \\ m_{12}(X \cup Y) &= m_1(X \cup Y)m_2(X \cup Y) = 0.0099, \\ m_{12}(\emptyset) &= m_1(X)m_2(Y) = 0.0099. \end{aligned}$$

Applying PCR6 redistribution principle, one gets finally

$$\begin{aligned} m_{12}^{PCR6}(X) &= 0.9801 + (0.99 \times 0.0099)/1 = 0.989901, \\ m_{12}^{PCR6}(Y) &= 0.0001 + (0.01 \times 0.0099)/1 = 0.010099, \end{aligned}$$

which yields  $BetP(X) = 0.989901$  and  $BetP(Y) = 0.010099$ . This result fits now perfectly with what we expect, that is  $X = (T, z_1)$  is obviously the best data association solution.

### B. Improvement of quality indicator calculating by using Belief Interval (BI) distance

In [11], [20] the Euclidean belief interval distance between two bbas  $m_1(\cdot)$  and  $m_2(\cdot)$  is defined on the powerset of a given  $\Theta = \{\theta_1, \dots, \theta_n\}$  as follows

$$d_{BI}(m_1, m_2) \triangleq \sqrt{N_c \cdot \sum_{X \in 2^\Theta} d_W^2(BI_1(X), BI_2(X))}, \quad (9)$$

where  $N_c = 1/2^{|\Theta|-1}$  is a normalization factor to have  $d_{BI}(m_1, m_2) \in [0, 1]$ , and  $d_W(BI_1(X), BI_2(X))$  is the Wasserstein's distance [22] between belief

intervals  $BI_1(X) \triangleq [Bel_1(X), Pl_1(X)] = [a_1, b_1]$  and  $BI_2(X) \triangleq [Bel_2(X), Pl_2(X)] = [a_2, b_2]$ . More specifically,

$$d_W([a_1, b_1], [a_2, b_2]) = \sqrt{\left[\frac{a_1 + b_1}{2} - \frac{a_2 + b_2}{2}\right]^2 + \frac{1}{3} \left[\frac{b_1 - a_1}{2} - \frac{b_2 - a_2}{2}\right]^2}. \quad (10)$$

In [20], we have proved that  $d_{BI}(x, y)$  is a true distance metric because it satisfies the properties of non-negativity ( $d_{BI}(x, y) \geq 0$ ), non-degeneracy ( $d_{BI}(x, y) = 0 \Leftrightarrow x = y$ ), symmetry ( $d_{BI}(x, y) = d_{BI}(y, x)$ ), and the triangle inequality ( $d_{BI}(x, y) + d_{BI}(y, z) \geq d_{BI}(x, z)$ ), for any bba  $x, y$  and  $z$  defined on  $2^\Theta$ . The choice of Wasserstein's distance in  $d_{BI}$  definition is justified by the fact that Wasserstein's distance is a true distance metric and it fits well with our needs because we have to compute a distance between  $[Bel_1(X), Pl_1(X)]$  and  $[Bel_2(X), Pl_2(X)]$ .

For notation convenience, we denote  $m_X$  the categorical bba having only  $X$  as focal element, where  $X \neq \emptyset$  is an element of the powerset of  $\Theta$ . More precisely,  $m_X$  is the particular (categorical) bba defined by  $m_X(X) = 1$  and  $m_X(Y) = 0$  for any  $Y \neq X$ . Such basic bba plays an important role in our new decision scheme because its corresponding belief interval reduces to the degenerate interval  $[1, 1]$  which represents the certainty on  $X$ . The basic principle of the new decision scheme we propose is very simple and intuitively makes sense. It consists in selecting as the final decision (denoted by  $\hat{X}$ ) the element of the powerset for which the belief interval distance between the bba  $m(\cdot)$  and  $m_X$ ,  $X \in 2^\Theta \setminus \{\emptyset\}$  is the smallest one. Therefore, take as the final decision  $\hat{X}$  given by

$$\hat{X} = \arg \min_{X \in 2^\Theta \setminus \{\emptyset\}} d_{BI}(m, m_X). \quad (11)$$

where  $d_{BI}(m, m_X)$  is computed according to (9).  $m(\cdot)$  is the bba under test, and  $m_X$  the categorical bba focused on  $X$  defined above.

This decision scheme is very general in the sense that the decision making can be done on any type of element of the power-set  $2^\Theta$ , and not necessarily only on the elements (singletons) of the FoD. This method not only provides the final decision  $\hat{X}$  to make, but also it evaluates how good this decision is with respect to its alternatives if we define the quality indicator  $q(\hat{X})$  as follows

$$q(\hat{X}) \triangleq 1 - \frac{d_{BI}(m, m_{\hat{X}})}{\sum_{X \in 2^\Theta \setminus \{\emptyset\}} d_{BI}(m, m_X)}. \quad (12)$$

One sees that the quality indicator  $q(\hat{X})$  of the decision  $\hat{X}$  will become maximum (equal to one) when the distance between the bba  $m(\cdot)$  and  $m_{\hat{X}}$  is zero, which means that the bba  $m(\cdot)$  is focused in fact only on the element  $X$ . The higher  $q(\hat{X})$  is, the more confident in the decision  $\hat{X}$  we should be.

Of course, if a decision must be made with some extra constraint defined by a (or several) condition(s), denoted  $c(X)$ , then we must take into account  $c(X)$  in (11), that is

$$\hat{X} = \arg \min_{X \in 2^\Theta \setminus \{\emptyset\} | c(X) \text{ is true}} d_{BI}(m, m_X).$$

and also in the derivation of quality indicator by taking  $\sum_{X \in 2^{\Theta} \setminus \{\emptyset\}} c(X) \text{ is true } d_{BI}(m, m_X)$  as denominator in (12). Theoretically any other strict distance metric, for instance Jousselme's distance [23], [24], could be used instead of  $d_{BI}(\cdot, \cdot)$ . We have chosen  $d_{BI}$  distance because of its ability to provide good and reasonable behavior [20] as will be shown. When there exists a tie between multiple decisions  $\{\hat{X}_j, j > 1\}$ , then the prudent decision corresponding to their disjunction  $\hat{X} = \cup_j \hat{X}_j$  should be preferred (if allowed), otherwise the final decision  $\hat{X}$  is made by a random selection among the elements of  $\{\hat{X}_j, j > 1\}$ .

### III. QADA BASED KALMAN FILTER

The aim of this paper is to compare the performance of the JPDAF based MTT algorithm with the classical MTT algorithm, using the CMKF based on kinematics measurements, but improved by the QADA method.

In [6], the authors discuss and propose the way in which Kalman filter (KF) could be improved in order to reflect the knowledge obtained based on the QADA method.

Let's briefly recall what kind of information is obtained, having in hand the quality matrix, derived by QADA, in the MTT context. It gives knowledge about the confidence  $q(i, j)$  in all pairings  $(T_i, z_j)$ ,  $i = 1, \dots, m$ ;  $j = 1, \dots, n$ , chosen in the first best assignment solution. The smaller quality (confidence) of hypothesis " $z_j$  belongs to  $T_i$ " means, that the particular measurement error covariance  $R$  was increased and the filter should not trust fully in the actual (true) measurement  $z(k+1)$ .

Having this conclusion in mind, the authors propose, such a behavior of the measurement error covariance to be modeled by  $R = R/q(T_i, z_j)$ , for every pairing, chosen in the first best assignment and based on the corresponding quality value obtained. Then, when the Kalman filter gain decreases the true measurement  $z_j(k+1)$  is trusted less in the updated state estimate  $\hat{x}(k+1|k+1)$ .

### IV. BUILDING ASSIGNMENT MATRIX FOR QADA

QADA assumes the reward matrix is known, regardless of the manner in which it is obtained by the user. In this paper we propose two versions of QADA-KF. The first one utilizes the assignment matrix built from the single normalized distances, provided by the Global Nearest Neighbor method, called QADA-GNN KF method. The second one utilizes the assignment matrix, built from the posterior association probabilities, provided by the Probabilistic Data Association (PDA) method, called QADA-PDA KF method.

#### A. Assignment matrix based on GNN method

The GNN method finds and propagates the single most likely hypothesis during each scan to update KF. It is a hard (i.e., binary) decision approach, as compared to the JPDAF which is a soft (i.e., probabilistic) decision approach using all validated measurements with their probabilities of association. GNN method was applied in [6] and [17] to obtain the assignment matrix, utilized in QADA. In this case

the elements of assignment matrix  $\omega(i, j)$  ( $i = 1, \dots, m$ ,  $j = 1, \dots, n$ ) represent the normalized distances  $d(i, j) = [(z_j(k) - \hat{z}_i(k|k-1))' S^{-1}(k)(z_j(k) - \hat{z}_i(k|k-1))]^{1/2}$  between the validated measurement  $z_j(k)$  and target  $T_i$  satisfying the condition  $d^2(i, j) < \gamma$ . The distance  $d(i, j)$  is computed from the measurement  $z_j(k)$  and its prediction  $\hat{z}_i(k|k-1)$  (see [1] for details), and the inverse of the covariance matrix  $S(k)$  of the innovation, computed by the tracking filter. The threshold  $\gamma$ , for which the probability of given observation to fall in the gate is 0.99, could be defined from the table of the Chi-square distribution with  $M$  degrees of freedom and allowable probability of a valid observation falling outside the gate. In this case the DA problem consists in finding the best assignment that minimizes the overall cost.

#### B. Assignment matrix based on PDA method

The Probabilistic Data Association (PDA) method [1] calculates the association probabilities for validated measurements at a current time moment to the target of interest. PDA assumes the following hypotheses according to each validated measurement:

- $H_i(k)$ :  $z_j$  is a measurement, originated from the target  $T_i$  of interest,  $i = 1, \dots, m$ ;
- $H_0(k)$ : no one of the validated measurement originated from the target of interest.

If  $N$  observations fall within the gate of track  $i$ ,  $N+1$  hypotheses will be formed. The probability of  $H_0$  is proportional to  $p_{i0} = \lambda_{FA}^N (1 - P_d)$ , and the probability of  $H_j$  ( $j = 1, \dots, N$ ) is proportional to

$$p_{ij} = \frac{\lambda_{FA}^{N-1} P_g P_d \cdot e^{-\frac{d_{ij}^2}{2}}}{(2\pi)^{M/2} \cdot \sqrt{|S_{ij}|}}. \quad (13)$$

where  $P_g$  is the a priori probability that the correct measurement is in the validation gate [1];  $P_d$  is the target detection probability;  $\lambda_{FA}$  is the spatial density of false alarms (FA). The probabilities  $p_{ij}$  can be rewritten as [1]

$$p_{ij} = \begin{cases} \frac{b}{b + \sum_{i=1}^N \alpha_{ii}} & \text{for } j = 0 \text{ (no valid obs.)}, \\ \frac{\alpha_{ij}}{b + \sum_{i=1}^N \alpha_{ii}} & \text{for } 1 \leq j \leq N, \end{cases} \quad (14)$$

where

$$b \triangleq (1 - P_g P_d) \lambda_{FA} (2\pi)^{M/2} \cdot \sqrt{|S_{ij}|}, \quad (15)$$

and

$$\alpha_{ij} \triangleq P_d \cdot e^{-\frac{d_{ij}^2}{2}}. \quad (16)$$

The assignment matrix used in QADA method is established from all  $p_{ij}$  given by (14) related with all association hypotheses. This matrix will have  $m$  rows (where  $m$  is the number of all targets of interest), and  $N+1$  columns for the hypotheses generated. The  $(N+1)$ -th column will include the values  $p_{i0}$  associated with  $H_0(k)$ .

## V. JOINT PROBABILISTIC DATA ASSOCIATION FILTER

The Joint Probabilistic Data Association Filter (JPDAF) is an extension of the Probabilistic Data Association Filter (PDAF) for tracking multiple targets in clutter [1], [2], [10], [11], [12]. This Bayesian tracking filter uses the probabilistic assignment of all validated measurements belonging to the target gate to update its estimate. The preliminary version of JPDAF was proposed by Bar-Shalom in 1974 [13], then updated and finalized in [7], [8], [9]. The assumptions of JPDAF are the following:

- the number  $N_T$  of established targets in clutter is known;
- all the information available from the measurements  $Z^k$  up to time  $k$  is summarized by the sufficient statistic  $\hat{x}^t(k)$  (the approximate conditional mean), and covariance  $P^t(k|k)$  for each target  $t$ ,  $t = 1, \dots, N_T$ ;
- the real state  $x^t(k)$  of a target  $t$  at time  $k$  is modeled by a Gaussian pdf  $\mathcal{N}(x^t(k); \hat{x}^t(k), P^t(k|k))$ ;
- each target  $t$  follows its own dynamic model;
- each target generates at most one measurement at each observation time and there are no merged measurements;
- each target is detected with some known detection probability  $P_d^t$ ;
- the false alarms (FA) are uniformly distributed in surveillance area and their number follows a Poisson pmf with FA density  $\lambda_{FA}$ .

In JPDAF, the measurement to target association probabilities are computed jointly across the targets and only for the latest set of measurements. This appealing theoretical approach however can give rise to very high combinatorics complexity if there are several persistent interferences, typically when several targets are crossing or if they move closely during several consecutive scans. Moreover, some track coalescence effects may also appear which degrades substantially the JPDAF performances as it will shown in section VI. These limitations of JPDAF have already been reported in [14]. Let's consider a cluster (a cluster is a group of targets which have some measurements in common in their validation gates, i.e. non-empty intersections) of  $T \geq 2$  targets  $t = 1, \dots, T$ . The set of  $m_k$  measurements available at scan  $k$  is denoted  $Z(k) = \{z_i(k), i = 1, \dots, m_k\}$ . Each measurement  $z_i(k)$  of  $Z(k)$  either originates from a target or from a FA. Denote  $\hat{z}^t(k|k-1)$  as the predicted measurement for target  $t$ , and all the possible innovations that could be used in the Kalman Filter to update the target state estimate are denoted  $\tilde{z}_i^t(k) \triangleq z_i(k) - \hat{z}^t(k|k-1)$ . In JPDAF, instead of using a particular innovation  $\tilde{z}_i^t(k)$ , it uses the weighted innovation  $\tilde{z}^t(k) = \sum_{i=1}^{m_k} \beta_i^t(k) \tilde{z}_i^t(k)$ , where  $\beta_i^t(k)$  is the probability that the measurement  $z_i$  originates from target  $t$ .  $\beta_0^t(k)$  is the probability that none measurements originate from the target  $t$ . The core of JPDAF is the computation of the a posteriori association probabilities  $\beta_i^t(k)$ , ( $i = 0, 1, \dots, m_k$ ) based on all possible joint association events  $\Theta(k) = \cap_{i=1}^{m_k} \Theta_i^{t_i}(k)$ , where  $\Theta_i^{t_i}(k)$  is the event that measurement  $z_i(k)$  originates from target  $t_i$  (by convention and notation convenience,  $t_i = 0$  means that the origin of measurement  $z_i$  is a FA.),

$0 \leq t_i \leq N_T$ . More precisely, one has to compute for  $i = 1, \dots, m_k$ ,  $\beta_i^t(k) = \sum_{\Theta(k)} P(\Theta(k)|Z^k) \hat{\omega}_{it}(\Theta(k))$  and  $\beta_0^t(k) = 1 - \sum_{i=1}^{m_k} \beta_i^t(k)$ , where  $Z^k$  is the set of all measurements available up to time  $k$ , and  $\hat{\omega}_{it}(\Theta(k))$  are the corresponding components of the association matrix characterizing the possible joint association  $\Theta(k)$ .

JPDAF is well theoretically founded and it does not require high memory. It provides pretty good results on simple MTT scenarios (with non-persisting interferences) with moderate FA densities. However the number of feasible joint association matrices increases exponentially with problem dimensions ( $m_k$  and  $N_T$ ) which makes the JPDAF intractable for complex dense MTT scenarios. For more details about JPDAF, please refer to [1], [2], [10]–[12], and [15].

## VI. SIMULATION RESULTS

The Converted Measurement KF (CMKF) is used in our MTT algorithm. We assume constant velocity target model. The process noise covariance matrix is:  $Q = \sigma_\nu^2 Q_T$ , where  $T$  is the sampling period,  $\sigma_\nu$  is the standard deviation of the process noise, and  $Q_T$  is as given in [3]. Here are the results of KDA KF, QADA-GNN KF, QADA-PDA KF, and JPDAF for the MTT scenario with maneuvering targets.

The noise-free group of targets simulation scenario (Fig.1) consists of four air targets moving from left to right (or from West to East). For the clear explanation of the results, targets are numbered starting at the beginning with 1st target that has the greater  $y$ -coordinate and continuing to 4th target with the smallest  $y$ -coordinate. The stationary sensor is located at the origin with range 10000 m. The sampling period is  $T_{\text{scan}} = 5$  sec, and the measurement standard deviations are 0.2 deg and 40 m for azimuth and range respectively. The targets move with constant velocity  $V = 100$  m/s. The first target for the first 8 scans moves without maneuvering keeping azimuth 120 deg from North. The group of two targets in the middle i.e. 2nd and 3rd move without maneuvering keeping azimuth 90 deg from North that means, horizontally from West to East. It is the main direction of the group movement. The 4th target starts with azimuth 60 deg and moves towards the middle group of rectilinearly moving targets. When it approaches the group, it starts a turn to the right with 30 deg. Its initial azimuth of 120 deg is decreased by the angle of turn and becomes 90 deg, i.e. coincides with the main direction. From 15th scan, the four targets move rectilinearly in parallel. The distance between them is 150 m. The absolute value of the corresponding transversal acceleration for the two maneuvers is  $1.495 \text{ m/s}^2$ . The total number of scans for the simulations is 30. The figure 2 shows the noised scenario for yielding to 0.15 FA per gate on average.

Our results are based on Monte Carlo (MC) simulations with 200 independent runs in applying KDA based KF, QADAGNN KF, QADA-PDA KF, and JPDAF. We compare the performance of these methods with different criteria, and we use an idealized track initiation in order to prevent uncontrolled impact of this stage on the statistical parameters of the tracking process during MC simulations.

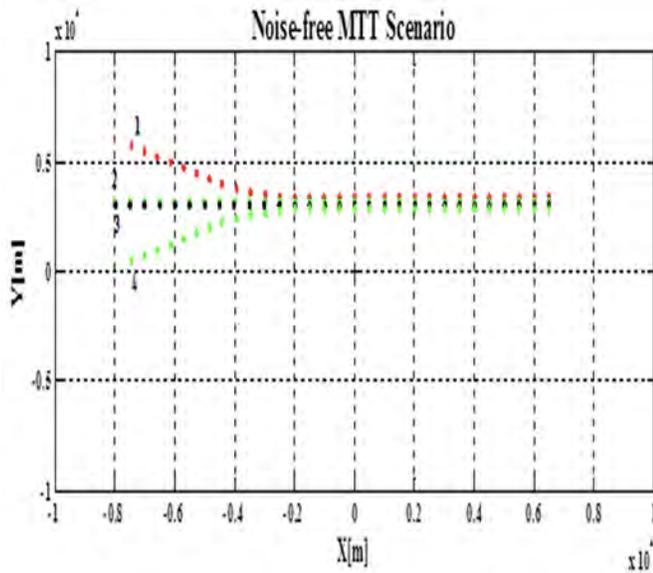

Fig. 1. Noise-free group of targets Scenario.

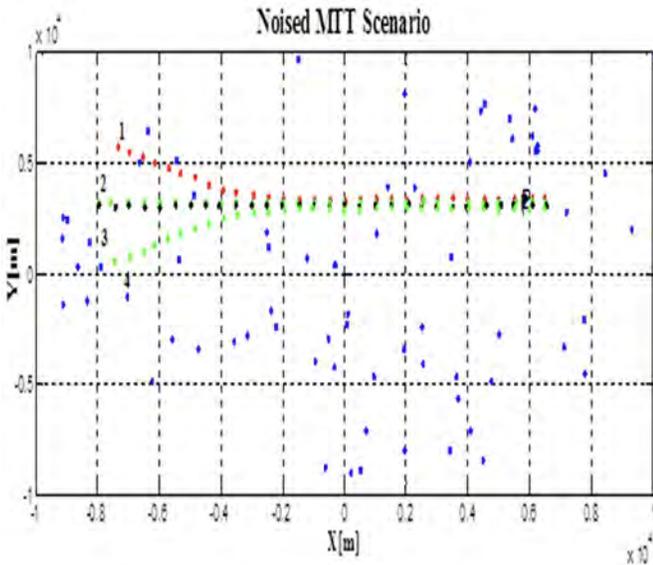

Fig. 2. Noised group of targets Scenario.

The true targets positions (known in our simulations) for the first two scans are used for track initiation. The evaluation of MTT performance is based on the criteria of Track Purity (TP), Track Life (TL), and percentage of miscorrelation (pMC):

- 1) TP criteria examines the ratio between the number of particular performed ( $j$ th observation -  $i$ th track) associations (in case of detected target) over the total number of all possible associations during the tracking scenario, but TP cannot be used with JPDAF because JPDAF is a soft assignment method. Instead of TP, we define the Probabilistic Purity Index (PPI). It considers the measurement that has the highest association probability computed by the JPDAF and check, (and count) if this

measurement originated from the target or not. PPI measures the ability of JPDAF to commit the highest probability to the correct target measurement in the soft assignment of all validated measurements.

- 2) TL is evaluated as an average number of scans before track's deletion. In our simulations, a track is canceled and deleted from the list of tracked tracks, when during 3 consecutive scans it cannot be updated with some measurement because there is no validated measurement in the validation gate. When using JPDAF, the track is canceled and deleted from the list of tracked tracks, when during 3 consecutive scans its own measurement does not fall in its gate. We call this, the "canceling/deletion condition". The status of the tracked tracks is denoted "alive".
- 3) pMC examines the relative number of incorrect observation-to-track associations during the scans. The MTT performance results for KDA only KF, QADAGNN KF, QADA-PDA KF, and JPDAF for average false alarms in gate  $FA = 0.15$  are given in Table 1. The MTT performance for QADA-PDA KF and QADA-GNN KF are estimated for both: Pignistic probabilities, and minimum Belief distance principles to compute the quality indicator.

TABLE I  
GROUP OF TARGETS SCENARIO: COMPARISON BETWEEN MTT PERFORMANCE RESULTS FOR 0.15 FA PER GATE.

(in %)	QADA-PDA		QADA-GNN		JPDAF	KDA
	BetP	Bld	BetP	Bld		
Average TL	88.12	<b>89.39</b>	84.31	<b>89.13</b>	78.42	70.02
Average pMC	2.67	<b>2.45</b>	3.28	<b>2.39</b>	5.92	5.71
Average TP	84.54	<b>86.14</b>	79.86	<b>85.92</b>	32.96 (PPI)	61.95

According to all criteria, QADA-PDA KF method shows the best performance, followed by QADA-GNN KF, and JPDAF. The KDA based KF approach, as one could expect, shows the worst performance. It is obvious that minimum Belief distance interval principle for computing the quality indicator leads to improved MTT performance (compared to the results based on Pignistic probabilities - BetP) for both QADA-PDA KF and QADA-GNN KF. Still QADA-PDA KF outperforms QADA-GNN KF based MTT.

In order to make a fair comparison between QADA KF and JPDAF, we will discuss also the root mean square errors (RMSE), associated with the filtered X and Y values, presented in Figs. 3–6. The results for QADA-GNN KF and QADA-PDA KF are obtained on the base of the improved QADA method using minimal Belief Interval distance criteria and with the new bba modeling, proposed in the paper.

Figs. 3 and 4 show the mean square X and Y error filtered, associated with target 1, and compared for KDA KF, QADA-GNN KF, QADA-PDA KF, and JPDAF. Figs. 5 and 6 consider the same errors for the middle track 3. All the results are compared to the sensor's errors along X and Y axis.

As a whole, one could see that rms errors, associated with QADA-PDA KF and QADA-GNN KF are a little bit less than the sensor's measurement errors, except around the scan

15th, where all the targets move in parallel. We see that the RMSE on Y filtered error for track 1 associated with KDA-JPDAF grows extremely after scan 12. This behavior could be explained by the fact, that from this scan on target 1 starts moving in parallel with the rest of targets, causing that way spatial persisting interferences and track coalescence effects in JPDAF. These effects degrade significantly the quality of JPDAF performance as already reported in [14]. The same effect of track coalescence could be observed for track 3, moving in parallel during all the scans. The RMSE on Y filtered associated with JPDAF performance is high during the whole tracking region.

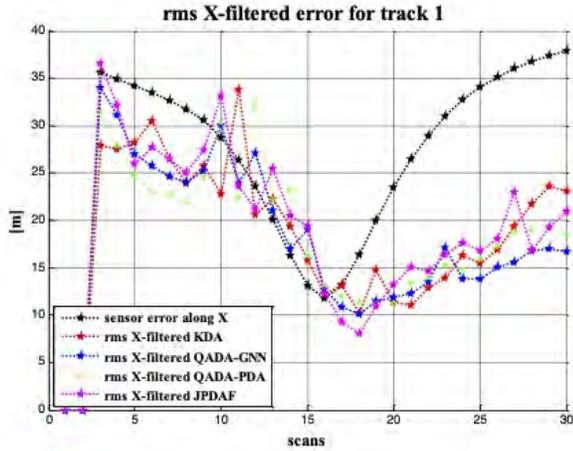

Fig. 3. RMSE on X for track 1 with the four tracking methods.

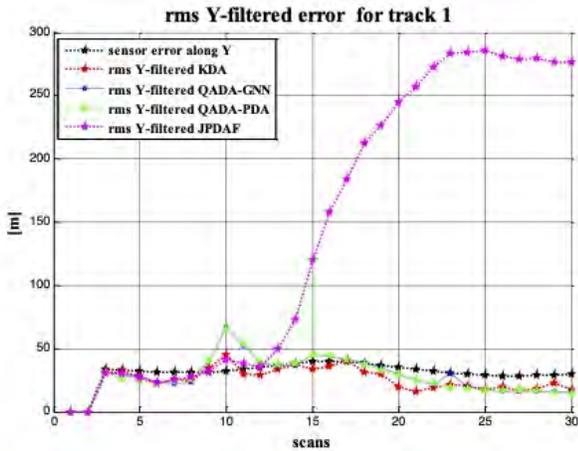

Fig. 4. RMSE on Y for track 1 with the four tracking methods.

## VII. CONCLUSIONS

This work evaluated with Monte Carlo simulations the efficiency of MTT performance in cluttered environment of four methods (a) classical MTT algorithm based on GNN approach for data association, utilizing Kinematic only Data; (b) QADA-GNN KF; (c) QADA-PDA KF; and (d) JPDAF.

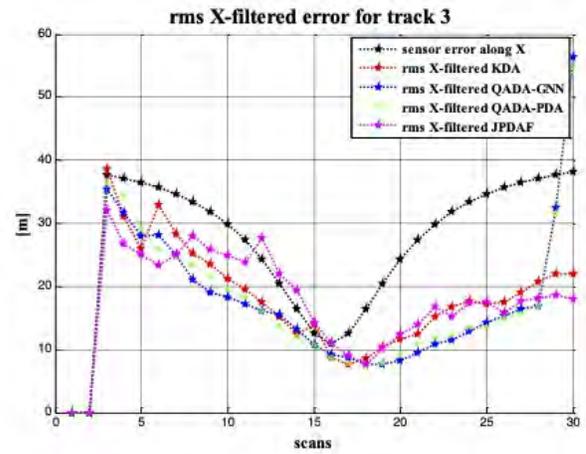

Fig. 5. RMSE on X for track 3 with the four tracking methods.

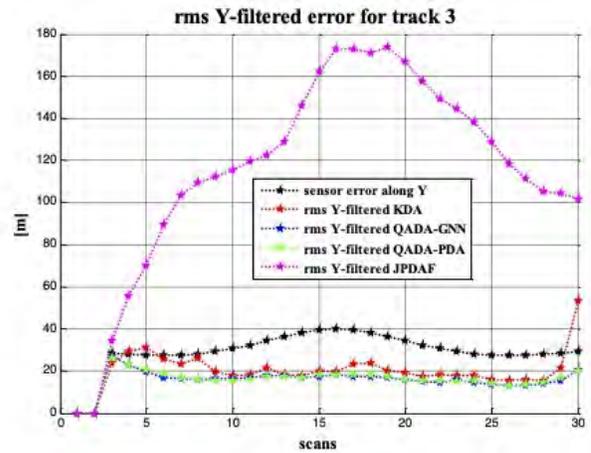

Fig. 6. RMSE on Y for track 3 with the four tracking methods.

QADA technique was improved by using new BBA modelling. It is also was modified by means of the new Belief interval distance applied for computing the quality indicator associated with the pairings in the optimal DA solution. The results were compared with those obtained by using Pignistic Probabilities. It was proved that this new approach leads to better MTT performance. The implemented groups of targets scenario show the advantages of applying QADA-KF. According to all performance criteria, the QADA-PDA KF gives the best performance, followed by QADA-GNN KF, and JPDAF. The KDA KF approach shows the worst performance (as expected). This scenario is particularly difficult for JPDAF because of several closely spaced and rectilinearly moving targets in clutter during many consecutive scans, and it leads to track coalescence effects due to persisting interferences. As a result, the tracking performance of JPDAF is degraded. Because the complexity of the calculation for joint association probabilities grows exponentially with the number of targets, JPDAF requires almost 3 times more computational time in comparison to other methods in the first (complex) scenario.

**Abstract**—This paper presents a comparative analysis of performances of two types of multi-target tracking algorithms: 1) the Joint Probabilistic Data Association Filter (JPDAF), and 2) classical Kalman Filter based algorithms for multi-target tracking improved with Quality Assessment of Data Association (QADA) method using optimal data association. The evaluation is based on Monte Carlo simulations for difficult maneuvering multiple-target tracking (MTT) problems in clutter.

**Keywords:** Data association, JPDAF, Belief Functions, QADA, PCR6 rule, Multitarget Tracking.

## I. INTRODUCTION

Multiple-target tracking (MTT) is a principle component of surveillance systems. The main objective of MTT is to estimate jointly, at each observation time moment, the number of targets continuously moving in a given region and their trajectories from the noisy sensor data. In a single-sensor case, the multitarget tracker receives a random number of measurements due to the uncertainty which results in low detection and false alarms, arising independently of the targets of interest. Because of the fact that detection probability is not perfect, some targets may go undetected at some sampling intervals. Additional complications appear, apart from the process and measurement noises, associated with a measurement origin uncertainty, missed detection, cancelling (death) of targets, etc.

Data association (DA) is a primary task of modern MTT systems [1]–[3]. It entails selecting the most trustable associations between uncertain sensor's measurements and existing targets at a given time. In the presence of a dense MTT environment, with false alarms and sensor detection probabilities less than unity, the problem of DA becomes more complex, because it should contend with many possibilities of pairings, some of which are in practice very imprecise, unreliable, and could lead to critical association mistakes in the overall tracking process.

In order to deal with these complex associations the most recent method to evaluate the Quality Assessment of Data Association (QADA) encountered in multiple target tracking applications in a mono-criterion context was proposed by Dezert and Benameur [4], and extended in [5] for the multi-criteria context. It is based on belief functions (BF) for achieving the quality of pairings belonging to the optimal data

assignment solution based on its consistency with respect to all the second best solutions, provided by a chosen algorithm. Most recently, in [6] the authors did discuss and propose the way in which Kalman filter (KF) could be enhanced in order to reflect the knowledge obtained based on the QADA method, called QADA-KF method.

Taking into account that QADA assumes the reward matrix is known, regardless of the manner in which it is obtained by the user, in this paper we propose and test the performance of two possible versions of QADA-KF. The first one utilizes the assignment matrix, provided by the Global Nearest Neighbour (GNN) method, called QADA-GNN KF approach. The second one utilizes the assignment matrix, provided by the Probabilistic Data Association (PDA) method, called QADA-PDA KF method.

These two QADA-KF methods are compared with the Joint Probabilistic Data Association Filter (JPDAF) [7]–[9] which is an extension of the Probabilistic Data Association Filter (PDAF) [1] to a fixed and known number of targets. JPDAF uses joint association events and joint association probabilities in order to avoid conflicting measurement-to-track assignments by making a soft (probabilistic) assignment of all validated measurements to multiple targets.

The main objective of this paper is to compare the performances of: (i) classical MTT algorithms based on the GNN approach for data association, utilizing Kinematic only Data (KDA) and Converted Measurement Kalman Filter (CMKF); (ii) QADA-GNN KF based MTT; (iii) QADA-PDA KF based MTT; (iiii) JPDAF based MTT. The evaluation is based on a Monte Carlo simulation for particular difficult maneuvering MTT problems in clutter.

This paper is organised as follows. In Section II the JPDAF is described and discussed. Section III is devoted to QADA based KF. Data association methods, providing an assignment matrix for QADA are discussed in Section IV. Two particular simulation MTT scenarios and results are presented for the KDA, QADA-GNN KF, QADA-PDA KF, and JPDAF in Section V. Conclusions are made in Section VI.

## II. JOINT PROBABILISTIC DATA ASSOCIATION FILTER

The Joint Probabilistic Data Association Filter (JPDAF) is an extension of the Probabilistic Data Association Filter (PDAF) for tracking multiple targets in clutter [1], [2], [10]–[12]. This Bayesian tracking filter uses the probabilistic assignment of all validated measurements belonging to the target gate to update its estimate. The preliminary version of JPDAF was proposed by Bar-Shalom in 1974 [13], then updated and finalized in [7]–[9]. The assumptions of JPDAF are the following:

- the number  $N_T$  of established targets in clutter is known;
- all the information available from the measurements  $\mathbf{Z}^k$  up to time  $k$  is summarized by the sufficient statistic  $\hat{\mathbf{x}}^t(k|k)$  (the approximate conditional mean), and covariance  $\mathbf{P}^t(k|k)$  for each target  $t$ ;
- the real state  $\mathbf{x}^t(k)$  of a target  $t$  at time  $k$  is modeled by a Gaussian pdf  $\mathcal{N}(\mathbf{x}^t(k); \hat{\mathbf{x}}^t(k|k), \mathbf{P}^t(k|k))$ ;
- each target  $t$  follows its own dynamic model;
- each target generates at most one measurement at each observation time and there are no merged measurements;
- each target is detected with some known detection probability  $P_d^t$ ;
- the false alarms (FA) are uniformly distributed in surveillance area and their number follows a Poisson pmf with FA density  $\lambda_{\text{FA}}$ .

In JPDAF, the measurement to target association probabilities are computed jointly across the targets and only for the latest set of measurements. This appealing theoretical (0-scan-back) approach however can give rise to very high combinatorics complexity if there are several persistent interferences, typically when several targets are crossing or if they move closely during several consecutive scans. Moreover some track coalescence effects may also appear which degrades substantially the JPDAF performances as it will shown in section V. These limitations of JPDAF have already been reported in [14]. Here we briefly recall the basics of JPDAF. For more details, please refer to [1], [2], [10]–[12], [15].

### A. JPDAF principle

Let's consider a cluster<sup>1</sup> of  $T \geq 2$  targets  $t = 1, \dots, T$ . The set of  $m_k$  measurements available at scan  $k$  is denoted  $\mathbf{Z}(k) = \{\mathbf{z}_i(k), i = 1, \dots, m_k\}$ . Each measurement  $\mathbf{z}_i(k)$  of  $\mathbf{Z}(k)$  either originates from a target or from a FA. Denote  $\hat{\mathbf{z}}^t(k|k-1)$  as the predicted measurement for target  $t$ , and all the possible innovations that could be used in the Kalman Filter to update the target state estimate are denoted  $\tilde{\mathbf{z}}_i^t(k) \triangleq \mathbf{z}_i(k) - \hat{\mathbf{z}}^t(k|k-1)$ ,  $i = 1, \dots, m_k$ . In JPDAF, instead of using a particular innovation  $\tilde{\mathbf{z}}_i^t(k)$ , it uses the weighted innovation  $\tilde{\mathbf{z}}^t(k) = \sum_{i=1}^{m_k} \beta_i^t(k) \tilde{\mathbf{z}}_i^t(k)$ , where  $\beta_i^t(k)$  is the probability that the measurement  $\mathbf{z}_i(k)$  originates from target  $t$ .  $\beta_0^t(k)$  is the probability that none measurements originate from the target  $t$ . The core of JPDAF is the computation of the a posteriori association probabilities  $\beta_i^t(k)$ ,  $i = 0, 1, \dots, m_k$  based on all

<sup>1</sup>A cluster is a group of targets which have some measurements in common in their validation gates (i.e. non-empty intersections).

possible joint association events  $\Theta(k) = \bigcap_{i=1}^{m_k} \Theta_i^{t_i}(k)$ , where  $\Theta_i^{t_i}(k)$  is the event that measurement  $\mathbf{z}_i(k)$  originates from target<sup>2</sup>  $t_i$ ,  $0 \leq t_i \leq N_T$ . More precisely, one has to compute for  $i = 1, \dots, m_k$ ,  $\beta_i^t(k) = \sum_{\Theta(k)} P\{\Theta(k)|\mathbf{Z}^k\} \hat{\omega}_{it}(\Theta(k))$  and  $\beta_0^t(k) = 1 - \sum_{i=1}^{m_k} \beta_i^t(k)$ , where  $\mathbf{Z}^k$  is the set of all measurements available up to time  $k$ , and  $\hat{\omega}_{it}(\Theta(k))$  are the corresponding components of the association matrix characterizing the possible joint association  $\Theta(k)$ .

### B. Feasible joint association events

Validation gates are used for finding the feasible joint events but not in the evaluation of their probabilities [12] (p. 388–389). To describe the observation situation, it uses the validation matrix  $\Omega = [\omega_{it}]$ ,  $i = 1, \dots, m_k$  and  $t = 0, \dots, N_T$  with elements  $\omega_{it} \in \{0, 1\}$  to indicate whether or not the measurement  $\mathbf{z}_i$  lies in the validation gate of target  $t$ . Because each measurement can potentially originate from a FA, all elements of the first column of  $\Omega$  corresponding to index  $t = 0$  (meaning FA, or none of the targets) are equal to one. From this validation matrix, all possible feasible joint association events  $\hat{\Omega}(\Theta(k)) = [\hat{\omega}_{it}(\Theta(k))]$  where  $\hat{\omega}_{it}(\Theta(k)) = 1$  if  $\Theta_i^{t_i}(k) \in \Theta(k)$ , and zero otherwise, are realized satisfying the following *feasibility conditions*:

- a measurement can have only one origin, that is for all  $i$

$$\sum_{t=0}^{N_T} \hat{\omega}_{it}(\Theta(k)) = 1. \quad (1)$$

- at most one measurement can originate from a target

$$\sum_{i=1}^{m_k} \hat{\omega}_{it}(\Theta(k)) \leq 1, \quad \text{for } t = 1, \dots, N_T. \quad (2)$$

The generation of all possible feasible joint association events is computationally expensive for complicated MTT scenarios, which is a serious limitation of JPDAF for real-world scenarios. A simple Matlab<sup>TM</sup> algorithm for the generation of matrices  $\hat{\Omega}(\Theta(k))$  is given in [15] (pp. 56–57), which is based on DFS (Depth First Search) detailed by Zhou in [16], [17], previously coded in FORTRAN in [18].

### C. Feasible joint association probabilities

Thanks to Bayes formula, the computation of the a posteriori joint association probabilities  $P\{\Theta(k)|\mathbf{Z}^k\}$  involved in the derivation of  $\beta_i^t(k)$  can be expressed as (see [1], [2], [10]–[12], [15] for full derivations)

$$\begin{aligned} P\{\Theta(k)|\mathbf{Z}^k\} &= \frac{1}{c} \cdot p[\mathbf{Z}(k)|\Theta(k), m_k, \mathbf{Z}^{k-1}] P\{\Theta(k)|m_k\} \\ &= \frac{1}{c} \cdot \frac{\phi(\Theta(k))!}{m_k!} \mu_F(\phi(\Theta(k))) V^{-\phi(\Theta(k))} \\ &\quad \times \prod_{i=1}^{m_k} [f_{t_i}(\mathbf{z}_i(k))]^{\tau_i(\Theta(k))} \\ &\quad \times \prod_{t=1}^T (P_d^t)^{\delta_t(\Theta(k))} (1 - P_d^t)^{1 - \delta_t(\Theta(k))}, \quad (3) \end{aligned}$$

<sup>2</sup>By convention and notation convenience,  $t_i = 0$  means that the origin of measurement  $\mathbf{z}_i$  is a FA.

where  $c$  is a normalization constant,  $V$  is the volume of the surveillance region, and the indicators  $\delta_t(\Theta(k))$  (target detection indicator),  $\tau_i(\Theta(k))$  (measurement association indicator),  $\phi(\Theta(k))$  (FA indicator) are defined by

$$\delta_t(\Theta(k)) \triangleq \sum_{i=1}^{m_k} \hat{\omega}_{it}(\Theta(k)) \leq 1 \quad t = 1, \dots, N_T, \quad (4)$$

$$\tau_i(\Theta(k)) \triangleq \sum_{t=1}^T \hat{\omega}_{it}(\Theta(k)), \quad (5)$$

$$\phi(\Theta(k)) \triangleq \sum_{i=1}^{m_k} [1 - \tau_i(\Theta(k))]. \quad (6)$$

$\mu_F(\phi(\Theta(k)))$  is the prior pmf of the number of false measurements (the clutter model) and

$$f_{t_i}(\mathbf{z}_i(k)) \triangleq \mathcal{N}[\mathbf{z}_i(k); \hat{\mathbf{z}}^{t_i}(k|k-1), \mathbf{S}^{t_i}(k)], \quad (7)$$

where  $\mathbf{S}^{t_i}(k)$  is the predicted covariance matrix of innovation  $\mathbf{z}_i(k) - \hat{\mathbf{z}}^{t_i}(k|k-1)$ .

Two versions of JPDAF have been proposed [1], [7]–[9]:

- **Parametric JPDAF:** Knowing the spatial density  $\lambda_{\text{FA}}$  of the false measurements, and using a Poisson pmf  $\mu_F(\phi(\Theta(k))) = \frac{(\lambda_{\text{FA}}V)^{\phi(k)}}{\phi(k)!} e^{-\lambda_{\text{FA}}V}$ , results in

$$P\{\Theta(k)|\mathbf{Z}^k\} = \frac{1}{c_1} \cdot \prod_{i=1}^{m_k} [\lambda_{\text{FA}}^{-1} \cdot f_{t_i}(\mathbf{z}_i(k))]^{\tau_i(\Theta(k))} \times \prod_{t=1}^{N_T} [P_d^t]^{\delta_t(\Theta(k))} [1 - P_d^t]^{1-\delta_t(\Theta(k))}, \quad (8)$$

where  $c_1$  is a normalization constant.

- **Non parametric JPDAF:** Using a diffuse prior pmf of number of FA  $\mu_F(\phi(k)) = \epsilon$ ,  $\forall \phi(k)$ , results in

$$P\{\Theta(k)|\mathbf{Z}^k\} = \frac{\phi(k)!}{c_2} \cdot \prod_{i=1}^{m_k} [V f_{t_i}(\mathbf{z}_i(k))]^{\tau_i(\Theta)} \times \prod_{t=1}^{N_T} [P_d^t]^{\delta_t(\Theta(k))} [1 - P_d^t]^{1-\delta_t(\Theta(k))}, \quad (9)$$

where  $c_2$  is a new normalization constant.

#### D. JPDAF state estimation

Once all feasible joint association events  $\Theta(k)$  have been generated and their a posteriori probabilities  $P\{\Theta(k)|\mathbf{Z}^k\}$  determined, all the marginal association probabilities  $\beta_i^t(k) = \sum_{\Theta(k)} P\{\Theta(k)|\mathbf{Z}^k\} \hat{\omega}_{it}(\Theta(k))$  and  $\beta_0^t(k) = 1 - \sum_{i=1}^{m_k} \beta_i^t(k)$  are computed. The state update and prediction are done with PDAF equations<sup>3</sup> given by

$$\hat{\mathbf{x}}^t(k|k) = \sum_{i=0}^{m_k} \beta_i^t(k) \hat{\mathbf{x}}_i^t(k|k), \quad (10)$$

<sup>3</sup>for the decoupled version of JPDAF. For the coupled version of JPDAF, see [10], [12].

with  $\hat{\mathbf{x}}_i^t(k|k)$  given by

$$\hat{\mathbf{x}}_{i>0}^t(k|k) = \hat{\mathbf{x}}^t(k|k-1) + \mathbf{K}^t(k) \tilde{\mathbf{z}}_i^t(k), \quad (11)$$

$$\hat{\mathbf{x}}_{i=0}^t(k|k) = \hat{\mathbf{x}}^t(k|k-1). \quad (12)$$

Using (11) and (12) in (10), then

$$\hat{\mathbf{x}}^t(k|k) = \hat{\mathbf{x}}^t(k|k-1) + \mathbf{K}^t(k) \sum_{i=1}^{m_k} \beta_i^t(k) \tilde{\mathbf{z}}_i^t(k), \quad (13)$$

$$\mathbf{P}^t(k|k) = \beta_0^t(k) \mathbf{P}^t(k|k-1) + (1 - \beta_0^t(k)) \mathbf{P}_c^t(k) + \tilde{\mathbf{P}}^t(k), \quad (14)$$

with

$$\mathbf{P}_c^t(k) = [\mathbf{I} - \mathbf{K}^t(k) \mathbf{H}(k)] \mathbf{P}^t(k|k-1), \quad (15)$$

$$\tilde{\mathbf{P}}^t(k) = \mathbf{K}^t(k) \left[ \sum_{i=1}^{m_k} \beta_i^t(k) \tilde{\mathbf{z}}_i^t(k) \tilde{\mathbf{z}}_i^{t'}(k) - \tilde{\mathbf{z}}(k) \tilde{\mathbf{z}}'(k) \right] \mathbf{K}'(k), \quad (16)$$

and

$$\mathbf{K}^t(k) \triangleq \mathbf{P}^t(k|k-1) \mathbf{H}'(k) \mathbf{S}^t(k)^{-1}, \quad (17)$$

$$\tilde{\mathbf{z}}_i^t(k) \triangleq \mathbf{z}_i(k) - \hat{\mathbf{z}}^t(k|k-1), \quad (18)$$

$$\tilde{\mathbf{z}}^t(k) \triangleq \sum_{i=1}^{m_k} \beta_i^t(k) \tilde{\mathbf{z}}_i^t(k). \quad (19)$$

It has been proved in [1] that  $\tilde{\mathbf{P}}^t(k)$  is always a semi-positive matrix. The target state prediction  $\hat{\mathbf{x}}^t(k+1|k)$  and  $\mathbf{P}^t(k+1|k)$  are obtained by the classical Kalman Filter (KF) equations [1] (assuming linear kinematic models), or by Extended KF equations. They will not be repeated here [2], [10].

In summary, JPDAF is well theoretically founded and it does not require high memory (0-scan-back). It provides pretty good results on simple MTT scenarios (with non persisting interferences) with moderate FA densities. However the number of feasible joint association matrices increases exponentially with problem dimensions ( $m_k$  and  $N_T$ ) which makes the JPDAF intractable for complex dense MTT scenarios.

### III. QADA BASED KALMAN FILTER

The aim of this paper is to compare the performance of the JPDAF based MTT algorithm with the classical<sup>4</sup> MTT algorithm, using the CMKF based on kinematics measurements, but improved by the QADA method.

The main idea behind the QADA method, proposed recently by Dezert and Benameur [4] is to compare the values  $a_1(i, j)$  in the first optimal DA solution  $\mathbf{A}_1$  with the corresponding values  $a_2(i, j)$  in second assignment solution  $\mathbf{A}_2$ , and to identify if there is a change of the optimal pairing  $(i, j)$ . In the MTT context  $(i, j)$  means an association between measurement  $\mathbf{z}_j$  and target  $T_i$ . QADA establishes a quality indicator associated with this pairing, depending on the stability of the pairing and also, on its relative impact in the global reward. The proposed method works also when the 1<sup>st</sup> and 2<sup>nd</sup> optimal assignments  $\mathbf{A}_1$  and  $\mathbf{A}_2$  are not unique, i.e., there are

<sup>4</sup>Classical MTT algorithms are those based on hard assignment of a chosen measurement to a given target.

multiplicities available. In such a situation, the establishment of quality indicators could help in selecting one particular optimal assignment solution among multiple possible choices.

The construction of the quality indicator is based on belief functions (BF) and the Proportional Conflict Redistribution fusion rule no.6 (PCR6), defined within Dezert-Smarandache Theory (DSMT) [19]. It depends on the type of the pairing matching, and it is described in detail in [4].

In [6], the authors discuss and propose the way in which Kalman filter could be improved in order to reflect the knowledge obtained based on the QADA method.

Let's briefly recall what kind of information is obtained, having in hand the quality matrix, derived by QADA, in the MTT context. It gives knowledge about the confidence  $q(i, j)$  in all pairings  $(T_i, \mathbf{z}_j)$ ,  $i = 1, \dots, m$ ;  $j = 1, \dots, n$ , chosen in the first best assignment solution. The smaller quality (confidence) of hypothesis “ $\mathbf{z}_j$  belongs to  $T_i$ ” means, that the particular measurement error covariance  $\mathbf{R}$  was increased and the filter should not trust fully in the actual (true) measurement  $\mathbf{z}(k+1)$ .

Having this conclusion in mind, the authors propose, such a behaviour of the measurement error covariance to be modelled by  $\mathbf{R} = \frac{\mathbf{R}}{q(T_i, \mathbf{z}_j)}$ , for every pairing, chosen in the first best assignment and based on the corresponding quality value obtained. Then, when the Kalman filter gain decreases the true measurement  $\mathbf{z}_j(k+1)$  is trusted less in the updated state estimate  $\hat{\mathbf{x}}(k+1|k+1)$ .

#### IV. BUILDING ASSIGNMENT MATRIX FOR QADA

Data Association (DA) is a central problem in the modern MTT systems [1], [2]. It consists in finding the global optimal assignments of targets  $T_i$ ,  $i = 1, \dots, m$  to some measurements  $\mathbf{z}_j$ ,  $j = 1, \dots, n$  at a given time  $k$  by maximizing the overall gain in such a way, that no more than one target is assigned to a measurement, and reciprocally. The  $m \times n$  reward (gain/payoff) matrix  $\Omega = [\omega(i, j)]$  is defined by its elements  $\omega(i, j) > 0$ , representing the gain of the association of target  $T_i$  with the measurement  $\mathbf{z}_j$ .

These values are usually homogeneous to the likelihood ratios and could be established in different ways, described below. They provide the assignment matrix utilized by QADA in order to obtain the quality of pairings (interpreted as a confidence score) belonging to the optimal data assignment solution based on its consistency (stability) with respect to all the second best solutions, provided for a chosen algorithm.

QADA assumes the reward matrix is known, regardless of the manner in which it is obtained by the user. In this paper we propose two versions of QADA-KF. The first one utilizes the assignment matrix built from the single normalized distances, provided by the Global Nearest Neighbour method, called QADA-GNN KF method. The second one utilizes the assignment matrix, built from the posterior association probabilities, provided by the Probabilistic Data Association (PDA) method, called QADA-PDA KF method.

##### A. Assignment matrix based on GNN method

The GNN method finds and propagates the single most likely hypothesis during each scan to update KF. It is a

hard (i.e., binary) decision approach, as compared to the JPDAF which is a soft (i.e., probabilistic) decision approach using all validated measurements with their probabilities of association. GNN method was applied in [6] and [20] to obtain the assignment matrix, utilized in QADA. In this case the elements of assignment matrix  $\omega(i, j)$ ,  $i = 1, \dots, m$ ;  $j = 1, \dots, n$  represent the normalized distances  $d(i, j) \triangleq [(\mathbf{z}_j(k) - \hat{\mathbf{z}}_i(k|k-1))' \mathbf{S}^{-1}(k)(\mathbf{z}_j(k) - \hat{\mathbf{z}}_i(k|k-1))]^{1/2}$  between the validated measurement  $\mathbf{z}_j$  and target  $T_i$  satisfying the condition  $d^2(i, j) \leq \gamma$ . The distance  $d(i, j)$  is computed from the measurement  $\mathbf{z}_j(k)$  and its prediction  $\hat{\mathbf{z}}_i(k|k-1)$  (see [1] for details), and the inverse of the covariance matrix  $\mathbf{S}(k)$  of the innovation, computed by the tracking filter. The threshold  $\gamma$ , for which the probability of given observation to fall in the gate is 0.99, could be defined from the table of the Chi-square distribution with  $M$  degrees of freedom and allowable probability of a valid observation falling outside the gate. In this case the DA problem consists in finding the best assignment, that minimizes the overall cost.

##### B. Assignment matrix based on PDA method

The Probabilistic Data Association (PDA) method [1] calculates the association probabilities for validated measurements at a current time moment to the target of interest. PDA assumes the following hypotheses according to each validated measurement:

- $H_i(k)$ :  $\mathbf{z}_j(k)$  is a measurement, originated from the target of interest,  $i = 1, \dots, m$
- $H_0(k)$ : no one of the validated measurement originated from the target of interest

If  $N$  observations fall within the gate of track  $i$ ,  $N + 1$  hypotheses will be formed.

The probability of  $H_0$  is proportional to  $p_{i0} = \lambda_{\text{FA}}^N (1 - P_g P_d)$ , and the probability of  $H_j$  ( $j = 1, 2, \dots, N$ ) is proportional to

$$p_{ij} = \frac{\lambda_{\text{FA}}^{N-1} P_g P_d \cdot e^{-\frac{d_{ij}^2}{2}}}{(2\pi)^{M/2} \cdot \sqrt{|\mathbf{S}_{ij}|}}, \quad (20)$$

where  $P_g$  is the a priori probability that the correct measurement is in the validation gate<sup>5</sup> [1];  $P_d$  is the target detection probability;  $\lambda_{\text{FA}}$  is the spatial density of FA. The probabilities  $p_{ij}$  can be rewritten as [1]

$$p_{ij} = \begin{cases} \frac{b}{b + \sum_{i=1}^N \alpha_{i0}} & \text{for } j = 0 \text{ (no valid observ.)}, \\ \frac{\alpha_{ij}}{b + \sum_{i=1}^N \alpha_{i0}} & \text{for } 1 \leq j \leq N, \end{cases} \quad (21)$$

where

$$b \triangleq (1 - P_g P_d) \lambda_{\text{FA}} (2\pi)^{M/2} \sqrt{|\mathbf{S}_{ij}|}, \quad (22)$$

and

$$\alpha_{ij} \triangleq P_d \cdot e^{-\frac{d_{ij}^2}{2}}. \quad (23)$$

<sup>5</sup>In our simulations, we use  $P_g = 0.99$  and  $P_d = 0.99$ .

The assignment matrix used in QADA method is established from all  $p_{ij}$  given by (21) related with all association hypotheses. This matrix will have  $m$  rows (where  $m$  is the number of all targets of interest), and  $N + 1$  columns for the hypotheses generated. The  $(N + 1)$ th column will include the values  $p_{i0}$  associated with  $H_0(k)$ .

## V. SIMULATION SCENARIOS AND RESULTS

The Converted Measurement KF is used in our MTT algorithm. We assume constant velocity target model. The process noise covariance matrix is:  $Q = \sigma_v^2 Q_T$ , where  $T$  is the sampling period,  $\sigma_v$  is the standard deviation of the process noise and  $Q_T$  is as given in [3]. Here are the results of KDA KF, QADA-GNN KF, QADA-PDA KF, and JPDAF for two interesting MTT scenarios.

### A. Groups of targets simulation scenario

The noise-free groups of targets simulation scenario (Fig.1) consists of five air targets moving from North-West to South-East. For the clear explanation of the results, targets are numbered starting at the beginning with 1st target that has the greater y-coordinate and continuing to 5th target with the smallest y-coordinate. The three targets 2nd, 3rd, and 4th move together between them<sup>6</sup>. The stationary sensor is located at the origin with range 20000 m. The sampling period is  $T_{scan} = 5$  sec and the measurement standard deviations are 0.2 deg and 35 m for azimuth and range respectively. The targets move with constant velocity  $V = 100m/sec$ . The group of three targets in the middle i.e. 2nd to 4th move without maneuvering keeping azimuth 135 deg from North. It is the main direction of the group's movement. The first target starts with azimuth 165 deg and moves towards the middle group of rectilinearly moving targets. When it approaches the group, it starts a turn to the left with  $-30$  deg. Its initial azimuth of 165 deg is decreased by the angle of turn and becomes 135 deg, the main direction. The fifth target makes similar maneuver but in opposite direction - to the right. Its initial azimuth of 105 deg is increased by the turn of 30 deg and becomes 135 deg, and also coincides with the main direction. From 21th scan to 48th scan all the targets move rectilinearly in parallel. The distance between them is 150 m. From 48th scan, the first target makes a left turn to azimuth of 105 deg, that means  $-30$  degrees with respect to the main direction and starts to go away from the middle group. The fifth target makes right turn to azimuth of 165 deg that means  $+30$  deg from the main direction and also starts to go away. All maneuvers are with one and the same value of the angle (angle= 30 deg by absolute value), the same time duration and linear velocity. The absolute value of the corresponding transversal acceleration for all maneuvers is  $1.163m/s^2$ . The total number of scans for the simulations is 65. Fig. 2 shows the noised scenario for  $\lambda_{FA} = 16 \cdot 10^{-10}m^{-2}$  yielding to 0.2 FA per gate on average.

Our results are based on Monte Carlo (MC) simulations with 200 independent runs in applying KDA based KF, QADA-

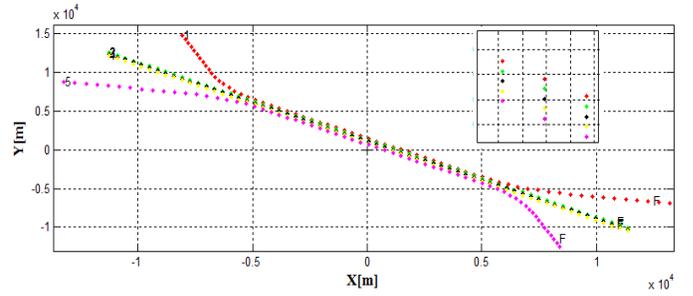

Figure 1. Noise-free groups of targets Scenario.

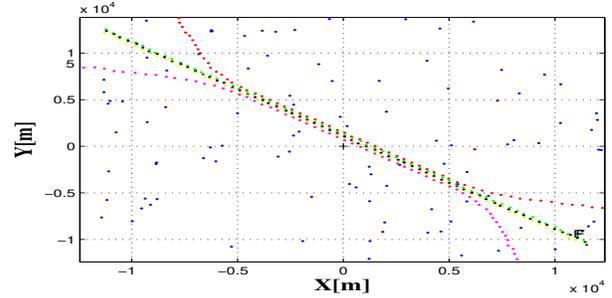

Figure 2. Noised groups of targets Scenario with  $\lambda_{FA} = 16 \cdot 10^{-10}m^{-2}$ .

GNN KF, QADA-PDA KF, and JPDAF<sup>7</sup>. We compare the performance of these methods with different criteria, and we use an idealized track initiation in order to prevent uncontrolled impact of this stage on the statistical parameters of the tracking process during MC simulations. The true targets positions (known in our simulations) for the first two scans are used for track initiation. The evaluation of MTT performance is based on the criteria of Track Purity (TP), Track Life (TL), and percentage of miscorrelation (pMC):

1) TP criteria examines the ratio between the number of particular performed ( $j$ th observation -  $i$ th track) associations (in case of detected target) over the total number of all possible associations during the tracking scenario, but TP cannot be used with JPDAF because JPDAF is a soft assignment method. Instead of TP, we define the Probabilistic Purity Index (PPI). It considers the measurement that has the highest association probability computed by the JPDAF and check, (and count) if this measurement originated from the target or not. PPI measures the ability of JPDAF to commit the highest probability to the correct target measurement in the soft assignment of all validated measurements.

2) TL is evaluated as an average number of scans before track's deletion. In our simulations, a track is cancelled and deleted from the list of tracked tracks, when during 3 consecutive scans it cannot be updated with some measurement because there is no validated measurement in the validation gate. When using JPDAF, the track is cancelled and deleted from the list of tracked tracks, when during 3 consecutive scans its own measurement does not fall in its gate. We call this,

<sup>6</sup>Note that three targets move together in the center.

<sup>7</sup>We have used the non parametric version of JPDAF in our simulations.

the “cancelling/deletion condition”. The status of the tracked tracks is denoted “alive”.

3) pMC examines the relative number of incorrect observation-to-track associations during the scans.

The MTT performance results for KDA only KF, QADA-GNN KF, QADA-PDA KF, and JPDAF for a low-noise case (0.2 FA per gate on average) are given in Table 1.

(in %)	KDA	JPDAF	QADA-GNN	QADA-PDA
Average TL	50.27	66.46	81.94	90.85
Average pMC	3.35	2.98	2.10	1.75
Average TP	45.61	PPI=29.14	79.32	87.61

Table 1

GROUPS OF TARGETS SCENARIO: COMPARISON BETWEEN MTT PERFORMANCE RESULTS FOR 0.2 FA PER GATE.

According to all criteria, the QADA-PDA KF method shows the best performance, followed by QADA-GNN KF, and JPDAF. The KDA based KF approach, as one could expect, shows the worst performance. Performance results for a more noisy scenario with 0.4 FA per gate on average are given in Table 2.

(in %)	KDA	QADA-GNN	JPDAF	QADA-PDA
Average TL	43.54	70.51	70.94	84.17
Average pMC	3.90	3.33	2.71	3.11
Average TP	38.22	66.43	PPI=25.65	78.51

Table 2

GROUPS OF TARGETS SCENARIO: COMPARISON BETWEEN MTT PERFORMANCE RESULTS FOR 0.4 FA PER GATE.

As we see, the results for 0.4 FA per gate scenario are degraded in comparison to the low-noise case. The average miscorrelation for QADA-PDA is slightly higher than for JPDAF, probably because QADA method is based on the 1<sup>st</sup> and 2<sup>nd</sup> best solutions only, and more information (i.e. the 3<sup>rd</sup> best assignment solution) should be used in such case to improve QADA performance, which is left for further research. According to TL and TP, still QADA-PDA KF based MTT shows stably better performance than JPDAF.

JPDAF based MTT outperforms QADA-GNN KF and KDA KF based MTT approaches according to the considered criteria. In order to make a fair comparison between QADA KF and JPDAF, we will discuss also the root mean square errors (RMSE), associated with the filtered X and Y values, presented in Figs. 3–7. Figs. 3 and 4 show the mean square X and Y error filtered, associated with target 1, and compared for KDA KF, QADA-GNN KF, QADA-PDA KF, and JPDAF. Figs. 5 and 6 consider the same errors for the middle of track 3. All the results are compared to the sensor’s errors along X and Y axis. We see that the RMSE on X filtered associated with KDA KF, QADA-GNN KF, and QADA-PDA KF are a little bit above from the sensor’s error in the region where target 1 makes maneuvers. For scans [20, 50], target 1 is moving in parallel to the group of other targets running rectilinearly and then these errors are less than respective sensors’s ones. The RMSE on X filtered associated with JPDAF performance is three times bigger in the region between scans 20th and 30th where target 1 starts moving in parallel to the rest of

rectilinearly moving targets. The RMSE on Y filtered is high during the whole region, where target 1 moves in parallel way.

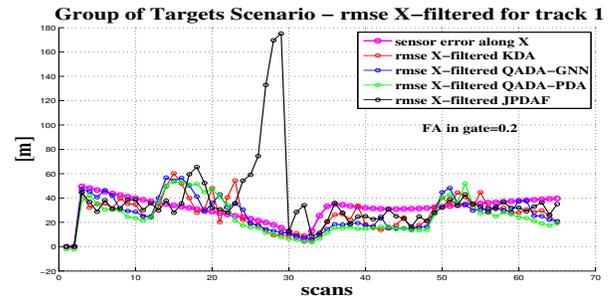

Figure 3. RMSE on X for track 1 with the four tracking methods.

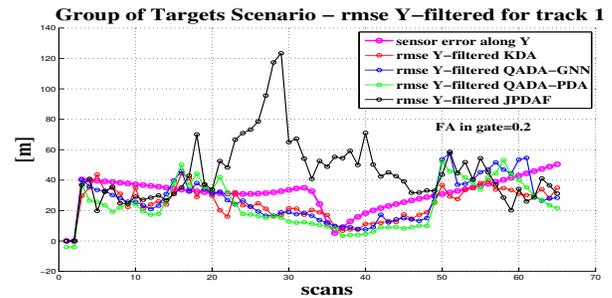

Figure 4. RMSE on Y for track 1 with the four tracking methods.

The RMSE on Y error filtered by JPDAF are especially critical for the middle track 3 which shows its poor performance in state estimation on Y direction. The RMSEs are more than 5 times bigger (in the region between scans 20th and 50th, where all five targets move in parallel) than the respective errors obtained by KDA KF, QADA-GNN KF, QADA-PDA KF, which are less than the sensor’s error. The RMSE on X filtered obtained with JPDAF is under the sensor’s error, beside KDA KF, QADA-GNN KF, QADA-PDA KF methods.

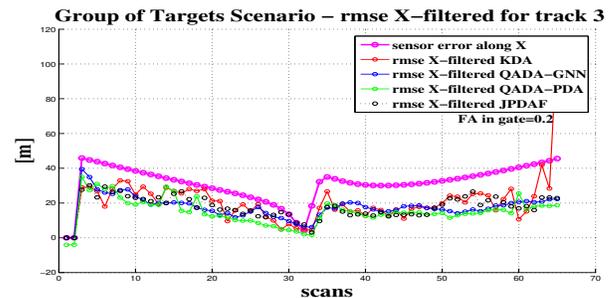

Figure 5. RMSE on X for track 3 with the four tracking methods.

The large value of RMSE on Y using the JPDAF can be explained by the specificity of the scenario because it has five targets moving closely during more than 30 consecutive scans with sensor’s measurement errors, and false alarms density, which yields to spatial persisting interferences and track coalescence effects in JPDAF, as shown in Fig. 7, where

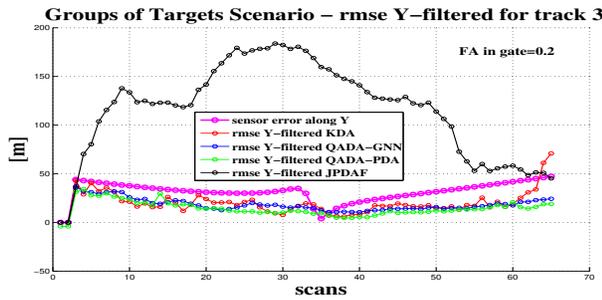

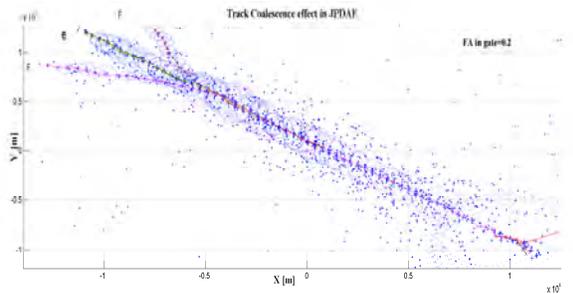

Figure 6. RMSE on Y for track 3 with the four tracking methods.

the red and green plots are the tracks estimates. These effects degrades significantly the quality of JPDAF performance as already reported in [14].

 Figure 7. JPDAF track coalescence (one run) with  $\lambda_{FA} = 16 \cdot 10^{-10} m^{-2}$ .

### B. Crossing targets simulation scenario

The second considered (crossing targets) scenario (Fig. 8) consists of two maneuvering targets moving with constant velocity  $38m/sec$ . At the beginning, both targets move from West to East. The stationary sensor is located at the origin with range 1200 m. The sampling period is  $T_{scan} = 1sec$  and the measurement standard deviations are 0.2 deg and 25 m for azimuth and range respectively.

The first target, having at the beginning greater y-coordinate, moves straightforward from West to East. Between the 8th and 12th scans it makes a 50 deg right turn, and then it moves straightforward during 8 scans. From the 20th scan to the 24th scan it makes a 50 deg left turn, and then it moves in East direction till the 41th scan. It makes a second 50 deg left turn between 41th and 45th scans, and then it moves straightforward during 8 scans. From 53th scan it makes a second 50 deg right turn till the 57th scan and then it moves in East direction. The trajectory of target 1 corresponds to the red plot of Fig. 8.

The second target makes a mirrored trajectory corresponding to the green plot of Fig. 8. From scan 1 to 8 it moves from West to East. During 8th to 12th scans it makes a 50 deg left turn. Then it moves straightforward during 8 scans. During 20th to 24th scans it makes a 50 deg right turn and then it moves in East direction till the 41th scan. It makes a second 50 deg right turn between the 41th and 45th scans, and then

it moves straightforward during 8 scans. From the 53th scan it makes a second 50 deg left turn till the 57th scan and then it moves in East direction. The total number of scans for the simulations is 65. Fig. 9 shows the respective noised scenario for  $\lambda_{FA} = 4 \cdot 10^{-7} m^{-2}$ .

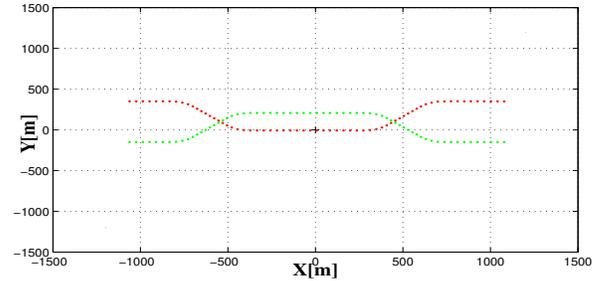

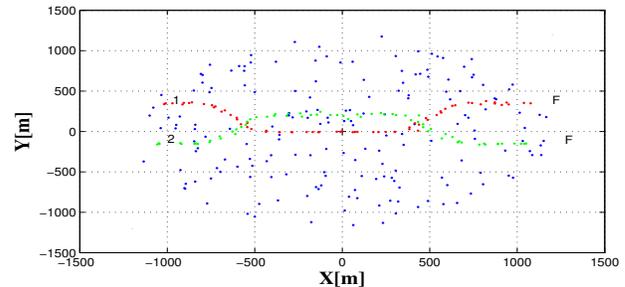

Figure 8. Noise-free Crossing targets Scenario.

 Figure 9. Noised Crossing targets Scenario with  $\lambda_{FA} = 4 \cdot 10^{-7} m^{-2}$ .

The MTT performance results obtained on the base of KDA only KF, QADA-GNN KF, QADA-PDA KF, and JPDAF for less noised case corresponding to 0.2 FA per gate are given in Table 3, and the performance results for a more noisy scenario with 0.4 FA per gate on average are given in Table 4.

(in %)	KDA	QADA-GNN	JPDAF	QADA-PDA
Average TL	77.06	88.93	91.25	93.47
Average pMC	2.40	2.24	2.08	2.11
Average TP	72.78	85.64	PPI=86.29	87.96

Table III

CROSSING TARGETS SCENARIO: COMPARISON BETWEEN MTT PERFORMANCE RESULTS FOR FA IN GATE = 0.2.

(in %)	KDA	QADA-GNN	JPDAF	QADA-PDA
Average TL	58.80	77.20	82.87	83.18
Average pMC	3.61	3.63	2.94	3.40
Average TP	52.90	72.01	PPI=76.94	77.15

Table IV

CROSSING TARGETS SCENARIO: COMPARISON BETWEEN MTT PERFORMANCE RESULTS FOR FA IN GATE = 0.4.

According to all criteria, the QADA-PDA KF shows again the best performance, but now JPDAF based MTT shows closed to QADA-PDA KF performance in comparison to the previous scenario, and exceeds the performance of QADA-GNN KF. Nevertheless the performances of all methods are

deteriorated in more noised case, when one has 0.4 FA in gate on average, this tendency is still kept. JPDAF has better (than in the previous scenario) performance, but still QADA-PDA KF exceeds its performance.

Figures 10-13 show that the RMS errors associated with X and Y filtered are below the sensor's error. They confirm the better performance of JPDAF in this particular scenario with only two maneuvering targets, which is simpler than the groups of targets scenario.

## VI. CONCLUSIONS

This work evaluated with Monte Carlo simulations the efficiency of MTT performance in cluttered environment of four methods (i) classical MTT algorithm based on the GNN approach for data association, utilizing Kinematic only Data based Kalman Filter; (ii) QADA-GNN KF; (iii) QADA-PDA

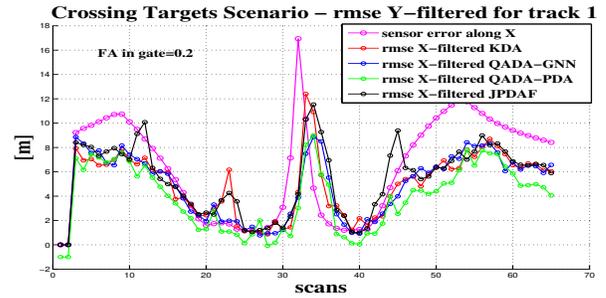

Figure 13. RMSE on Y for track 2 with the four tracking methods.

KF; and (iii) JPDAF. The first scenario (groups of targets) shows the advantages of applying QADA-KF. According to all performance criteria, the QADA-PDA KF gives the best performance, followed by QADA-GNN KF, and JPDAF. The KDA KF approach shows the worst performance (as expected). This scenario is particularly difficult for JPDAF because of several closely spaced and rectilinearly moving targets in clutter during many consecutive scans, and it leads to track coalescence effects due to persisting interferences. As a result, the tracking performance of JPDAF is degraded. Because the complexity of the calculation for joint association probabilities grows exponentially with the number of targets, JPDAF requires almost 3 times more computational time in comparison to other methods in the first (complex) scenario. In the second (only two crossing targets) MTT scenario, JPDAF shows better tracking performances in comparison to QADA-GNN KF. It is able to track more precisely these only two targets, because of non persisting interferences. Overall, our analysis shows that QADA-PDA KF method is the best of the four approaches to track multiple targets in clutter with a tractable complexity.

**Abstract**—In 2016 we developed a new approach for Multi-Criteria Decision-Making (MCDM) inspired by the technique for order preference by similarity to ideal solution (TOPSIS) and based on belief functions (BF). Our BF-TOPSIS (Belief Function based TOPSIS) approach assumes that the input score of each hypothesis for each criterion was a real precise number which is a quite restrictive assumption. In this paper we extend our BF-TOPSIS to deal with imprecise score values (intervals of real numbers) and we call it Imp-BF-TOPSIS. This new approach follows main ideas of BF-TOPSIS but extends its applicability for more realistic MCDM problems where the scores are given with a finite precision. Imp-BF-TOPSIS is based on Interval Arithmetic (IA), new probabilistic order relations between intervals and belief functions. We also present results of Imp-BF-TOPSIS for simple examples for illustrating its effectiveness.

**Keywords:** Information fusion, multi-criteria decision-making, MCDM, belief functions, TOPSIS.

## I. INTRODUCTION

The Multi-Criteria Decision-Making (MCDM) aims to choose an alternative among a known set of alternatives based on their quantitative or qualitative evaluations (scores) obtained with respect to different criteria. MCDM can be considered as a decision-level information fusion, and it has been widely used in many decision-making applications. In classical MCDM problem, all the criteria and all alternatives are known, and the score values are usually real numbers (precisely known). Depending on the context of the MCDM problem, the score can be interpreted either as a cost/expense or as a reward/benefit. In the sequel, by convention and without loss of generality we will interpret the score as a reward having monotonically increasing preference. Thus, the best alternative with respect to a given criteria will be the one providing the highest reward/benefit. The set of score values is represented by a quantitative benefit or payoff matrix. Each criterion can also have a relative importance weight. Many methods have been proposed in the literature to solve the classical MCDM [1]. When the score values are incomplete or imprecise (quantitative or qualitative), traditional approaches for classical MCDM problems do not work. In this paper, we focus on these unclassical MCDM problems. We propose to extend the BF-TOPSIS approach to deal with imprecise score values to cover a broader spectrum of real MCDM

applications. We use the theory of belief functions and the interval arithmetic. This extension of BF-TOPSIS method is referred as Imp-BF-TOPSIS method in the sequel, where *Imp* is an abbreviation standing for *Imprecise* to specify that the BF-TOPSIS will work with imprecise score values (or more generally with imprecise basic belief assignments (BBAs)). The rest of this paper is organized as follows. In section II, the formulation of classical MCDM problem is provided. In Section III, we introduce Interval Arithmetic and propose new (probabilistic) order relations for intervals as well as distances between intervals. In section IV, basics of belief functions are recalled. In section V we recall the principle of BF-TOPSIS for classical (precise scores) MCDM. The Imp-BF-TOPSIS for imprecise score values is presented in section VI, with simple examples in section VII. Section VIII concludes this paper.

## II. FORMULATION OF CLASSICAL MCDM

A classical MCDM problem has a given set of alternatives  $\mathbf{A} \triangleq \{A_1, A_2, \dots, A_M\}$  ( $M > 2$ ), and a given set of criteria  $\mathbf{C} \triangleq \{C_1, C_2, \dots, C_N\}$  ( $N \geq 1$ ). Each alternative  $A_i$  represents a possible choice (a possible decision to make). In a general context, each criterion is also characterized by a relative importance weighting factor  $w_j \in [0, 1]$ ,  $j = 1, \dots, N$  which are normalized by imposing the condition  $\sum_j w_j = 1$ . The set of normalized weighting factors is denoted by  $\mathbf{w} \triangleq \{w_1, w_2, \dots, w_N\}$ . The score of each alternative  $A_i$  with respect to each criteria  $C_j$  is expressed by a real number  $S_{ij}$  called the score value of  $A_i$  based on  $C_j$ . We denote  $\mathbf{S}$  the score  $M \times N$  matrix which is defined as  $\mathbf{S} \triangleq [S_{ij}]$ . The MCDM problem aims to select the best alternative  $A^* \in \mathbf{A}$  given  $\mathbf{S}$  and the weighting factors  $\mathbf{w}$  of criteria.

## III. CALCULUS WITH INTERVALS

A closed interval  $\mathbf{x}$  is denoted by  $\mathbf{x} = [\underline{x}, \bar{x}] = \{x | \underline{x} \leq x \leq \bar{x}\}$ .  $\underline{x} = \inf(\mathbf{x})$  is the infimum (lower endpoint) of  $\mathbf{x}$  and  $\bar{x} = \sup(\mathbf{x})$  is the supremum (upper endpoint) of  $\mathbf{x}$  taken values in  $\mathbb{R}$ . The set of intervals over  $\mathbb{R}$  is denoted by  $\mathbb{IR}$ . An interval in which one endpoint is included and the other is excluded is called a half-closed interval (or half-open interval) and it is called an open interval if its endpoints are excluded.

Any precise number  $x$  can be expressed with *imprecise number notation* as the degenerate interval  $\mathbf{x} = [x, x]$ . A non-degenerate interval is called a *proper interval*. The numbers  $wid(\mathbf{x}) \triangleq \bar{x} - \underline{x}$ ,  $rad(\mathbf{x}) = wid(\mathbf{x})/2$  and  $mid(\mathbf{x}) \triangleq \frac{1}{2}(\underline{x} + \bar{x})$  are respectively the width, the radius and the midpoint of  $\mathbf{x}$ . If  $\mathbf{x}$  is a precise number (i.e. a degenerate interval), then  $wid(\mathbf{x}) = 0$  and  $\mathbf{x} = [mid(\mathbf{x}), mid(\mathbf{x})]$ . The number  $mag(\mathbf{x}) \triangleq \max\{|x| \mid x \in \mathbf{x}\} = \max\{|\underline{x}|, |\bar{x}|\}$  is the magnitude of  $\mathbf{x}$ , and  $mig(\mathbf{x}) \triangleq \min\{|x| \mid x \in \mathbf{x}\} = \min\{|\underline{x}|, |\bar{x}|\}$  is the mignitude of  $\mathbf{x}$ . If  $\mathbf{x}$  and  $\mathbf{y}$  are overlapped intervals then  $\mathbf{x} \cap \mathbf{y}$  and  $\mathbf{x} \cup \mathbf{y}$  are also intervals defined by  $\mathbf{x} \cap \mathbf{y} = [\max\{\underline{x}, \underline{y}\}, \min\{\bar{x}, \bar{y}\}]$  and  $\mathbf{x} \cup \mathbf{y} = [\min\{\underline{x}, \underline{y}\}, \max\{\bar{x}, \bar{y}\}]$ . If  $\mathbf{x}$  and  $\mathbf{y}$  do not overlap, then  $\mathbf{x} \cap \mathbf{y}$  is empty, and  $\mathbf{x} \cup \mathbf{y}$  is not a proper interval but the union of two disjoint<sup>1</sup> intervals. In this case, the interval  $[\min\{\underline{x}, \underline{y}\}, \max\{\bar{x}, \bar{y}\}]$  is the tightest interval that includes  $\mathbf{x} \cup \mathbf{y}$  and it is called the *interval hull* of  $\mathbf{x}$  and  $\mathbf{y}$ . The interval  $\mathbf{x}$  is a subset of  $\mathbf{y}$  if  $(\underline{y} \leq \underline{x}) \wedge (\bar{x} \leq \bar{y})$ . The interval  $\mathbf{x}$  is equal to  $\mathbf{y}$  if  $(\underline{x} = \underline{y}) \wedge (\bar{x} = \bar{y})$ .

### A. Interval Arithmetic

Interval Arithmetic (IA) is an arithmetic defined on intervals of  $\mathbb{IR}$ . Its modern development started with Moore's works [4]–[7] and yielded recently to an IEEE Standard [8]. The INTLAB Matlab™ toolbox for IA has been developed and proposed by Rump in [9] with a tutorial in [10]. Other tools implementing IA are listed in [7] with more resources available on Kreinovich's interval computation web site [11]. The basic operations<sup>2</sup> on intervals are:

- **Addition:**  $\mathbf{x} + \mathbf{y} = [\underline{x} + \underline{y}, \bar{x} + \bar{y}]$
- **Subtraction:**  $\mathbf{x} - \mathbf{y} = [\underline{x} - \bar{y}, \bar{x} - \underline{y}]$ . In particular,  $-\mathbf{x} = [-\bar{x}, -\underline{x}]$ , because  $-\mathbf{x} = [0, 0] - [\underline{x}, \bar{x}]$ .
- **Multiplication:**  $\mathbf{x} \times \mathbf{y} = [\min\{S_{\times}(\mathbf{x}, \mathbf{y})\}, \max\{S_{\times}(\mathbf{x}, \mathbf{y})\}]$ , where  $S_{\times}(\mathbf{x}, \mathbf{y}) \triangleq \{\underline{x}\underline{y}, \underline{x}\bar{y}, \bar{x}\underline{y}, \bar{x}\bar{y}\}$  is the set of all possible products<sup>3</sup> of endpoints of  $\mathbf{x}$  and  $\mathbf{y}$ . In particular,  $-\mathbf{x} = [-\bar{x}, -\underline{x}]$  because  $-\mathbf{x} = [-1, -1] \times [\underline{x}, \bar{x}] = [\underline{x}, \bar{x}] \times [-1, -1]$ .
- **Division:**  $\mathbf{x}/\mathbf{y} = [\min\{S_{\div}(\mathbf{x}, \mathbf{y})\}, \max\{S_{\div}(\mathbf{x}, \mathbf{y})\}]$ , if  $0 \notin \mathbf{y}$  and where  $S_{\div}(\mathbf{x}, \mathbf{y}) \triangleq \{\underline{x}/\underline{y}, \underline{x}/\bar{y}, \bar{x}/\underline{y}, \bar{x}/\bar{y}\}$  is the set of all possible divisions of endpoints of  $\mathbf{x}$  and  $\mathbf{y}$ . If  $0 \in \mathbf{y}$  then the division by  $\mathbf{y}$  can be handled with more effort using extended interval arithmetic [7], [12] not detailed in this paper.
- **Inverse:** if  $\underline{x} > 0$  or  $\bar{x} < 0$ ,  $\frac{1}{\mathbf{x}} = [1/\bar{x}, 1/\underline{x}]$ .

The following algebraic properties hold for all  $\mathbf{x}, \mathbf{y}, \mathbf{z} \in \mathbb{IR}$ :

- **Associativity:**  $(\mathbf{x} + \mathbf{y}) + \mathbf{z} = \mathbf{x} + (\mathbf{y} + \mathbf{z})$  and  $(\mathbf{x}\mathbf{y})\mathbf{z} = \mathbf{x}(\mathbf{y}\mathbf{z})$ .
- **Commutativity:**  $(\mathbf{x} + \mathbf{y}) = (\mathbf{y} + \mathbf{x})$  and  $(\mathbf{x}\mathbf{y}) = (\mathbf{y}\mathbf{x})$ .
- **Neutral elements:**  $\mathbf{0} + \mathbf{x} = \mathbf{x} + \mathbf{0} = \mathbf{x}$  where  $\mathbf{0} \triangleq [0, 0]$ ,  $\mathbf{0} \cdot \mathbf{x} = \mathbf{x} \cdot \mathbf{0} = \mathbf{0}$  and  $\mathbf{1} \cdot \mathbf{x} = \mathbf{x} \cdot \mathbf{1} = \mathbf{x}$  where  $\mathbf{1} \triangleq [1, 1]$ .

Proper intervals do not have additive or multiplicative inverses and the distributivity law does not hold for intervals. Instead, the following *sub-distributivity law* (weaker version of distributivity) holds:  $\forall \mathbf{x}, \mathbf{y}, \mathbf{z} \in \mathbb{IR}, \mathbf{x}(\mathbf{y} + \mathbf{z}) \subseteq \mathbf{x}\mathbf{y} + \mathbf{x}\mathbf{z}$ .

Although the interval arithmetic is appealing and looks simple for basic operations with intervals, the so-called dependency problem is a major obstacle to its application when

complicate expressions have to be calculated to find tightest range enclosure. In fact, we must take care of dependencies of variables involved in formulas before applying IA in order to get tightest results. To reduce the dependency effect in the result, we need to replace (if possible) the original expression to compute by an equivalent simpler one having less (or none) redundant variables. For example, the derivation of  $\mathbf{x}/[\mathbf{x} + \mathbf{y}]$  for  $0 \notin \mathbf{x}$  must be computed with IA by  $1/[1 + \mathbf{y}/\mathbf{x}]$  to get tightest result. Also, the power 2 of  $\mathbf{x}$  must not be computed by  $[\underline{x}, \bar{x}] \times [\underline{x}, \bar{x}]$  because the unknown precise value of  $x$  in  $[\underline{x}, \bar{x}]$  must be exactly the same (strong dependency) in the multiplication operation in the derivation of  $\mathbf{x}^2$ . Hence,  $\mathbf{x}^2 = \{x^2 \mid -2 \leq x \leq 2\} = [0, 4]$  is different of  $[-2, 2] \times [-2, 2] = [-4, 4]$ .

### B. Basic interval functions

Here several functions that are used in the sequel. More interval functions can be found in [7], [13].

- **Absolute value** [13]:

$$|\mathbf{x}| = \begin{cases} [|\bar{x}|, |\underline{x}|], & \text{if } \bar{x} \leq 0 \\ [|\underline{x}|, |\bar{x}|], & \text{if } \underline{x} \geq 0 \\ [0, \max\{|\underline{x}|, |\bar{x}|\}], & \text{if } \underline{x} < 0 \text{ and } \bar{x} > 0 \end{cases} \quad (1)$$

- **Power** [7]:

- If  $n > 0$  is an odd number:  $\mathbf{x}^n = [\underline{x}^n, \bar{x}^n]$
- If  $n > 0$  is an even number

$$\mathbf{x}^n = \begin{cases} [\underline{x}^n, \bar{x}^n], & \text{if } \underline{x} > 0 \\ [\bar{x}^n, \underline{x}^n], & \text{if } \bar{x} < 0 \\ [0, \max\{\underline{x}^n, \bar{x}^n\}], & \text{if } 0 \in \mathbf{x}. \end{cases}$$

- If  $z > 0$  and  $\underline{x} > 0$ ,  $\mathbf{x}^z = [\underline{x}^z, \bar{x}^z]$ .

- **Square root** [7]:

$$\mathbf{x}^{\frac{1}{2}} = \sqrt{\mathbf{x}} = \begin{cases} [\sqrt{\underline{x}}, \sqrt{\bar{x}}], & \text{for } \underline{x} > 0 \\ [0, \sqrt{\bar{x}}], & \text{if } 0 \in \mathbf{x}. \end{cases}$$

### C. Order relations for intervals

The real numbers are ordered by the relation  $<$  (or  $>$ ) and comparing two real numbers is in general not a difficult task. In the methods developed in this paper, we need to compare imprecise numbers represented by intervals. We interpret an interval to mean "there is a point that lies between the bounds" and the relation between two intervals is a relation between the two points belonging to intervals (i.e. a *possibly* relation). Comparing intervals is not obvious in the general case when the intervals have a non-empty intersection. For this, we propose a method for comparing intervals and we then explain how to find the min (or max) element of a set of intervals. To make comparisons, we assume that the unknown precise value belonging to an imprecise number is uniformly distributed in the interval under concern. This assumption is motivated by the principle of insufficient reason. The comparative test that we propose does not provide a true or false answer (boolean function), but only a probability value that the test is satisfied or not. To implement the comparison between to intervals  $\mathbf{x}$

<sup>1</sup> $\mathbf{x} = [\underline{x}, \bar{x}]$  and  $\mathbf{y} = [\underline{y}, \bar{y}]$  are disjoint if  $(\bar{x} < \underline{y}) \vee (\bar{y} < \underline{x})$ .

<sup>2</sup>For simplicity, we use operations on closed intervals.

<sup>3</sup>The product of  $\mathbf{x}$  and  $\mathbf{y}$  will also be denoted  $\mathbf{x} \cdot \mathbf{y}$ , or  $\mathbf{x}\mathbf{y}$  for simplicity.

and  $\mathbf{y}$  of  $\mathbb{IR}$ , we define  $W \triangleq \text{wid}(\mathbf{x})\text{wid}(\mathbf{y})$  for notation convenience and we need to distinguish all possible situations as follows:

- Case 1:  $\underline{x} < \bar{x} < \underline{y} < \bar{y}$ . In this case,  $\mathbf{x} < \mathbf{y}$  with probability  $P(\mathbf{x} < \mathbf{y}) = 1$ .
- Case 2:  $\underline{y} < \bar{y} < \underline{x} < \bar{x}$ . In this case,  $\mathbf{x} < \mathbf{y}$  with probability  $P(\mathbf{x} < \mathbf{y}) = 0$ .
- Case 3:  $\underline{x} < \underline{y} < \bar{x} < \bar{y}$ . In this case,  $\mathbf{x} < \mathbf{y}$  with

$$P(\mathbf{x} < \mathbf{y}) = \frac{1}{W}[\text{wid}(\mathbf{a})\text{wid}(\mathbf{b}) + \text{wid}(\mathbf{a})\text{wid}(\mathbf{c}) + (\text{wid}(\mathbf{b})^2/2) + \text{wid}(\mathbf{b})\text{wid}(\mathbf{c})] \quad (2)$$

where  $\mathbf{a} \triangleq [\underline{x}, \underline{y}]$ ,  $\mathbf{b} \triangleq [\underline{y}, \bar{x}]$  and  $\mathbf{c} \triangleq [\bar{x}, \bar{y}]$ .

- Case 4:  $\underline{x} < \underline{y} < \bar{y} < \bar{x}$ . In this case,  $\mathbf{x} < \mathbf{y}$  with

$$P(\mathbf{x} < \mathbf{y}) = \frac{1}{W}[\text{wid}(\mathbf{a})\text{wid}(\mathbf{b}) + (\text{wid}(\mathbf{b})^2/2)] \quad (3)$$

where  $\mathbf{a} \triangleq [\underline{x}, \underline{y}]$  and  $\mathbf{b} \triangleq [\underline{y}, \bar{y}]$ .

- Case 5:  $\underline{y} < \underline{x} < \bar{y} < \bar{x}$ . In this case,  $\mathbf{x} < \mathbf{y}$  with

$$P(\mathbf{x} < \mathbf{y}) = \frac{1}{W}(\text{wid}(\mathbf{b})^2/2) \quad (4)$$

where  $\mathbf{b} \triangleq [\underline{x}, \bar{y}]$ .

- Case 6:  $\underline{y} < \underline{x} < \bar{x} < \bar{y}$ . In this case,  $\mathbf{x} < \mathbf{y}$  with

$$P(\mathbf{x} < \mathbf{y}) = \frac{1}{W}[\text{wid}(\mathbf{b})\text{wid}(\mathbf{c}) + (\text{wid}(\mathbf{b})^2/2)] \quad (5)$$

where  $\mathbf{b} \triangleq [\underline{x}, \bar{x}]$  and  $\mathbf{c} \triangleq [\bar{x}, \bar{y}]$ .

Formulae (2)-(5) are obtained by the probability calculus using uniform distributions over intervals and the total probability theorem. For case 3, one has  $P(\mathbf{x} < \mathbf{y}) = P(\mathbf{x} < \mathbf{y}, x \in \mathbf{a}, y \in \mathbf{b}) + P(\mathbf{x} < \mathbf{y}, x \in \mathbf{a}, y \in \mathbf{c}) + P(\mathbf{x} < \mathbf{y}, x \in \mathbf{b}, y \in \mathbf{b}) + P(\mathbf{x} < \mathbf{y}, x \in \mathbf{b}, y \in \mathbf{c})$  with  $P(\mathbf{x} < \mathbf{y}, x \in \mathbf{a}, y \in \mathbf{b}) = 1 \cdot \frac{\text{wid}(\mathbf{a}) \text{wid}(\mathbf{b})}{\text{wid}(\mathbf{x}) \text{wid}(\mathbf{y})}$ ,  $P(\mathbf{x} < \mathbf{y}, x \in \mathbf{a}, y \in \mathbf{c}) = 1 \cdot \frac{\text{wid}(\mathbf{a}) \text{wid}(\mathbf{c})}{\text{wid}(\mathbf{x}) \text{wid}(\mathbf{y})}$ ,  $P(\mathbf{x} < \mathbf{y}, x \in \mathbf{b}, y \in \mathbf{b}) = \frac{1}{2} \cdot \frac{\text{wid}(\mathbf{b}) \text{wid}(\mathbf{b})}{\text{wid}(\mathbf{x}) \text{wid}(\mathbf{y})}$  and  $P(\mathbf{x} < \mathbf{y}, x \in \mathbf{b}, y \in \mathbf{c}) = 1 \cdot \frac{\text{wid}(\mathbf{b}) \text{wid}(\mathbf{c})}{\text{wid}(\mathbf{x}) \text{wid}(\mathbf{y})}$ , which gives formula (2).

The value of  $P(\mathbf{x} > \mathbf{y})$  can be computed by a similar approach. Of course,  $P(\mathbf{x} \geq \mathbf{y}) = 1 - P(\mathbf{x} < \mathbf{y})$  and  $P(\mathbf{x} \leq \mathbf{y}) = 1 - P(\mathbf{x} > \mathbf{y})$ . Also, one has  $P(\mathbf{x} \neq \mathbf{y}) = P(\mathbf{x} < \mathbf{y}) + P(\mathbf{x} > \mathbf{y}) = 1 - P(\mathbf{x} = \mathbf{y})$ .

**Example 1:**  $\mathbf{x} = [-3, 0]$ ,  $\mathbf{y} = [-1, 4]$ , then  $P(\mathbf{x} < \mathbf{y}) = 0.9667$ .

Because we know how to compute the probability  $P(\mathbf{x} < \mathbf{y})$  for any two imprecise numbers  $\mathbf{x}$  and  $\mathbf{y}$ , we are able to find the min (or max) elements of a set of imprecise numbers  $X = \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_M\}$  with a given associated probability. For instance, for finding the min element of  $X$  we proceed as follows:

- Calculate the  $M \times M$  square matrix<sup>4</sup>:

$$\mathbf{P} \triangleq [P_{ij} = P(\mathbf{x}_i < \mathbf{x}_j)] \quad (6)$$

<sup>4</sup>By construction all diagonal elements  $P_{ii}$  equal zero.

- Calculate the likelihood  $\lambda_i \triangleq \lambda(\mathbf{x}_i)$  of  $\mathbf{x}_i$  to be the min of  $X$  as the sum of  $P_{ij}$  for  $j \neq i$ , that is

$$\lambda_i = \sum_{j=1, \dots, M | j \neq i} P(\mathbf{x}_i < \mathbf{x}_j) = \sum_{j \neq i} P_{ij} \quad (7)$$

- The index of the most likely min element of  $X$  is

$$i_{\min} = \arg \max_{i=1, \dots, M} \lambda_i \quad (8)$$

The most likely min element of  $X$  is given by  $\mathbf{x}_{i_{\min}}$  with the probability  $P(\mathbf{x}_{i_{\min}} = \min\{X\}) = \lambda_i / (M - 1)$ .

An approach similar is applied to find the max element of  $X$  using the likelihood  $\lambda_i = \sum_{j \neq i} P(\mathbf{x}_i > \mathbf{x}_j)$  and  $i_{\max} = \arg \max_i \lambda_i$ . The max element of  $X$  will be given by  $\mathbf{x}_{i_{\max}}$  with the associated probability  $P(\mathbf{x}_{i_{\max}} = \max\{X\}) = \lambda_i / (M - 1)$ . Moreover and if needed, we can also sort (probabilistically) all the elements of  $X$  by decreasing (or increasing) order based on the likelihood values  $\lambda_i$ .

**Example 2:** Let's consider the set of intervals  $X = \{\mathbf{x}_1 = [-2, 2], \mathbf{x}_2 = [-3, 0], \mathbf{x}_3 = [0, 5], \mathbf{x}_4 = [-1, 3]\}$ . From formulas of  $P(\mathbf{x} < \mathbf{y})$  given for aforementioned cases 1–6, one obtains

$$\mathbf{P} \triangleq [P(\mathbf{x}_i < \mathbf{x}_j)] = \begin{bmatrix} 0 & 0.1667 & 0.9000 & 0.7188 \\ 0.8333 & 0 & 1.0000 & 0.9583 \\ 0.1000 & 0 & 0 & 0.2250 \\ 0.2812 & 0.0417 & 0.7750 & 0 \end{bmatrix}$$

with the likelihood values

$$\begin{bmatrix} \lambda_1 = \lambda(\mathbf{x}_1) \\ \lambda_2 = \lambda(\mathbf{x}_2) \\ \lambda_3 = \lambda(\mathbf{x}_3) \\ \lambda_4 = \lambda(\mathbf{x}_4) \end{bmatrix} = \begin{bmatrix} 1.7854 \\ 2.7917 \\ 0.3250 \\ 1.0979 \end{bmatrix}$$

The maximum likelihood is  $\lambda_2 = 2.7917$  and the corresponding index is  $i_{\min} = 2$ . This means that  $\mathbf{x}_2 = [-3, 0]$  is most likely the min element of  $X$  with the probability  $P(\mathbf{x}_2 = \min\{X\}) = 2.7917/3 = 0.9306$ . Using a similar approach, one will find that the max of  $X$  is  $\mathbf{x}_3 = [0, 5]$  with the probability  $P(\mathbf{x}_3 = \max\{X\}) = 2.6750/3 = 0.8917$ . Based on the likelihood values of the min element of  $X$  sorted in decreasing order, we obtain  $\mathbf{x}_2 < \mathbf{x}_1 < \mathbf{x}_4 < \mathbf{x}_3$ , which corresponds to what we intuitively expect in such example.

#### D. Distances between intervals

There are many ways to define strict distance metrics between two intervals. The simplest one is the Hausdorff distance between two intervals  $\mathbf{x}$  and  $\mathbf{y}$  of  $\mathbb{IR}$  which is the maximum distance  $d(x, y)$  of  $x \in \mathbf{x}$  to its nearest point  $y \in \mathbf{y}$ , where  $d(x, y)$  is any chosen metric [14], more precisely  $d_H(\mathbf{x}, \mathbf{y}) = \max_{x \in \mathbf{x}} \{\min_{y \in \mathbf{y}} d(x, y)\}$ . For simplicity, if we choose the  $L_1$  distance metric  $d_{L_1}(x, y) \triangleq |x - y|$ , then Hausdorff's distance is given by

$$d_H(\mathbf{x}, \mathbf{y}) = \max\{|\underline{x} - \underline{y}|, |\bar{x} - \bar{y}|\} = |\text{mid}(\mathbf{x}) - \text{mid}(\mathbf{y})| + |\text{rad}(\mathbf{x}) - \text{rad}(\mathbf{y})| \quad (9)$$

Another interesting distance successfully used for decision-making under uncertainty in the belief functions framework

[1], [15], [16], is Wassertein's distance metric [17], [18]  $d_W(\mathbf{x}, \mathbf{y})$  defined as

$$d_W(\mathbf{x}, \mathbf{y}) \triangleq \sqrt{[\text{mid}(\mathbf{x}) - \text{mid}(\mathbf{y})]^2 + \frac{1}{3}[\text{rad}(\mathbf{x}) - \text{rad}(\mathbf{y})]^2} \quad (10)$$

which corresponds to Mallows' distance [19] between two probability distributions when we assume that each interval is the support of a uniform distribution.

**Example 3:** If  $\mathbf{x} = [-3, 0]$  and  $\mathbf{y} = [-1, 4]$ , then  $d_H(\mathbf{x}, \mathbf{y}) = 4$  whereas  $d_W(\mathbf{x}, \mathbf{y}) \approx 3.0551$ .

#### IV. BASICS OF BELIEF FUNCTIONS

Belief functions have been introduced by Shafer in [20] to model epistemic uncertainty. We assume that the answer<sup>5</sup> of the problem under concern belongs to a known (or given) finite discrete frame of discernment (FoD)  $\Theta = \{\theta_1, \theta_2, \dots, \theta_n\}$ , with  $n > 1$ , and where all elements of  $\Theta$  are exclusive<sup>6</sup>. The set of all subsets of  $\Theta$  (including empty set  $\emptyset$  and  $\Theta$ ) is the power-set of  $\Theta$  denoted by  $2^\Theta$ . A basic belief assignment (BBA) associated with a given source of evidence is defined [20] as the mapping  $m(\cdot) : 2^\Theta \rightarrow [0, 1]$  satisfying  $m(\emptyset) = 0$  and  $\sum_{A \in 2^\Theta} m(A) = 1$ . The quantity  $m(A)$  is called the mass of  $A$  committed by the source of evidence. Belief and plausibility functions are respectively defined by

$$\text{Bel}(A) = \sum_{\substack{B \subseteq A \\ B \in 2^\Theta}} m(B), \quad \text{and} \quad \text{Pl}(A) = 1 - \text{Bel}(\bar{A}). \quad (11)$$

If  $m(A) > 0$ ,  $A$  is called a focal element of  $m(\cdot)$ . When all focal elements are singletons then  $m(\cdot)$  is called a *Bayesian BBA* [20] and its corresponding  $\text{Bel}(\cdot)$  function is homogeneous to a (subjective) probability measure. The vacuous BBA, or VBBA for short, representing a totally ignorant source is defined as<sup>7</sup>  $m_v(\Theta) = 1$ .

Shafer [20] proposed to combine  $s \geq 2$  distinct sources of evidence represented by BBAs  $m_1(\cdot), \dots, m_s(\cdot)$  over the same FoD with Dempster's rule (i.e. the normalized conjunctive rule). The justification and behavior of Dempster's rule have been disputed over the years from many counter-examples involving high or low conflicting sources (from both theoretical and practical standpoints) as reported in [22]–[25]. Many rules of combination exist<sup>8</sup>, and we recommend the new interesting rules based on the proportional conflict redistribution (PCR) principle, see [21], Vol. 3 for details.

A true distance metric between two BBAs  $m_1(\cdot)$  and  $m_2(\cdot)$  defined on the same FoD, has been defined in [15] as follows<sup>9</sup>

$$d_{BI}(m_1, m_2) \triangleq \sqrt{N_c \cdot \sum_{X \in 2^\Theta} d_W^2(BI_1(X), BI_2(X))} \quad (12)$$

<sup>5</sup>i.e. the solution, or the decision to take.

<sup>6</sup>This is so-called Shafer's model of FoD [21].

<sup>7</sup>The complete ignorance is denoted  $\Theta$  in Shafer's book [20].

<sup>8</sup>see [21], Vol. 2 for a detailed list of fusion rules.

<sup>9</sup>Another well-known real distance metric  $d_J(m_1, m_2)$  had been proposed before by Josselme et al. in [26] which could also be used but we prefer to work with  $d_{BI}(m_1, m_2)$  distance for reasons explained in [27].

where the *Belief-Intervals* are defined by  $BI_1(X) \triangleq [\text{Bel}_1(X), \text{Pl}_1(X)]$  and  $BI_2(X) \triangleq [\text{Bel}_2(X), \text{Pl}_2(X)]$ , and where  $d_W(BI_1(X), BI_2(X))$  is Wassertein's distance between intervals calculated by (10).  $N_c = 1/2^{|\Theta|-1}$  is a normalization factor to get  $d_{BI}(m_1, m_2) \in [0, 1]$ .

Making decision on an element of FoD from a given BF ( $\text{Bel}(\cdot)$ ,  $\text{Pl}(\cdot)$ , or  $m(\cdot)$ ) can be done in many manners. For instance,

- in taking the argument of max of  $\{\text{Bel}(\theta_i), i = 1, \dots, n\}$ . This is a pessimistic decisional attitude.
- in taking the argument of max of  $\{\text{Pl}(\theta_i), i = 1, \dots, n\}$ . This is an optimistic decisional attitude.
- in approximating the BBA  $m(\cdot)$  by a subjective probability measure  $P(\cdot)$  and taking the argument of max of  $\{P(\theta_i), i = 1, \dots, n\}$ . This is a compromise decisional attitude.
- in taking the argument of min of  $\{d_{BI}(m(\cdot), m_{\theta_i}), i = 1, \dots, n\}$ , where  $m_{\theta_i}$  is the BBA entirely focused on  $\theta_i$  defined by  $m_{\theta_i}(X) = 1$ , if  $X = \theta_i$  and  $m_{\theta_i}(X) = 0$ , if  $X \neq \theta_i$ .

In the sequel, we will use the latter method which has been proved very effective in [16], [27].

#### V. BF-TOPSIS WITH PRECISE SCORES

Four BF-TOPSIS methods have been proposed in [1] with an increasing complexity and robustness to rank reversal phenomenon for MDCM support. In this section we briefly recall the main ideas of BF-TOPSIS. For further mathematical details, please refer to [1]. All these methods start with constructing BBAs from the precise score values of the score matrix  $\mathbf{S}$  as briefly explained. Only the way those BBAs are processed differs from one BF-TOPSIS method to another one.

##### A. From precise scores to precise BBAs

In [1], one has proved that BBAs can be consistently built from the precise score matrix  $\mathbf{S}$  as follows:

$$\text{Bel}_{ij}(A_i) \triangleq \begin{cases} \frac{\text{Sup}_j(A_i)}{A_{\max}^j} & \text{if } A_{\max}^j \neq 0 \\ 0 & \text{if } A_{\max}^j = 0 \end{cases} \quad (13)$$

$$\text{Bel}_{ij}(\bar{A}_i) \triangleq \begin{cases} \frac{\text{Inf}_j(A_i)}{A_{\min}^j} & \text{if } A_{\min}^j \neq 0 \\ 0 & \text{if } A_{\min}^j = 0 \end{cases} \quad (14)$$

where  $\bar{A}_i$  is the complement of  $A_i$  in the FoD  $\Theta \triangleq \{A_1, A_2, \dots, A_M\}$  ( $M > 2$ ), and

$$\text{Sup}_j(A_i) \triangleq \sum_{k \in \{1, \dots, M\} | S_{kj} \leq S_{ij}} |S_{ij} - S_{kj}| \quad (15)$$

$$\text{Inf}_j(A_i) \triangleq - \sum_{k \in \{1, \dots, M\} | S_{kj} \geq S_{ij}} |S_{ij} - S_{kj}| \quad (16)$$

The denominators involved in Eqs. (13)–(14), are defined by  $A_{\max}^j \triangleq \max_i \text{Sup}_j(A_i)$  and  $A_{\min}^j \triangleq \min_i \text{Inf}_j(A_i)$ , and they are supposed different from zero<sup>10</sup>. Therefore, the belief

<sup>10</sup>If  $A_{\max}^j = 0$  then  $\text{Bel}_{ij}(A_i) = 0$ , and if  $A_{\min}^j = 0$  then  $\text{Pl}_{ij}(A_i) = 1$ , so that  $\text{Bel}_{ij}(\bar{A}_i) = 0$ .

interval of choosing hypothesis  $A_i$  considering criterion  $C_j$  is given by:

$$[Bel_{ij}(A_i); Pl_{ij}(A_i)] \triangleq \left[ \frac{Sup_j(A_i)}{A_{\max}^j}, 1 - \frac{Inf_j(A_i)}{A_{\min}^j} \right] \quad (17)$$

From this belief interval, we deduce the BBA  $m_{ij}(\cdot)$  which is the triplet  $(m_{ij}(A_i), m_{ij}(\bar{A}_i), m_{ij}(A_i \cup \bar{A}_i))$  defined by:

$$m_{ij}(A_i) \triangleq Bel_{ij}(A_i) \quad (18)$$

$$m_{ij}(\bar{A}_i) \triangleq Bel_{ij}(\bar{A}_i) = 1 - Pl_{ij}(A_i) \quad (19)$$

$$m_{ij}(A_i \cup \bar{A}_i) \triangleq m_{ij}(\Theta) = Pl_{ij}(A_i) - Bel_{ij}(A_i) \quad (20)$$

If a numerical value  $S_{ij}$  is missing in  $\mathbf{S}$ , one uses  $m_{ij}(\cdot) \triangleq (0, 0, 1)$ , i.e. one takes the vacuous belief assignment.

Using the formulae (13)–(20), we obtain from any  $M \times N$  precise score matrix<sup>11</sup>  $\mathbf{S}$  the general  $M \times N$  matrix  $\mathbf{M} \triangleq [m_{ij}(\cdot)]$  of BBAs that are involved in BF-TOPSIS methods. This construction of BBAs is very interesting for applications because it is invariant to the bias and scaling effects of score values [1]. Also, it allows us to model our lack of evidence (if any) with respect to an (or several) alternative(s) when their corresponding score values are missing for any reason.

### B. BF-TOPSIS1 method

From the BBA matrix  $\mathbf{M}$  and for each alternative  $A_i$ , one computes distances  $d_{BI}(m_{ij}, m_{ij}^{\text{best}})$  between  $m_{ij}(\cdot)$  and the ideal best BBA defined by  $m_{ij}^{\text{best}}(A_i) \triangleq 1$ , and the distances  $d_{BI}(m_{ij}, m_{ij}^{\text{worst}})$  between  $m_{ij}(\cdot)$  and the ideal worst BBA defined by  $m_{ij}^{\text{worst}}(\bar{A}_i) \triangleq 1$ . Then, one computes the weighted average distances with relative importance weighting factor  $w_j$  of criteria  $C_j$  as follows:

$$d^{\text{best}}(A_i) \triangleq \sum_{j=1}^N w_j \cdot d_{BI}(m_{ij}, m_{ij}^{\text{best}}) \quad (21)$$

$$d^{\text{worst}}(A_i) \triangleq \sum_{j=1}^N w_j \cdot d_{BI}(m_{ij}, m_{ij}^{\text{worst}}) \quad (22)$$

The relative closeness of the alternative  $A_i$  with respect to the ideal best solution  $A^{\text{best}}$  defined by

$$C(A_i, A^{\text{best}}) \triangleq \frac{d^{\text{worst}}(A_i)}{d^{\text{worst}}(A_i) + d^{\text{best}}(A_i)} \quad (23)$$

is used to make the preference ordering according to the descending order of  $C(A_i, A^{\text{best}}) \in [0, 1]$ , where a larger  $C(A_i, A^{\text{best}})$  value means a better alternative (higher preference).

<sup>11</sup>Note that each element  $m_{ij}(\cdot)$  is in fact a 3-uple of masses given by (18)–(20).

### C. BF-TOPSIS2 method

For each criteria  $C_j$ , one computes at first the relative closeness of each alternative  $A_i$  w.r.t. its ideal best solution  $A^{\text{best}}$  by

$$C_j(A_i, A^{\text{best}}) \triangleq \frac{d_{BI}(m_{ij}, m_{ij}^{\text{worst}})}{d_{BI}(m_{ij}, m_{ij}^{\text{worst}}) + d_{BI}(m_{ij}, m_{ij}^{\text{best}})} \quad (24)$$

The global relative closeness  $C(A_i, A^{\text{best}})$  of each alternative  $A_i$  with respect to its ideal best solution  $A^{\text{best}}$  used to make the final preference ordering is then obtained by the weighted average of  $C_j(A_i, A^{\text{best}})$ , that is

$$C(A_i, A^{\text{best}}) \triangleq \sum_{j=1}^N w_j \cdot C_j(A_i, A^{\text{best}}) \quad (25)$$

### D. BF-TOPSIS3 method

For each alternative  $A_i$ , one fuses the  $N$  precise BBAs  $m_{ij}(\cdot)$  discounted with importance factor  $w_j$  (see [28]) with PCR6 rule of combination [21] (Vol. 3) to get the precise fused BBA  $m_i^{\text{PCR6}}$ , from which one computes the distance  $d^{\text{best}}(A_i) = d_{BI}(m_i^{\text{PCR6}}, m_i^{\text{best}})$  between  $m_i^{\text{PCR6}}(\cdot)$  and its ideal best BBA  $m_i^{\text{best}}(A_i) \triangleq 1$ . Similarly, one computes the distance  $d^{\text{worst}}(A_i) = d_{BI}(m_i^{\text{PCR6}}, m_i^{\text{worst}})$  between  $m_i^{\text{PCR6}}(\cdot)$  and  $m_i^{\text{worst}}(\bar{A}_i) \triangleq 1$ . The relative closeness of each  $A_i$  with respect to ideal best solution  $C(A_i, A^{\text{best}})$  is computed by (23), and is used to make the preference ordering according to the descending order of  $C(A_i, A^{\text{best}})$ .

### E. BF-TOPSIS4 method

This method is similar to BF-TOPSIS3 except that we use the more complicate ZPCR6 fusion rule taking into account Zhang's degree of intersection of focal elements in the conjunctive consensus operator, see [29] for details.

## VI. BF-TOPSIS WITH IMPRECISE SCORES

In this section we present the extension of BF-TOPSIS methods to deal with imprecise score values  $S_{ij} = [\underline{S}_{ij}, \bar{S}_{ij}]$ ,  $i = 1, \dots, M$  and  $j = 1, \dots, N$ . These extensions will be referred as Imp-BF-TOPSIS in the sequel. The basic idea is to follow principles of BF-TOPSIS using Interval Arithmetic (IA) instead of classical arithmetic on reals.

### A. From imprecise scores to imprecise BBAs

The application of formulae (13)–(20) using IA operations does not work directly because of potential division by intervals including zero, and because of comparison tests involving boolean  $\leq$  and  $\geq$  functions. To circumvent these problems, we need to avoid intervals including zero, and replace boolean  $\leq$  and  $\geq$  functions by their probabilistic counterpart presented in section III-C. This is done as follows:

- Step 1 (Offset correction): To work only with positive intervals, we apply at first an offset correction of imprecise score values  $S_{ij} = [\underline{S}_{ij}, \bar{S}_{ij}]$  for each column  $j$  of imprecise score matrix  $\mathbf{S} = [S_{ij}]$ . This is a preprocessing step. We are allowed to do this because, by construction, the BBAs based on formulae (13)–(20) are invariant to

bias and scaling effects [1]. Therefore, we can always replace the original imprecise score  $[\underline{S}_{ij}, \bar{S}_{ij}]$  by

$$[\underline{S}'_{ij}, \bar{S}'_{ij}] = [\underline{S}_{ij}, \bar{S}_{ij}] + [\delta_j + \epsilon, \delta_j + \epsilon] \quad (26)$$

where  $\epsilon > 0$  is an arbitrary positive number to ensure the strict positivity of intervals, and the offset correction value  $\delta_j$  is given for  $j = 1, \dots, N$  by

$$\delta_j = - \min_{i=1, \dots, M} \{ \underline{S}_{ij} \} \quad (27)$$

**Example 4:** Let's consider the FoD  $\Theta \triangleq \{A_1, A_2, A_3, A_4\}$  with four alternatives, a criterion  $C_1$  and the following associated imprecise scores  $S_{11} = [-2, 2]$ ,  $S_{21} = [-3, 0]$ ,  $S_{31} = [0, 5]$  and  $S_{41} = [-1, 3]$ . The offset correction is then  $\delta_1 = -\min\{-2, -3, 0, -1\} = 3$ . If we take,  $\epsilon = 1$  then we will get the corrected (positive) imprecise scores

$$S'_{11} = [-2, 2] + [3 + 1, 3 + 1] = [2, 6]$$

$$S'_{21} = [-3, 0] + [3 + 1, 3 + 1] = [1, 4]$$

$$S'_{31} = [0, 5] + [3 + 1, 3 + 1] = [4, 9]$$

$$S'_{41} = [-1, 3] + [3 + 1, 3 + 1] = [3, 7]$$

- Step 2: Replace the  $S_{kj} \leq S_{ij}$  and  $S_{kj} \geq S_{ij}$  tests involved in (15) and (16), by their probabilistic counterparts  $P(S_{kj} \leq S_{ij}) \geq 0.5$  and  $P(S_{kj} \geq S_{ij}) \geq 0.5$  because  $S_{kj}$  and  $S_{ij}$  are imprecise numbers (i.e. intervals), where  $P(S_{kj} \leq S_{ij})$  and  $P(S_{kj} \geq S_{ij})$  are computed as in section III-C.

In the sequel, we assume that the offset correction of score as been applied (step 1 done) and for notation simplicity we denote these (corrected) strictly positive imprecise scores  $S_{ij}$ . The imprecise BBAs can now be computed from the (offset-corrected) imprecise scores values as follows<sup>12</sup>:

$$[\underline{Bel}_{ij}(A_i), \overline{Bel}_{ij}(A_i)] \triangleq \begin{cases} \frac{Sup_j(A_i)}{A_{\max}^j} & \text{if } A_{\max}^j \neq [0, 0] \\ [0, 0] & \text{if } A_{\max}^j = [0, 0] \end{cases} \quad (28)$$

$$[\underline{Bel}_{ij}(\bar{A}_i), \overline{Bel}_{ij}(\bar{A}_i)] \triangleq \begin{cases} \frac{Inf_j(A_i)}{A_{\min}^j} & \text{if } A_{\min}^j \neq [0, 0] \\ [0, 0] & \text{if } A_{\min}^j = [0, 0] \end{cases} \quad (29)$$

where

$$\begin{aligned} Sup_j(A_i) &= [\underline{Sup}_j(A_i), \overline{Sup}_j(A_i)] \\ &\triangleq \sum_{k \in \{1, \dots, M\} | P(S_{kj} \leq S_{ij}) \geq 0.5} |S_{ij} - S_{kj}| \end{aligned} \quad (30)$$

$$\begin{aligned} Inf_j(A_i) &= [\underline{Inf}_j(A_i), \overline{Inf}_j(A_i)] \\ &\triangleq - \sum_{k \in \{1, \dots, M\} | P(S_{kj} \geq S_{ij}) \geq 0.5} |S_{ij} - S_{kj}| \end{aligned} \quad (31)$$

The denominators involved in Eqs. (28)-(29), are defined by  $A_{\max}^j = [\underline{A}_{\max}^j, \bar{A}_{\max}^j] \triangleq \max_i Sup_j(A_i)$  and  $A_{\min}^j =$

$[\underline{A}_{\min}^j, \bar{A}_{\min}^j] \triangleq \min_i Inf_j(A_i)$ , and they are supposed different from  $[0, 0]$ <sup>13</sup>. Therefore, in non-degenerate case (when  $A_{\max}^j \neq [0, 0]$  and  $A_{\min}^j \neq [0, 0]$ ) the belief interval of hypothesis  $A_i$  considering criterion  $C_j$  has now imprecise bounds given by

$$Bel_{ij}(A_i) = [\underline{Bel}_{ij}(A_i), \overline{Bel}_{ij}(A_i)] = \frac{Sup_j(A_i)}{A_{\max}^j} \quad (32)$$

$$Pl_{ij}(A_i) = [\underline{Pl}_{ij}(A_i), \overline{Pl}_{ij}(A_i)] = [1, 1] - \frac{Inf_j(A_i)}{A_{\min}^j} \quad (33)$$

From these imprecise bounds, we calculate the imprecise BBAs  $m_{ij}(\cdot) = [\underline{m}_{ij}(\cdot), \bar{m}_{ij}(\cdot)]$  which is the triplet of intervals ( $m_{ij}(A_i) = [\underline{m}_{ij}(A_i), \bar{m}_{ij}(A_i)]$ ,  $m_{ij}(\bar{A}_i) = [\underline{m}_{ij}(\bar{A}_i), \bar{m}_{ij}(\bar{A}_i)]$ ,  $m_{ij}(A_i \cup \bar{A}_i) = [\underline{m}_{ij}(A_i \cup \bar{A}_i), \bar{m}_{ij}(A_i \cup \bar{A}_i)]$ ) defined by:

$$m_{ij}(A_i) \triangleq Bel_{ij}(A_i) \quad (34)$$

$$m_{ij}(\bar{A}_i) \triangleq Bel_{ij}(\bar{A}_i) = [1, 1] - Pl_{ij}(A_i) \quad (35)$$

$$m_{ij}(A_i \cup \bar{A}_i) \triangleq m_{ij}(\Theta) = Pl_{ij}(A_i) - Bel_{ij}(A_i) \quad (36)$$

If a numerical (imprecise) value  $S_{ij}$  is missing in  $\mathbf{S}$ , one uses  $m_{ij}(\cdot) \triangleq ([0, 0], [0, 0], [1, 1])$ , i.e. one takes the vacuous belief assignment expressed in its degenerate interval form.

Using the formulae (28)-(36), we obtain from any  $M \times N$  imprecise score matrix  $\mathbf{S}$  the general  $M \times N$  matrix  $\mathbf{M} \triangleq [m_{ij}(\cdot) = [\underline{m}_{ij}(\cdot), \bar{m}_{ij}(\cdot)]]$  of imprecise BBAs that are necessary in Imp-BF-TOPSIS methods.

It is worth to note that formulae (28)–(36) are fully consistent with (13)–(20) when all the elements  $S_{ij}$  of imprecise score matrix are degenerate (are precise numbers), that is when  $\underline{S}_{ij} = \bar{S}_{ij}$ . By choosing the midpoints of imprecise score values, we can always build a precise BBA that satisfies Shafer's BBA definition [1]. This midpoint-based BBA is always included in imprecise BBA bounds because of IA. Therefore, imprecise BBAs are always admissible and they can be combined by Dempster's or PCR6 rules thanks to IA operations. This has to be implemented with caution to avoid dependency effect [7].

### B. Imp-BF-TOPSIS1 and Imp-BF-TOPSIS2 methods

These methods are similar to BF-TOPSIS1 and BF-TOPSIS2 except that we use IA operations. The distances  $d_{BI}(m_{ij}, m_{ij}^{\text{best}})$  and  $d_{BI}(m_{ij}, m_{ij}^{\text{worst}})$  become imprecise numbers computed with formula (12) adapted for interval calculus, where  $m_{ij}^{\text{best}}(A_i) \triangleq [1, 1]$  and  $m_{ij}^{\text{worst}}(\bar{A}_i) \triangleq [1, 1]$ . Of course, all scalars involved in the formulae (12), (21), (22), and (25) must be expressed in their degenerate interval form in order to apply IA operations, for instance  $N_c$  is replaced by  $[N_c, N_c]$ ,  $w_j$  by  $[w_j, w_j]$ , etc. The final preference ordering is found according to the descending order of imprecise  $C(A_i, A^{\text{best}})$  obtained by the method explained at the end of section II-C, where a larger  $C(A_i, A^{\text{best}})$  means a better alternative (higher preference).

<sup>12</sup>Remember that operations involved in the formulas of this section are IA operations defined in section III.

<sup>13</sup>If  $A_{\max}^j = [0, 0]$  then  $Bel_{ij}(A_i) = [0, 0]$ , and if  $A_{\min}^j = [0, 0]$  then  $Pl_{ij}(A_i) = [1, 1]$ , so that  $Bel_{ij}(\bar{A}_i) = [0, 0]$ .

C. Imp-BF-TOPSIS3 and Imp-BF-TOPSIS4 methods

These methods are similar to BF-TOPSIS3 and BF-TOPSIS4<sup>14</sup> but with special adaptation of PCR6 and ZPCR6 formulae to reduce dependency effects with IA operations. For example, the expression  $\frac{m_1^2(X)m_2(X)}{m_1(X)+m_2(Y)}$  involved in PCR6 formula [21] (Vol. 3) for the fusion of two BBAs must be computed as  $[\frac{1}{m_1(X)m_2(Y)} + \frac{1}{m_1^2(X)}]^{-1}$  with IA to get the tightest range enclosure. The implementation of conjunctive rule must also be done with precaution when using IA to reduce the dependency effect in the derivation.

VII. EXAMPLES

A. Example 5 (mono-criterion)

• **Precise scores case** [1]: Let's consider a criterion  $C_1$  and seven alternatives  $A_i$ , ( $i = 1, \dots, 7$ ) with the precise score values  $S_{11} = 10$ ,  $S_{21} = 20$ ,  $S_{31} = -5$ ,  $S_{41} = 0$ ,  $S_{51} = 100$ ,  $S_{61} = -11$ , and  $S_{71} = 0$ . The direct ranking with the preference "greater is better" yields<sup>15</sup>  $A_5 \succ A_2 \succ A_1 \succ (A_4 \sim A_7) \succ A_3 \succ A_6$ . In applying formulas (13)–(20), we get the BBAs listed in Table I. Using BF-TOPSIS methods<sup>16</sup>, we get the distances, and the relative closeness measures of Table II. In sorting  $C(A_i, A^{best})$  by the descending order, we get the correct preferences order  $A_5 \succ A_2 \succ A_1 \succ (A_4 \sim A_7) \succ A_3 \succ A_6$  which is consistent with the direct ranking result.

Table I  
BBAS CONSTRUCTED FROM PRECISE SCORE VALUES.

	$m_{ij}(A_i)$	$m_{ij}(\bar{A}_i)$	$m_{ij}(A_i \cup \bar{A}_i)$
$A_1$	0.0955	0.5236	0.3809
$A_2$	0.1809	0.4188	0.4003
$A_3$	0.0102	0.8115	0.1783
$A_4$	0.0273	0.6806	0.2921
$A_5$	1.0000	0	0
$A_6$	0	1.0000	0
$A_7$	0.0273	0.6806	0.2921

Table II  
DISTANCES AND RELATIVE CLOSENESS MEASURES.

	$d_{BI}(m_{ij}, m_{ij}^{best})$	$d_{BI}(m_{ij}, m_{ij}^{worst})$	$C(A_i, A^{best})$
$A_1$	0.7380	0.0940	0.1130
$A_2$	0.6676	0.1615	0.1948
$A_3$	0.8112	0.0214	0.0257
$A_4$	0.7954	0.0405	0.0485
$A_5$	0	0.8229	1.0000
$A_6$	0.8229	0	0
$A_7$	0.7954	0.0405	0.0485

• **Imprecise scores case:** For simplicity, consider now the imprecise score values with midpoints consistent with previous example. For instance suppose  $S_{11} = [8, 12]$ ,  $S_{21} = [18, 22]$ ,  $S_{31} = [-7, -3]$ ,  $S_{41} = [-1, 1]$ ,  $S_{51} = [97, 103]$ ,  $S_{61} =$

$[-12, -10]$ , and  $S_{71} = [-1, 1]$ . The offset factor is equal to  $\delta_1 = 12$ . After offset corrections with  $\epsilon = 1$ , we get the corrected positive imprecise scores  $S_{11} = [21, 25]$ ,  $S_{21} = [31, 35]$ ,  $S_{31} = [6, 10]$ ,  $S_{41} = [12, 14]$ ,  $S_{51} = [110, 116]$ ,  $S_{61} = [1, 3]$ , and  $S_{71} = [12, 14]$ . In applying formulas (28)–(36), we get the imprecise BBAs listed in Table III.

Table III  
IMPRECISE BBAS CONSTRUCTED FROM IMPRECISE SCORE VALUES.

	$m_{ij}(A_i)$	$m_{ij}(\bar{A}_i)$	$m_{ij}(A_i \cup \bar{A}_i)$
$A_1$	[0.0701,0.1234]	[0.4375,0.6264]	[0.2501,0.4924]
$A_2$	[0.1452,0.2200]	[0.3606,0.4885]	[0.2915,0.4942]

$A_5$	[0.9119,1.0000]	[0,0]	[0,0.0881]
$A_6$	[0,0]	[0.8365,1.0000]	[0,0.1635]
$A_7$	[0.0179,0.0376]	[0.5769,0.8046]	[0.1578,0.4051]

As we see all imprecise BBAs values of Table III include precise BBAs values of Table I. Note that all negative bounds encountered in derivations (if any) are set to zero, and all bounds greater than one in derivations (if any) are set to one because masses values must belong to  $[0, 1]$ . Each imprecise BBA represented by a row of Table III is said *admissible* because for a given hypothesis  $A_i$  one can find at least a point (a precise mass value) in each interval  $m_{ij}(A_i)$ ,  $m_{ij}(\bar{A}_i)$  and  $m_{ij}(A_i \cup \bar{A}_i)$  such that the sum of the masses equals one. If all imprecisions of scores reduce to zero, the results of Table III will coincide with results of Table I. Using Imp-BF-TOPSIS methods, we get the imprecise distances, and the imprecise relative closeness measures listed in Table IV.

Table IV  
IMPRECISE DISTANCES AND RELATIVE CLOSENESS MEASURES.

	$d_{BI}(m_{ij}, m_{ij}^{best})$	$d_{BI}(m_{ij}, m_{ij}^{worst})$	$C(A_i, A^{best})$
$A_1$	[0.5421,0.9338]	[0.0301,0.2864]	[0.0312,0.3457]
$A_2$	[0.5034,0.8313]	[0.0511,0.3253]	[0.0579,0.3926]
$A_3$	[0.5324,1.0000]	[0.0006,0.2977]	[0.0006,0.3586]
$A_4$	[0.5960,0.9956]	[0.0131,0.2317]	[0.0130,0.2800]
$A_5$	[0,0.1135]	[0.7176,0.8591]	[0.8634,1.0000]
$A_6$	[0.6900,0.9533]	[0,0.1360]	[0,0.1647]
$A_7$	[0.5960,0.9956]	[0.0131,0.2317]	[0.0130,0.2800]

For each element of  $\mathcal{C} = \{C(A_i, A^{best}), i = 1, \dots, M\}$ , we compute its likelihood  $\lambda_i \triangleq \lambda(C(A_i, A^{best}))$  to be the max of  $\mathcal{C}$  by the method explained in section III-C. Here, one gets

$$[\lambda_1, \lambda_2, \lambda_3, \lambda_4, \lambda_5, \lambda_6, \lambda_7] \approx [3.00, 3.57, 2.80, 2.29, 6.00, 1.02, 2.29]$$

In sorting  $\lambda_i$  by the descending order, we get  $A_5 \succ A_2 \succ A_1 \succ A_3 \succ A_6 \succ (A_4 \sim A_7)$ . This result is of course a bit different of what we obtain with precise midpoints of scores because of imprecision degree in the input scores, which is normal. However when the imprecision degree (i.e. the width of each score interval) of the input scores reduces to zero, we always obtain the same result as with (precise) midpoint of

<sup>14</sup>See their mathematical derivations in [1].

<sup>15</sup>where the symbol  $\succ$  means *better than* (or *is preferred to*).

<sup>16</sup>in mono-criterion case, all BF-TOPSIS methods are equivalent because there is no need of making fusion.

score intervals because of the consistency of interval arithmetic operators with arithmetic on real numbers.

### B. Example 6 (Multi-criteria)

An investor wants to invest some money in a company to get the highest profit. He considers four companies  $\mathcal{A} = \{A_1, A_2, A_3, A_4\}$  and must take a decision according to the following two criteria:  $C_1$  is the risk analysis (the min is better) with weight  $w_1 = 0.6$  and  $C_2$  is the growth analysis (the max is better) with  $w_2 = 0.4$ . Assume the imprecise scores are

$$S = \begin{array}{c} C_1(\text{in } \%) \quad C_2(\text{in } \%) \\ \begin{array}{c} A_1 \\ A_2 \\ A_3 \\ A_4 \end{array} \left[ \begin{array}{cc} [8, 12] & [8, 10] \\ [17, 19] & [15, 19] \\ [3, 5] & [8, 12] \\ [4, 8] & [5, 7] \end{array} \right] \end{array}$$

We get the final preference orderings with:

- Imp-BF-TOPSIS1: we get  $A_3 \succ A_4 \succ A_1 \succ A_2$  because  $[\lambda_1, \lambda_2, \lambda_3, \lambda_4] \approx [1.4939, 1.0013, 1.9396, 1.5652]$
- Imp-BF-TOPSIS2: we get  $A_3 \succ A_4 \succ A_1 \succ A_2$  because  $[\lambda_1, \lambda_2, \lambda_3, \lambda_4] \approx [1.4968, 0.9323, 2.0535, 1.5175]$
- Imp-BF-TOPSIS3: we get  $A_3 \succ A_4 \succ A_1 \succ A_2$  because  $[\lambda_1, \lambda_2, \lambda_3, \lambda_4] \approx [1.5300, 1.3487, 1.5639, 1.5574]$
- Imp-BF-TOPSIS4: we get  $A_4 \succ A_3 \succ A_1 \succ A_2$  because  $[\lambda_1, \lambda_2, \lambda_3, \lambda_4] \approx [1.5093, 1.4686, 1.5101, 1.5120]$

Imp-BF-TOPSIS1–3 methods provide here the same preference order  $A_3 \succ A_4 \succ A_2 \succ A_1$ , hence  $A_3$  is the preferred choice. One sees that Imp-BF-TOPSIS3 and Imp-BF-TOPSIS4 have difficulties to provide very distinct likelihood values because unsurmountable dependency effects arise in IA operations when applying PCR6 and ZPCR6 rules which degrade substantially the final precision of the result. Based on this analysis, we recommend to use either Imp-BF-TOPSIS1 or Imp-BF-TOPSIS2 because they provide tightest enclosure results and they are much simpler to implement than Imp-BF-TOPSIS3 and Imp-BF-TOPSIS4.

## VIII. CONCLUSIONS

Four new methods (Imp-BF-TOPSIS1–Imp-BF-TOPSIS4) for MCDM have been proposed. We have shown how to calculate imprecise BBAs from imprecise scores, and how to evaluate the relative imprecise closeness of each alternative to the ideal best and worst solutions for making the preference ordering. These methods avoid scores normalization, and they can deal with imprecise scores, with missing scores, with the reliability of the sources as well, and they could also work with imprecise weightings of criteria. They are more complicated to implement (and slower) than their precise counterparts because of IA. They are consistent with BF-TOPSIS1–4 when the imprecision of scores reduces to zero. However because IA suffers of dependency effects, IA is not the *universal panacea* to work with imprecise values to get best results, specially

for combining imprecise BBAs. More research efforts need to be done to circumvent these problems (if possible) by better implementations (or by Monte-Carlo approach) in order to improve the performance of Imp-BF-TOPSIS3 and Imp-BF-TOPSIS4 methods. Application of these methods for natural risk assessment in mountains is under development and will be reported in future publications.

**Abstract**—Multimodal images encompass diverse information that can be both complementary and redundant, thereby addressing the challenges associated with unimodal classification. By modeling and integrating these different pieces of information, multimodal approaches offer improved solutions. However, despite yielding acceptable results, this classification approach still falls short of the level achieved by the human brain’s powerful mechanism for effortlessly classifying visually observed scenes. To enhance the classification task within the realm of multimodal images, we present a methodology that leverages the Dezert-Smarandache Theory (DSMT). This approach involves fusing spectral and dense SURF features extracted from each modality, which are then pre-classified by the SVM classifier. Additionally, we incorporate the visual perception model into the fusion process. In order to demonstrate the effectiveness of incorporating salient features into the fusion process using DSMT, we conducted tests and validation on extensive datasets obtained from cultural heritage wall paintings. Each dataset consists of four imaging modalities, namely UV, IR, Visible, and fluorescence. The results obtained from these experiments show great promise.

**Keywords:** Visual saliency model, fusion, DSMT, SVM, Dense SURF features, Spectral features, Multimodal images, Classification.

## I. INTRODUCTION

Nowadays, multimodal imaging has gained increasing importance in computer vision application, and significant efforts have been put into developing methods of different tasks, such as Registration [1]–[4], Data fusion [5], Representation learning [6], Classification [7] and so on. In classification task, the unimodal image presents various problems as noisy data, incomplete information and distorted ones, etc. This often led to a misclassification. These limitations are overcome by using multimodal images, which are acquired from multiple sensors, and taken for the same object or scene. Each image or modality allows to provide different information that can sometimes be redundant, because the same area/scene is presented in a different sensor, and complementary for another modality, regarding the diversity of sensor technologies and their physical interaction mechanism. The use of this set of images together presents a real-world benefit to resolve a given problem with some various available information. The fusion of these data form a better quality classification.

However, these data are crippled with some imperfections such as conflict, ignorance, uncertainty and so on, which must be handled and taken into account by dedicated formalism as long as they present an aspect of reality. To fix such problem, several formalism exist as probability theory [8], Fuzzy theory [9], belief function formalism [10] and Dezert-Smarandache (DSMT) formalism [11], [12]. In this work, we benefit from the latest theory which is the most recent one, and it was introduced in order to deal with the high conflicted and uncertainty data thanks to its rich modelization and the combination operators (PCR5 and PCR6) that it integrates.

In classification task, belief function theory is widely exploited in many works [13]–[16]. Whereas DSMT or so-called plausible and paradoxical reasoning shows its efficiency in many applications, it was performed for multi-source remote sensing application [17] for supervised classification purpose by integrating contextual information obtained from ICM classifier with constraint and temporal information in hybrid DSMT process with adaptive decision rule, the authors also proposed a new decision rule based on DSMT transformation for change detection purpose [18]. In [19], the authors present an effective use of DSMT for multi-class classification by combining two SVM OAA (One-Against-All) implementation using PCR6 combination rule. A new method, based on fusing the attribute type information obtained from Ground Moving Target Indicator and imagery sensor using DSMT for tracking and classification, has been presented in [20]. Multidate fusion has been proposed in [21], [22] for the short-term prediction of the winter land cover. DSMT is also used in the medical case retrieval by [23], the authors used DSMT to fuse heterogeneous features of several sensors which will be included in CBR systems.

According to our study of the state of the art, all studied research works disregard the power of perceptual attention to well classify any scene thanks to the high human brain capacities. We benefit from this ability in our approach by integrating the visual perception model, using DSMT, with spectral and dense SURF features obtained from SVM classification for significant classification improvement.

The paper is organized as follows. After a brief presentation of mathematical background of DSMT formalism in section II, we present the overall system of the proposed method in

section III. Data and experiments are then given in section IV in order to evaluate the performance of our approach on real image datasets. A conclusion is given in section V.

## II. MATHEMATICAL BACKGROUND OF DSMT

Dezert-Smarandache theory was proposed jointly by Jean Dezert and Florentin Smarandache [24], and was an attempt to overcome belief function limitations by handling a high uncertainty and conflicting information. This theory can be described as follows:

We denote  $\Theta = \{\theta_1, \theta_2, \dots, \theta_N\}$  the discernment space of the  $N$  class classification problem, and  $D^\Theta$  the hyper-power-set [25] that is the set of subsets of  $\Theta$ , with the union of classes and also their intersection, so that if  $X, Y \in D^\Theta$ , then  $X \cup Y \in D^\Theta$  and  $X \cap Y \in D^\Theta$ . Each source  $S_i$  contributes its belief mass  $m_i$  to  $X$ , known by the generalized basic belief assignment (gbba) step, and satisfying following properties:

$$m_i(X) : D^\Theta \rightarrow [0, 1], \quad (1)$$

$$m_i(\emptyset) = 0, \quad (2)$$

where  $\emptyset$  is the null set, and

$$\sum_{X \in D^\Theta} m_i(X) = 1. \quad (3)$$

The size of hyper-power-set presents a real limit in DSMT when  $N > 6$  ( $N$  number of classes) in Free model [26] which corresponds to the full hyper-power-set without any constraints, in contrary to hybrid model [26] which allows integrating constraints that can be exclusive and refined, and therefore minimizing  $D^\Theta$  size. The assigned generalist mass obtained from different sources are then combined and a new mass distribution is provided to  $D^\Theta$  elements. Combination step presents the kernel of the fusion process and each formalism proposed several combination operators. In DSMT formalism, all combination operators can be found in detail in [27], we quote the most used as Smets rule, Dempster-Shafer (normalized) operator, Yager operator, Zhang operator, DSMT rule, Dubois and Prade rule, PCR5 operator for  $N = 2$  and PCR6 operator for  $N > 2$ . To deal with a large number of the sources used in this work and the high uncertainty and conflicting information provided, we benefit from the performance of PCR6 combination rule in handling such problem.

The generalized belief functions Credibility noted  $Bel(\cdot)$  or  $Cr(\cdot)$ , Plausibility noted  $Pl(\cdot)$ , and DSMT transformation are derived from the function of basic mass and respectively defined for  $D^\Theta$  in  $[0, 1]$ :

$$Cr(X) = \sum_{\substack{x \in D^\Theta \\ x \subseteq X}} m(x) \quad (4)$$

$$Pl(X) = \sum_{\substack{x \in D^\Theta \\ x \cap X \neq \emptyset}} m(x) \quad (5)$$

$$DSmP_\epsilon(\emptyset) = 0, \text{ and } \forall X \in G^\Theta \setminus \{\emptyset\}$$

$$DSmP_\epsilon(X) = \sum_{Y \in G^\Theta} \frac{\sum_{\substack{Z \subseteq X \cap Y \\ C(Z)=1}} m(Z) + \epsilon \cdot C(X \cap Y)}{\sum_{\substack{Z \subseteq Y \\ C(Z)=1}} m(Z) + \epsilon \cdot C(Y)} \cdot m(Y) \quad (6)$$

where  $G^\Theta$  can present full  $D^\Theta$ , or reduced  $D^\Theta$  with constraint, depending on the model used (free, or hybrid).  $\epsilon$  is an adjustment parameter,  $C(X \cap Y)$  and  $C(Y)$  are respectively the cardinality of  $X \cap Y$  and  $Y$ .

The last step in DSMT process is making a final decision, which presents a real challenge in many applications. In this work, we are interested in improving classification, we have to take a decision about pixels' belonging to a simple class also called Singleton class, and in this case there are two ways: taking decision based on maximum of generalized basic belief mass (gbba), or based on generalized belief function already computed as follows:

- Maximum of credibility  $Cr(\cdot)$  is widely used in many applications [28], and it is considered as a pessimistic decision.
- Maximum of plausibility  $Pl(\cdot)$  which is considered as an optimistic decision.
- Maximum of DSMT that is a compromise decision between the above decisions which are based on using probabilistic transformation  $P(\cdot)$  in the interval of  $[Cr(\cdot), Pl(\cdot)]$ .

## III. OVERALL SYSTEM

### A. Pre-processing

Generally, the pre-processing that precedes classification aims to eliminate imperfections that taint information by a set of actions as filtering, gradient operations, etc. However, in the classification based on the theories of the uncertain, these imperfections are protected, modeled and combined to help to make a decision.

The registration is the usually used pre-processing in the fusion process, it aims at setting correspondence between two or more images of a scene obtained from one or various sensors potentially at different spatial positions and scales, by using an optimal spatial and radiometric transformations between the images.

In the case of multimodal images, registration is an issue because of the significant difference between images [29], [30]. An original methodology was proposed in a previous work to answer the particular issue of the registration with multimodal imaging inputs in which we exploit the SURF scale- and rotation-invariant descriptors for the identification and the description of the interest points and we introduce a relevance filtering based on both SURF distance and orientation features in matching step [1].

### B. Feature Extraction

Feature extraction is a pivotal step in the classification process. It aims to underline the relevant features that are correspondent to various classes. It is worth stating that the

appropriate choice of extracted features improves the performance of classification step. Spectral, Spatial and perceptual features are extracted in this work.

1) *Spectral Information*: The spectral information is widely used on large classification methods. In this work, we have extracted the spectral values of each pixel as a vector of attributes and then converted them to Cielab space model for a better correlation with human color processing.

2) *Dense SURF Description*: Speeded up robust feature (SURF) proposed by Herbert Bay [31] is a spatial descriptor which consists originally of two phases, Detection and description of keypoints. We proposed in a previous work [32] to skip the detection phase and to perform description one to each pixel in the image. This is done, at the first by assigning to each pixel the dominant orientation calculated by combining the Haar wavelets results within a circular neighborhood around each pixel, and then creating  $4 \times 4$  sub regions around the pixel. In each sub-region, a pixel wise Haar wavelets responses are computed, which in turn are summed up to form 64-elements descriptor.

3) *Saliency Information*: Based on a performed comparative analysis of saliency detection in our multimodal data [33], we extract the saliency features by using the method proposed by Rahtu et al [34]. This method used local features contrast in illuminance, color mapped to feature space  $F(x)$  that is divided into disjoint bins. A saliency measure is calculated by applying a sliding windows  $w$  divided into inner windows  $K$  and border  $B$  in which a hypothesis that points in  $K$  are salient and points in  $B$  are not, the measure can be defined as probability conditional and computed through the Bayes Formula as

$$S_0(x) = \frac{h_K(x)p_0}{h_K(x)p_0 + h_B(x)(1-p_0)}, \quad (7)$$

with  $0 < p_0 < 1$ , and  $h_B(x) = P(F(x)|H1)$ . A regularized saliency measure is then introduced to make it more robust to the noise.

The motivation of integrating saliency information in the fusion process is the fact that usually visual perception succeeds easily to classify any objet or scene.

### C. SVM Pre-Classification

Support vector machine is a supervised classification method introduced by Vapnik [35], [36], widely used in classification applications thanks to its performance to deal with high-dimensional data. Basically, it is designed for binary class by finding an optimal hyperplan that separates the two classes linearly-separated. In non-linear separable class, the feature space is mapped to some higher dimensional feature space where the classes are separable using a Kernel function  $K$  that should fulfill Mercers conditions, the most kernels used are Radial Basis Function RBF, in which the decision function is expressed as a flow

$$h(x) = \text{Sign}\left(\sum_{i=1}^N \alpha_i \exp\{-|x - x_i|^2 / (2 \cdot \sigma^2)\}\right), \quad (8)$$

where  $\alpha_i$  are Lagrange multipliers, and the associated Kernel function is

$$k(x, x') = e^{-\frac{|x-x'|^2}{2\sigma^2}} \quad (9)$$

In case of multiclass problem, two main approaches were proposed: One-Versus-Rest approach in which  $k$  binary classifiers  $SVM_k$  are constructed for  $k$ -class classification, and One-versus-One in which  $(k(k-1))/2$  binary classifiers are applied on each pair of classes.

In order to generate the probabilities for DSMT, we have performed a pre-classification [32] based on combining spectral information (see III-B1) and Dense SURF information (see III-B2) using SVM classifier with RBF kernel to handle non-linear high-dimensional data in our multimodal dataset, and One-Versus-Rest approach to deal with incomplete information provided from diverse modalities.

### D. DSMT Classification

1) *Mass function estimation*: Mass estimation function step is very crucial in fusion process, because the imperfections such as uncertainty, imprecision, paradox will be introduced. The most generation used for these masses is the probabilities from pre-classification. The SVM classification of  $k$  images generates the matrices of the probabilities  $P(x_S|\theta_i)$  of pixels belonging to the singleton class of the frame of discernment  $\Theta = \{\theta_1, \theta_2, \dots, \theta_n\}$ , the same for  $k$  saliency map generated using the proposed method in [34]. Each source (modality/saliency map) noted  $S_i^b$  ( $i = 1, \dots, K$ ) gives the probability of belonging to one, or two classes, and their complementary classes which presents the mass of the partial ignorance. Based on [19], we denote  $\Theta = \{\theta_1, \theta_2, \dots, \theta_n\}$ , and the gbba mass of each source is given by:

$$\begin{cases} m_S(\theta_i) = \frac{P(x|\theta_i)}{z}, \forall \theta_i \in \Theta, \\ m_S(\bar{\theta}_i) = \frac{P(x|\cup_{0 < j < n} \theta_j)}{z}, \forall \theta_j \in \Theta, \\ m_S(\emptyset) = 0. \end{cases} \quad (10)$$

where  $z = \sum_{j=0}^n P(x|\theta_j)$  is a normalization term used in order to make sure that the sum of masses is equal to one.

2) *Combination of masses and decision*: The estimated masses must be combined with appropriate rules that handles the conflict generated from different sources  $S_i^b$ . In this work, we have used PCR6 [37] rule in combination step because it shows a better performance compared with all combination rules cited in the previous section and tested on our datasets. The PCR6 is computed as follows:

Considering  $S$  independent sources, the combined  $m_{PCR6}(\cdot)$  masses acquired from  $S > 2$  sources are computed

as  $m_{PCR6}(\cdot) = 0$ , and  $\forall X \in D^\Theta \setminus \{\emptyset\}$  as

$$m_{PCR6}(X) = m_{12\dots S}(X) + \sum_{\substack{X_1, X_2, \dots, X_S \in D^\Theta \setminus \{\emptyset\} \\ X_1 \cap X_2 \cap \dots \cap X_S = \emptyset}} \left[ \sum_{r=1}^S \delta_{X_r}^X m_r(X_r) \right] \frac{m_1(X_1) m_2(X_2) \dots m_S(X_S)}{m_1(X_1) + m_2(X_2) + \dots + m_S(X_S)} \quad (11)$$

where

$$\delta_{X_r}^X \triangleq \begin{cases} 1, & \text{if } X = X_r, \\ 0, & \text{if } X \neq X_r, \end{cases} \quad (12)$$

and where the mass  $m_{12\dots S}(X)$  corresponds to the conjunctive consensus on  $X$  between  $N > 2$  sources, which is given by

$$m_{12\dots S}(X) \triangleq \sum_{\substack{X_1, X_2, \dots, X_S \in D^\Theta \setminus \{\emptyset\} \\ X_1 \cap X_2 \cap \dots \cap X_S = X}} m_1(X_1) m_2(X_2) \dots m_S(X_S)$$

Once the combination step is achieved, we calculate the generalized belief function and we use a probabilistic transformation DSMP that converts the combined masses measure to a probability measure using (6) to make a final decision.

#### IV. DATA AND EXPERIMENTS

##### A. Data

Large sets of multimodal images acquired on wall paintings from the Germolles palace are used to demonstrate our proposed method. This palace was offered by Dukes of Burgundy Philip to his wife Margaret Flanders in 1380, and it was the only remaining castle of the Dukes of Burgundy so well preserved, its wall painting was restored between 1989 and 1991. However, there were no conservation reports of the applied restoration. In order to detect the original from restored area, the conservator of Germolles used the multimodal images that have the advantage of being fast and relatively inexpensive solution for the examination of large areas of wall paintings. This technical photography consists of recording a set of images with a commercial digital photographic camera which has been modified by removing the thermal filter regularly positioned in front of the CCD. In this way it is possible to record images of reflected visible light (Vis), reflected infrared light (IRr), reflected ultraviolet light (UVr) and UV-fluorescence (UVf). This set of images provides information about the optical behaviour of the surface when reached by the different types of light and therefore provides information about the original portions of wall paintings from recent repainting.

For illustration purpose, we select an area of a south wall of the dressing room of Margaret represented in Figure 1. This area presents a large white P (for Philip) that covers the walls and painted in green, which is presented by four modalities VIS, UVF, UVR and IRR. Each modality measures  $3744 \times 5616$  pixels. IRR modality shows very well the parts over non-original green surface. The image of the UV-induced

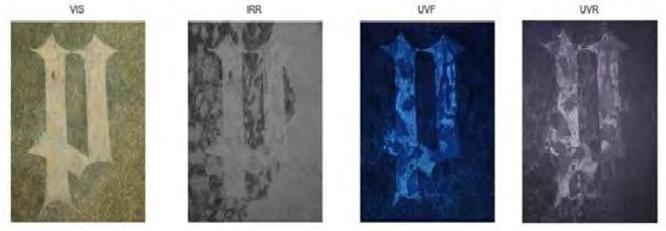

Figure 1. Multi-modal images of the same area.

fluorescence modality shows a relatively strong fluorescence corresponding to remains of an old/original paint layer over the white. The UVR image helps to identify the repainting original over the white of the letter P.

##### B. Experiments

The adopted methodology can be divided into four steps as illustrated in figure 2, which is started with the preprocessing by aligning each image with the VIS image that is used as a reference image.

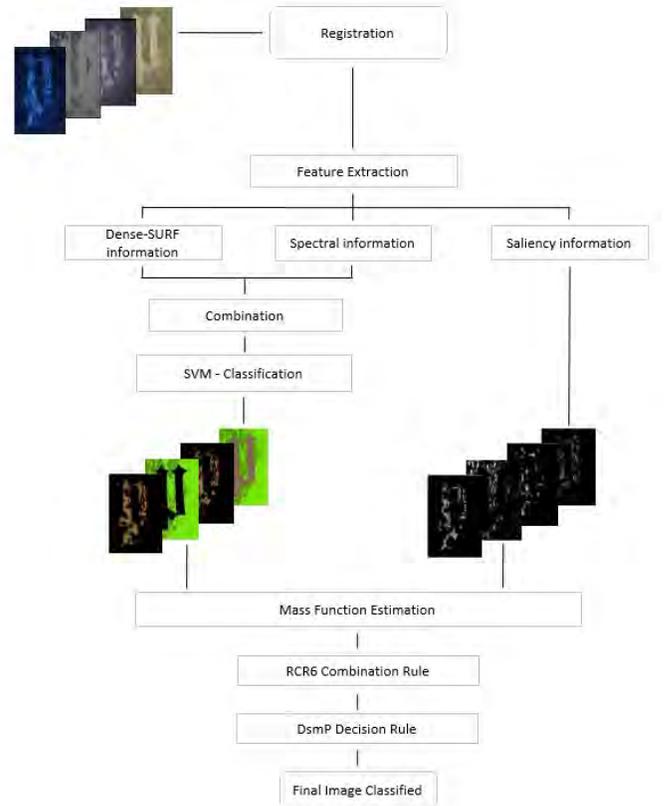

Figure 2. A representative illustration of the workflow.

In the second step, four topics have been identified: White original (WO), White repainted (WR), Green original (GO) and Green repainted (GR). Then spectral and Dense-SURF information is extracted and used jointly as the entry of the

SVM classifier using the RBF kernel. In parallel, Saliency information is extracted using the proposed method in [34], the provided maps are shown in figure 3.

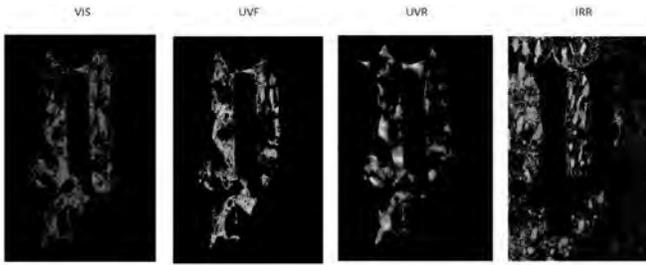

Figure 3. Saliency maps.

The third step is pre-classification using the SVM classifier that is applied to the images, in order to recover the probability matrixes of pixels belonging to classes. Each used modality highlights the presence of one or two classes. The UV-induced fluorescence modality shows a relatively strong fluorescence corresponding to the remains of an old painted layer of the white (WO) that reaches an accuracy of 92% using SVM, also UVR modality emphasizes WO class with a classification accuracy of 98%. Infrared light shows very well the parts over the original and repainted surface of the green and gets accuracy of 94% [32]. The provided maps are presented in figure 4.

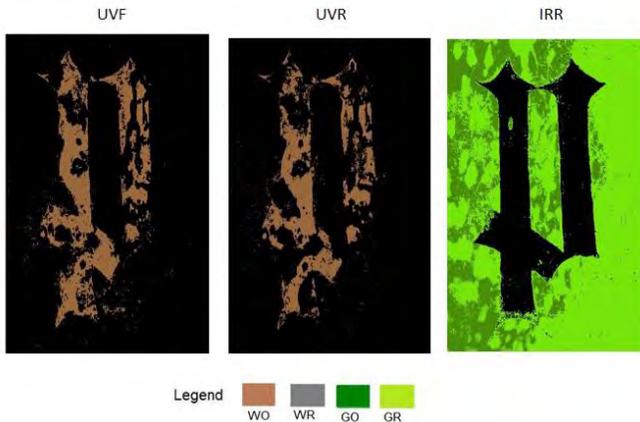

Figure 4. Multimodal SVM Classification.

The VIS modality reaches an accuracy of 98% with the classification of the two classes GO and GR, whereas this precision is reduced when classifying four classes because of the increase of the conflict. The classified image is presented in figure 5.

The last step presents the fusion process that is started with defining the frame of discernment  $\Theta = \{WO, WR, GO, GR\}$ . Due to the obtained information by SVM classification and saliency maps, there are some constraints that can be taken into account to deal with the real situation and to reduce the hyper power set  $D^\Theta$ , for example  $WO \cap GR = \emptyset$ .

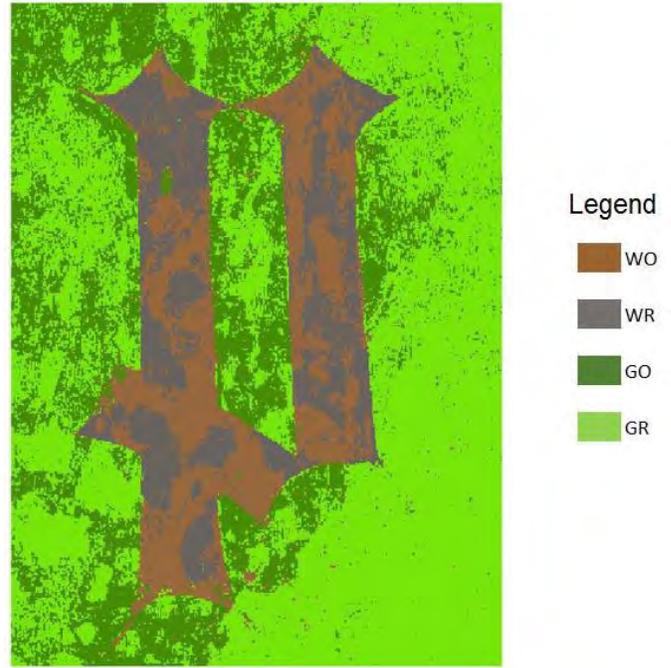

Figure 5. SVM classification of VIS modality.

Then the mass function that is associated with the emphasized class and its complementary in each modality are computed using equation (10). The PCR6 combination rule is used for combining the calculated masses basing on the equation (11), and as a final task, the decision is taken using maximum DsmP.

The final classified map, provided by DSMT only, is given in figure 6, and the final classified map obtained using DSMT-Saliency is shown in figure 7.

The results have progressed with the integration of the perceptual model in DSMT process, the visual analysis of the classification maps shows that the result of the proposed method much better with the ground truth over the WR and WO classes and appears to be closer to the reality, rather than the result obtained using DSMT only for the same classes, while the obtained map using unimodal image present a degraded result in terms of smoothness and connectivity between classes.

In this work, in order to evaluate the performance of the used methods and to compare the results, we have used the Overall accuracy (OA) that presents a percentage of correctly classified pixels, and Mean Error Rate (MER) that presents the percentage of misclassified pixels. Table I summarizes the obtained results using the different methods, from the results, we can note that the proposed method produces a better overall accuracy of 95.39% compared with the DSMT classification which provides an overall accuracy of 91.46% and the SVM classification that gives an overall accuracy of 86.43%, in terms of the error rate, the proposed method gives the low MER score of 4.61% compared with DSMT-Classification

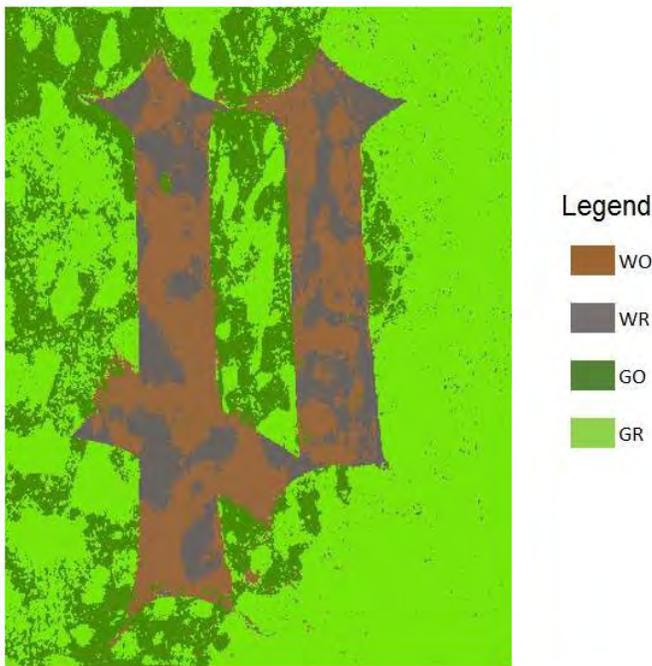

Figure 6. DSMT classification of multimodal images.

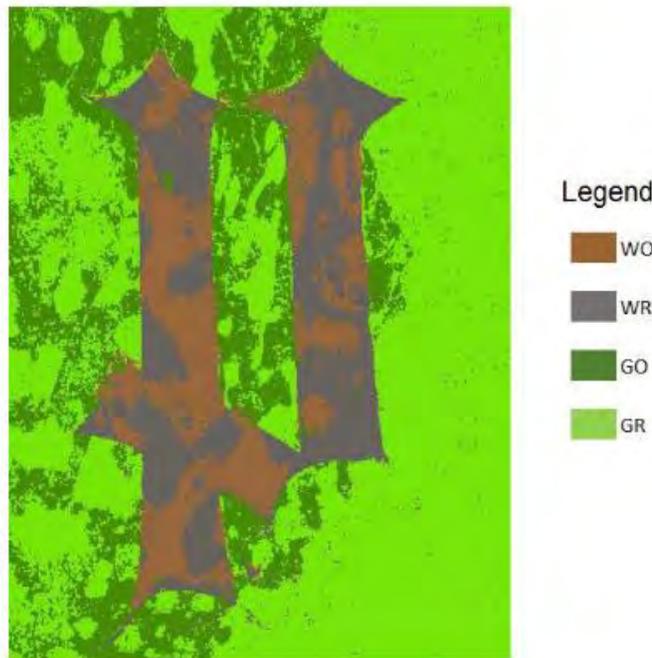

Figure 7. DSMT-Saliency classification of multimodal images.

and SVM-Classification that provides a MER of 8.53% and 12.60% respectively.

In conclusion, the use of DSMT theory with PCR6 combination rule provides a better result thanks to its effectiveness in managing correctly the conflict information that is provided from the different sources, and shows a significant

classification improvement compared with the unimodal SVM classification. Thus, the integration of saliency information in the fusion process presents a real benefit due to the powerful mechanism of the human brain in classification tasks.

Methods	OA	MER
SVM-Classification	86.43 %	12.60 %
DSMT-Classification	91.46 %	8.53 %
DSMT-Saliency-Classification	<b>95.39 %</b>	<b>4.61 %</b>

ACCURACY AND ERRORS OF CLASSIFICATION RESULTS FROM DIFFERENT METHODS.

## V. CONCLUSION

In this paper, we have proposed a new method for multimodal image classification. As a first step, we have extracted spatial (Dense-SURF), spectral and saliency information. The extracted spatial and spectral information are combined and passing to the classifier SVM for pre-classification step. The SVM-classification results that are obtained from each modality is then fused using DSMT theory, the use of DSMT and SVM jointly provides better performance compared with the unimodal SVM classification. In the second step, the extracted saliency information is then modeled and combined with SVM classification results using DSMT process based on PCR6 combination rule and DSMT decision rule, the proposed method yields the best performance in terms of accuracy and error rate compared with DSMT-SVM classification and unimodal SVM classification.

## VI. ACKNOWLEDGEMENT

The authors thank the Château de Germolles managers for providing data and expertise and the COST Action TD1201 “Colour and Space in Cultural Heritage (COSCH)” ([www.cosch.info](http://www.cosch.info)) for supporting this case study. The authors also thank the PHC Toubkal/16/31: 34676YA program for the financial support.

**Abstract**—The study of alternative probabilistic transformation (PT) in DS theory has emerged recently as an interesting topic, especially in decision making applications. These recent studies have mainly focused on investigating various schemes for assigning both the mass of compound focal elements to each singleton in order to obtain Bayesian belief function for real-world decision making problems. In this paper, work by us also takes inspiration from both Bayesian transformation camps, with a novel evolutionary-based probabilistic transformation (EPT) to select the qualified Bayesian belief function with the maximum value of probabilistic information content (PIC) benefiting from the global optimizing capabilities of evolutionary algorithms. Verification of EPT is carried out by testing it on a set of numerical examples on 4D frames. On each problem instance, comparisons are made between the novel method and those existing approaches, which illustrate the superiority of the proposed method in this paper. Moreover, a simple constraint-handling strategy with EPT is proposed to tackle target type tracking (TTT) problem, simulation results of the constrained EPT on TTT problem prove the rationality of this modification.

**Keywords:** Evidence Reasoning, Probabilistic Transformation, Evolutionary Algorithm, Target Type Tracking problems, Decision Making.

## I. INTRODUCTION

Since the pioneering work of Dempster and Shafer [1], [2], which is known as Dempster-Shafer evidence theory (DST), in the late 70's regarding the possibility of distinguishing “unknown” and “imprecision” and fusing different evidences based on associative and commutative Dempster's combination rule, this new area of research (now known as evidence reasoning) has grown considerably as indicated by the notable increment of technical papers in peer-reviewed journals, conference and special sessions. However, the computational complexity of reasoning with DST is one of the major points of criticism this formalism has to face.

To overcome this difficulty, various approximating methods have been suggested that aim at reducing the number of focal elements in the frame of discernment (FoD) so as to maintain the tractability of computation computation. One common strategy is to simplify FoD by removing and/or aggregating focal elements for approximating original belief function [3]. Among these methods, probability transformations (PTs) seem particularly desirable for reducing such computation complexity by means of assigning the mass of non-singleton elements to each singleton [4], [5]. The research on this probabilistic

measure has received a lot of attentions and accordingly many efficient PTs have been pointed out by scholars in recent years. In them, a classical transformation, denoted as BetP [4], which offers a good compromise between the maximum of credibility (Bel) and the maximum of plausibility (Pl) for decision making. Unfortunately, BetP does not provide the highest probabilistic information content (PIC) [7]; Sudano [8] also proposed series of alternatives and principles of these similar to BetP, which were called PrPl, PrBel and PrHyb; CuzzP [9], which was proposed by Cuzzolin in the framework of DST in 2009, showed its ability of probabilistic transformation; Another novel transformation was proposed by Dezert and Smarandache in the framework of DSMT (free DSMT model, hybrid DSMT model or Shafer's model), which was called DSMT [7] and comprehensive comparisons have been made in [7] to prove the capabilities of DSMT in probabilistic transformation.

However, most mentioned aforementioned PTs have been always concentrated mainly on two crucial issues: (1) How to implement this operation (or assignment)? (2) How to evaluate the quality of this transformation? In this paper, we suggest a novel PT method based on evolutionary algorithm, namely, evolutionary-based probabilistic transformation (EPT), which alleviates the above two difficulties together based on optimization using a reasonable criteria. A similar idea was proposed by Han et.al [10] and the difference lies in the optimization approaches and objective functions. In the EPT method, the global search replaces the assigning operator used in the classical PTs and the evaluation criteria is embedded into EPT to provide important guidance for the searching procedure. Specifically, the mass of the singletons are randomly generated in evolutionary-based framework, which need to satisfy the constraints of probability distributions in evidence reasoning. Also, a selection operator is presented to assess the best individual in all populations by a special objective function (desirable evaluation criteria). Referring to the previous works [7], the PIC is used in this paper to select the best<sup>1</sup> solution as an objective function in EPT. Simulation results on 4D frames test cases show that the proposed EPT, in these problems, is able to outperform other PTs that pay special attention to some ratio created from the available information

<sup>1</sup>based on the highest PIC value.

(i.e. Bel or Pl). Moreover, we suggest a simple constraint-handling strategy with EPT that suits well for two target type tracking (TTT) problems. These first appealing results of EPT method encourage its use for more complex and real-world decision making problems.

The rest of this paper is organized as follows. In Section II we briefly summarize the basis of DST and several classical PT formulas. A novel EPT approach is presented in details in Section III. In Section IV several cases and comprehensive comparisons borrowed from previous papers are carried out to demonstrate the superiority of proposed method. Also, target type tracking problem and the pertinent analysis of EPT in TTT are described in detail in this section. Moreover, the limitation of EPT are also discussed in Section. V. The conclusion is drawn in Section. VI.

## II. BASIS OF BELIEF FUNCTIONS

In this section, we introduce the belief functions terminology of DST and the notations used in the sequel of this paper.

### A. DST basis

In DST [2], the elements  $\theta_i$  ( $i = 1, \dots, N$ ) of the frame of discernment (FoD)  $\Theta \triangleq \{\theta_1, \dots, \theta_N\}$  must be mutually exhaustive and exclusive. The power set of the FoD is denoted  $2^\Theta$  and a basic belief assignment (BBA), also called a mass function, is defined by the mapping:  $2^\Theta \rightarrow [0, 1]$ , which satisfies  $m(\emptyset) = 0$  and

$$\sum_{A \subseteq 2^\Theta} m(A) = 1 \quad (1)$$

where  $m(A)$  is defined as the BBA of  $A$ . The element  $A$  is called a focal element of  $m(\cdot)$  if  $m(A) > 0$ . The belief and plausibility functions, which are in one-to-one mapping with the BBA  $m(\cdot)$ , are defined for all  $A \subseteq \Theta$  by

$$Bel(A) = \sum_{B \subseteq A} m(B) \quad (2)$$

$$Pl(A) = 1 - Bel(\bar{A}) = \sum_{A \cap B \neq \emptyset} m(B), \forall A \subseteq \Theta \quad (3)$$

where  $\bar{A} \triangleq \Theta \setminus A$  is the complement of  $A$  in  $\Theta$ . The belief interval  $[Bel(A), Pl(A)]$  represents the uncertainty committed to  $A$  and the bounds of this interval are usually interpreted as lower and upper bounds of the unknown (possibly subjective) probability of  $A$ . This interval plays an important role in the implementation of EPT as shown in details in Section III.

### B. DSMT basis

In the framework of Dezert-Smarandache Theory (DSMT) [5], the FoD  $\Theta$  is considered as a finite set of  $N$  exhaustive elements only (without the requirement of exclusivity of the elements). The BBA  $m(\cdot)$  is then defined on the hyper-power set of the FoD (i.e. the free Dedekind's lattice  $D^\Theta$ ), taking eventually into account some integrity constraints (if any). The main differences between DST and DSMT frameworks are: (1) the model on which one works with, and (2) the combination

rule. In the sequel, we will work with BBA defined only on the classical power-set for simplicity. Instead of distributing equally total conflicting mass onto elements of  $2^\Theta$  as within Dempster's rule through the normalization step, or transferring the partial conflicts onto partial uncertainties as within DSMT rule [4], we use the Proportional Conflict Redistribution rules (PCRs) [5] based on the transfer of conflicting masses (total or partial) proportionally to non-empty sets involved in the model according to all integrity constraints. In DSMT, the most effective rule is the PCR6 rule which is defined<sup>2</sup> for the fusion of two BBA's  $m_1(\cdot)$  and  $m_2(\cdot)$  as  $m_{PCR6}(\emptyset) = 0$  and  $\forall A \in 2^\Theta \setminus \{\emptyset\}$

$$m_{PCR6}(A) = m_{12}(A) + \sum_{B \in 2^\Theta \setminus \{A\} | A \cap B = \emptyset} \left[ \frac{m_1(A)^2 m_2(B)}{m_1(A) + m_2(B)} + \frac{m_2(A)^2 m_1(B)}{m_2(A) + m_1(B)} \right] \quad (4)$$

where  $m_{12}(A)$  is the conjunctive operator, and each element  $A$  and  $B$  are expressed in their disjunctive normal form.

### C. Classical Probabilistic Transformations

The efficiency of probabilistic transformation (PT) in the field of decision making has been analyzed in deep by Smets [4]. Various PTs have been proposed in the open literature and the main transformations are briefly recalled in this section.

1) *BetP*: Smets in [4], [6] first proposed pignistic probability to make decision which aims to transfer the mass of belief of each non-specific element onto the singletons. The classical pignistic probability is defined as  $BetP(\emptyset) = 0$ , and  $\forall A \in 2^\Theta \setminus \{\emptyset\}$ :

$$BetP(\theta_i) \triangleq \sum_{A \subseteq 2^\Theta, A \neq \emptyset} \frac{|\theta_i \cap A|}{|A|} \frac{m(A)}{1 - m(\emptyset)} \quad (5)$$

Because in Shafer's framework  $m(\emptyset) = 0$ , the formula (5) can simply be rewritten for any singleton  $\theta_i \in \Theta$  as

$$BetP(\theta_i) = \sum_{B \in 2^\Theta, \theta_i \subseteq B} \frac{1}{|B|} m(B) = m(\theta_i) + \sum_{B \in 2^\Theta, \theta_i \subset B} \frac{1}{|B|} m(B) \quad (6)$$

2) *CuzzP*: An intersection probability denoted as CuzzP [9] was proposed using the proportional repartition of the total non-specific mass (total non-specific mass ( $TNSM$ ) =  $\sum_{A \in 2^\Theta, |A|} m(A)$ ) for each contribution of the non-specific masses involved. CuzzP is defined by  $CuzzP(\emptyset) = 0$ , and for any singleton  $\theta_i \in \Theta$  by

$$CuzzP(\theta_i) \triangleq m(\theta_i) + \frac{Pl(\theta_i) - m(\theta_i)}{\sum_j (Pl(\theta_i) - m(\theta_j))} \cdot TNSM \quad (7)$$

<sup>2</sup>PCR6 rule coincides with PCR5 rule when combining only two BBA's [5].

3) *DSmP*: In 2008, Dezert and Smarandache [7] have proposed a new generalized pignistic transformation defined by  $DSmP_\varepsilon(\emptyset) = 0$  and for any singleton  $\theta_i \in \Theta$  by

$$DSmP_\varepsilon(\theta_i) \triangleq m(\theta_i) + (m(\theta_i) + \varepsilon) \times \left\{ \sum_{A \in 2^\Theta, \theta_N \subset A, |A| \geq 2} \frac{m(A)}{\sum_{B \in 2^\Theta, B \subset A, |B|=1} m(B) + \varepsilon \cdot |A|} \right\} \quad (8)$$

As shown in [7], DSmP makes a remarkable improvement compared with BetP, and CuzzP, since a more judicious redistribution of the ignorance masses to the singletons have been adopted by DSmP.

4) *PrBP1 and PrBP2*: Two novel pignistic probabilistic transformations were proposed by Pan in [11], which assume that the BBA is proportional to the product of  $Bel(\theta_i)$  and  $Pl(\theta_i)$  among each singleton element  $\theta_i$  of  $A \subseteq \Theta$ .

$$PrBP1(\theta_i) = \sum_{\theta_j \subseteq A} \left( \frac{Bel(\theta_j)Pl(\theta_j)}{\sum_{\theta_j \subseteq A} Bel(\theta_j)Pl(\theta_j)} \right) \cdot m(A) \quad (9)$$

Also, Pan et.al. assume that the masses are distributed proportionally to some given parameters  $s_i = Bel(\theta_i)/(1 - Pl(\theta_i))$  or  $s_i = Pl(\theta_i)/(1 - Bel(\theta_i))$ :

$$PrBP2(\theta_i) = \sum_{A, \theta_i \subseteq A} \left( \frac{s_i}{\sum_{j, \theta_j \subseteq A} s_j} \right) \cdot m(A) \quad (10)$$

As we can see, a Bayesian mass function which has only singleton focal elements can be obtained by any of these PTs.

#### D. Probabilistic Information Content (PIC)

The PIC criterion [12] is classically adopted to evaluate the performances of a probabilistic transformation of a BBA. If  $m(\cdot)$  is a Bayesian BBA defined on a discrete finite FoD  $\Theta = \{\theta_1, \theta_2, \dots, \theta_N\}$ , its PIC value is defined as<sup>3</sup>

$$PIC(m) \triangleq 1 + \frac{1}{\log_2 N} \sum_{i=1}^N m(\theta_i) \log_2 m(\theta_i) \quad (11)$$

The PIC metric actually measures the information content of a (probabilistic) source characterized by a Bayesian BBA  $m(\cdot)$ , which the value of this metric always belong to  $[0; 1]$ . It corresponds to the (normalized) dual of Shannon's entropy measure. When the Bayesian BBA is uniform over the FoD  $\Theta$ , one has  $m(\theta_i) = 1/N$  for  $i = 1, 2, \dots, N$  and the PIC metric is minimum, i.e.  $PIC(m) = PIC_{\min} = 0$ . The PIC metric is maximum, i.e.  $PIC(m) = PIC_{\max} = 1$  if the Bayesian BBA  $m(\cdot)$  is deterministic, that is if there exists an element  $\theta_i$  of  $\Theta$  such that  $m(\theta_i) = 1$ . While simple, appealing and generally adopted by the community, the PIC criteria is however not always sufficient to evaluate the efficiency of a PT as discussed in [14]. This point will be addressed in Section V.

<sup>3</sup>where  $0 \log_2(0) = 0$  by convention.

### III. EVOLUTIONARY-BASED PROBABILISTIC TRANSFORMATION (EPT)

The idea to approximate any BBA into a Bayesian BBA (i.e. a subjective probability measure) using the minimization of the Shannon entropy under compatibility constraints has been proposed recently by Han et al. in [10], [14] using "on-the-shelf" optimization techniques. In this paper, we present in details a new optimization method to achieve this PT based on a random evolutionary algorithm to acquire maximization of the PIC value. That is why we call it the Evolutionary-based Probabilistic Transformation (EPT) method.

Let's assume that the FoD of the original BBA  $m(\cdot)$  to approximate by a Bayesian BBA is  $\Theta \triangleq \{\theta_1, \theta_2, \dots, \theta_N\}$ . The EPT method consists of the following steps:

- Step 0 (setting parameters):  $t_{\max}$  is the max number of iterations;  $n_{\max}$  is the population size in each iteration;  $P_c$  is the crossover probability, and  $P_m$  is the mutation probability.
- Step 1 (population generation): A set  $\mathbf{P}_t$  of  $j = 1, 2, \dots, n_{\max}$  random probability values  $P_t^j = \{P^j(\theta_1), \dots, P^j(\theta_N)\}$  is generated such that the constraints (12)–(14) for  $j = 1, 2, \dots, n_{\max}$  are satisfied in order to make each random set of probabilities  $P_t^j$  compatible with the original BBA  $m(\cdot)$

$$P^j(\theta_i) \in [0; 1], \quad i = 1, 2, \dots, N \quad (12)$$

$$\sum_{i=1}^N P^j(\theta_i) = 1 \quad (13)$$

$$Bel(\theta_i) \leq P^j(\theta_i) \leq Pl(\theta_i), \quad i = 1, 2, \dots, N \quad (14)$$

- Step 2 (fitness assignment): To each probability set  $P_t^j$ , ( $j = 1, 2, \dots, n_{\max}$ ), we compute its PIC value and use it as its fitness factor  $F$ . More precisely, one takes  $F(P_t^j) = PIC(P_t^j)$ .
- Step 3 (best approximation of  $m(\cdot)$ ): the best set of probability  $P_t^{j_{\text{best}}}$  with highest PIC value is sought, and its associated index  $j_{\text{best}}$  are stored respectively in "Best-Individual" and "Index-of-BestIndividual".
- Step 4 (selection, crossover and mutation): The tournament selection, crossover and mutation operators drawn from evolutionary theory framework [13] are implemented to create the associated offspring population  $\mathbf{P}'_t$  based on the parent population  $\mathbf{P}_t$ . If  $F(P_t^{j_{\text{best}}}) \geq F(P_t'^{j_{\text{best}}})$ , then the "Best-Individual" remains unchanged; otherwise, Best-Individual =  $P_t'^{j_{\text{best}}}$ .
- Step 5 (Stopping EPT): The steps 1–4 illustrate the  $t$ -th iteration of EPT method. If  $t \geq t_{\max}$  then EPT method is completed, otherwise another iteration must be done by taking  $t + 1 = t$  and going back to step 1.

The scheme of EPT method is shown in Fig.1 and its pseudo-code is given in Algorithm 1.

### IV. SIMULATION RESULTS

In this section we compare EPT's results to other mentioned PTs. In particular, we show the important gain of PIC we

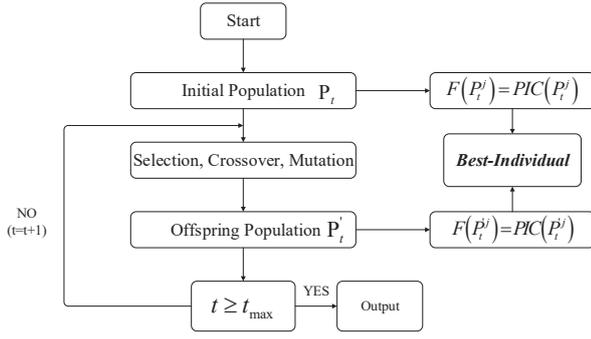

Figure 1: Scheme of EPT algorithm.

**Algorithm 1** Evolutionary-Based PT (EPT)

- 1: Define Stopping Criteria, ( $t \leq t_{\max}$ ); population Size  $n_{\max}$  for each iteration; crossover probability  $P_c$ , and mutation probability  $P_m$ .
- 2: Generate an initial random population  $\mathbf{P}_t$  of consistent probabilities  $P_t^j$  with  $m(\cdot)$ .
- 3: For each individual  $P_t^j$  in  $\mathbf{P}_t$  do
- 4: Calculate Fitness  $F(P_t^j) = PIC(P_t^j)$  of  $P_t^j$
- 5: Store the best individual  $P_t^{j_{\text{best}}}$
- 6: End
- 7: Repeat:
- 8: Selection: Select 2 individuals based on fitness
- 9: Crossover: exchange parts of 2 individuals with probability  $P_c$
- 10: Mutation: mutate the child individuals with probability  $P_m$
- 11: After these three sub-steps, the updated population  $\mathbf{P}'_t$  is obtained
- 12: Calculate the fitness of individuals of  $\mathbf{P}'_t$ , and store the best individual  $P_t^{j_{\text{best}}}$
- 13: If  $F(P_t^{j_{\text{best}}}) \geq F(P_t^{j_{\text{best}}})$
- 14: Best-Individual remains unchanged
- 15: else
- 16: Best-Individual =  $P_t^{j_{\text{best}}}$
- 17: If  $t \geq t_{\max}$  then stops, otherwise  $t + 1 \rightarrow t$  and go back to line 7

can obtain, and the capability of EPT to improve target type tracking.

### A. Examples and comparisons

In order to compare different PTs with EPT, two cases borrowed from [11] and [12] are considered, where PIC is used for evaluation. In all the following cases, the parameters  $t_{\max}$ ,  $n_{\max}$ ,  $P_c$  and  $P_m$  necessary to EPT method have been set to  $t_{\max} = 50$ ,  $n_{\max} = 1000$ ,  $P_c = 0.9$  and  $P_m = 0.1$  respectively.

**Example 1:**  $\Theta = \{\theta_1, \theta_2, \theta_3, \theta_4\}$

The BBA  $m(\cdot)$  to approximate by a Bayesian BBA (probability measure) is

$$\begin{aligned}
 m(\theta_1) &= 0.16, m(\theta_2) = 0.14, m(\theta_3) = 0.01, m(\theta_4) = 0.02 \\
 m(\theta_1 \cup \theta_2) &= 0.20, m(\theta_1 \cup \theta_3) = 0.09, m(\theta_1 \cup \theta_4) = 0.04 \\
 m(\theta_2 \cup \theta_3) &= 0.04, m(\theta_2 \cup \theta_4) = 0.02, m(\theta_3 \cup \theta_4) = 0.01 \\
 m(\theta_1 \cup \theta_2 \cup \theta_3) &= 0.10, m(\theta_1 \cup \theta_2 \cup \theta_4) = 0.03 \\
 m(\theta_1 \cup \theta_3 \cup \theta_4) &= 0.03, m(\theta_2 \cup \theta_3 \cup \theta_4) = 0.03 \\
 m(\Theta) &= 0.08
 \end{aligned}$$

The Bayesian BBA obtained by classical PT (5)–(10) and EPT with their corresponding PIC values calculated by (11) are given in Table I. As expected, the EPT provides the maximum PIC.

Table I: Results of Different PTs in Example 1.

	$\theta_1$	$\theta_2$	$\theta_3$	$\theta_4$	PIC
<i>CuzzP</i>	0.3860	0.3382	0.1607	0.1151	0.0790
<i>BetP</i>	0.3983	0.3433	0.1533	0.1051	0.0926
<i>DSmP<sub>0</sub></i>	0.5176	0.4051	0.0303	0.0470	0.3100
<i>DSmP<sub>0,001</sub></i>	0.5162	0.4043	0.0319	0.0476	0.3058
<i>PrBP1</i>	0.5419	0.3998	0.0243	0.0340	0.3480
<i>PrBP2</i>	0.5578	0.3842	0.0226	0.0354	0.3529
<b>EPT</b>	<b>0.7246</b>	<b>0.2218</b>	<b>0.0266</b>	<b>0.0270</b>	<b>0.4508</b>

**Example 2:**  $\Theta = \{\theta_1, \theta_2, \theta_3, \theta_4\}$

In this case, we randomly generate BBAs and compare EPT with classical PTs (*CuzzP*, *BetP*, *DSmP*, *PrBP1* and *PrBP2* given by (5)–(10)). The original BBAs to approximate are generated according to Algorithm 2 of [15].

**Algorithm 2** Random generation of BBA

- 1: Input: Frame of Discernment  $\Theta = \{\theta_1, \theta_2, \theta_3, \theta_4\}$
- 2:  $N_{\max}$ : Maximum number of focal element
- 3: Output: BBA-m
- 4: Generate  $K(\Theta)$ , which is the power set of  $\Theta$
- 5: Generate a random permutation of  $K(\Theta) \rightarrow R(\Theta)$
- 6: Generate an integer between 1 and  $N_{\max} \rightarrow l$
- 7: For each First  $k$  elements of  $R(\Theta)$  do
- 8: Generate a value within  $[0, 1] \rightarrow m_i, i = 1, \dots, l$
- 9: End
- 10: Normalize the vector  $m = [m_1, m_2, \dots, m_l] \rightarrow m'$
- 11:  $m(\theta_i) = m'_i$

In our test, we have set the cardinality of the FoD to 4 and fixed the number of focal elements to  $l = N_{\max} = 15$ . We randomly generate  $L = 30$  BBA's. Six PT methods are tested and PIC is used to evaluate the quality of their corresponding results are shown in Fig.2. As we can see, EPT outperforms significantly other methods based on maximum of PIC criterion, which is normal.

### B. Evaluation of EPT in Target Type Tracking problem

Target Type Tracking (TTT) problem can be briefly described below [16]:

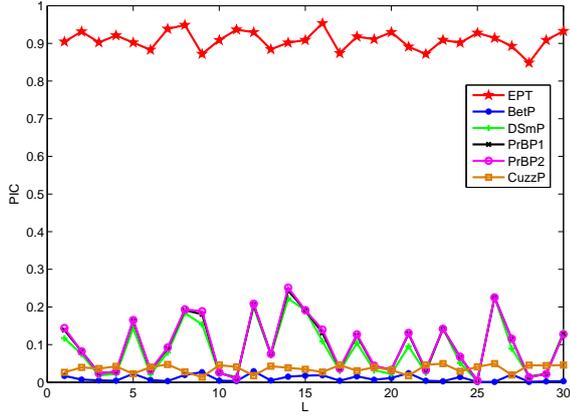

Figure 2: PIC values obtained with EPTs and classical PTs.

### 1) Target Type Tracking Problem (TTT):

1. Considering  $\zeta = 1, 2, \dots, \zeta_{max}$  be the time index and let  $N$  possible target types  $Tar_{\zeta} \in \Theta = \{\theta_1, \theta_2, \dots, \theta_N\}$  in the surveillance area; For instance, in the normal air target surveillance systems the FoD could be  $\Theta = \{Fighter, Cargo\}$ . That is,  $Tar_1 = \theta_1 \triangleq Fighter$ ,  $Tar_2 = \theta_2 \triangleq Cargo$ . Similarly, the FoD in a ground target surveillance systems could be  $\Theta_{ground} = \{Tank, Truck, Car, Bus\}$ . In this paper, we just consider the air target surveillance systems to prove the practicability of EPT.
2. At every time  $\zeta$ , the true type of the target  $Tar(\zeta) \in \Theta$  is immediately observed by an attribute-sensor (here, we assume a possible target probability).
3. A defined classifier is applied to process the attribute measurement of the sensor which provides the probability  $Tar_d(\zeta)$  on the type of the observed target at each instant  $\zeta$ .
4. The sensor is in general not totally reliable and is characterized by a  $N \times N$  confusion matrix:

$$\mathbf{M} = [M_{ij} = P(Tar_d = Tar_j | TrueType = Tar_i)] \quad (15)$$

where  $0 \leq i \leq N; 0 \leq j \leq N$ .

Here, we briefly summarize the main steps of TTT using EPT.

1. Initialization. Determine the target type frame  $\Theta = \{\theta_1, \theta_2, \dots, \theta_N\}$  and set the initial BBA  $m^{initial}(\theta_1 \cup \theta_2 \cup \dots \cup \theta_N) = 1$  since there is no information about the first target type that will be observed;
2. Updating BBA. An observed BBA  $m_{obs}(\cdot)$  on types of unknown observed target is defined from current target type declaration and confusion matrix  $\mathbf{M}$ ;
3. Combination. We combine the current BBA  $m_{obs}(\cdot)$  with initial BBA  $m^{initial}(\cdot)$  according to PCR6 combination rule:  $m_{PCR6}(\cdot) = m_{obs}(\cdot) \oplus m^{initial}(\cdot)$ ;

4. Approximation. Using  $EPT(\cdot)$  to approximate  $m_{PCR6}(\cdot)$  into a Bayesian BBA;
5. Decision Making. Taking a final decision about the type of the target at current observation time based on the obtained Bayesian BBA;
6. Updating BBA. Set  $m^{initial}(\cdot) = m_{PCR6}(\cdot)$ , and increase time index  $\zeta = \zeta + 1$  and go back to step 2.

2) Raw Dataset of TTT: We have tested our EPT-based TTT on a very simple scenario for a 2D TTT, namely  $\Theta = \{Fighter, Cargo\}$  for two types of classifiers. The matrix  $\mathbf{M}_1$  corresponds to the confusion matrix of the good classifier, and  $\mathbf{M}_2$  corresponds to the confusion matrix of the poor classifier.

$$\mathbf{M}_1 = \begin{bmatrix} 0.95 & 0.05 \\ 0.05 & 0.95 \end{bmatrix}; \mathbf{M}_2 = \begin{bmatrix} 0.75 & 0.25 \\ 0.25 & 0.75 \end{bmatrix} \quad (16)$$

In our scenario, a true Target Type sequence over 120 scans is generated according to Fig. 3. We can observe clearly from Fig. 3 that Cargo (which is denoted as Type 2) appears at first in the sequence, and then the observation of the Target Type switches three times onto Fighter Type (Type 1) during different time duration (namely, 20s, 10s, 5s).

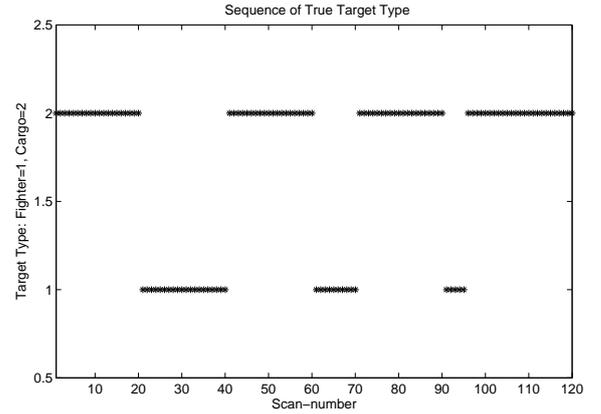

Figure 3: Raw Sequence of True Target Type.

**A pathological case for TTT:** Our analysis has shown that EPT can nevertheless be in troubles for tracking two target types as proved in this simple particular example (when  $0 \leq m(\theta_1 \cup \theta_2) \leq 0.1$ ). Let's consider the following BBA

$$m_{target}(\cdot) = [\theta_1, \theta_2, \theta_1 \cup \theta_2] = [0, 1, 0]$$

According to the compatibility constraints (12)–(14), the population  $\mathbf{P}'_t$  is obtained from  $\mathbf{P}_t$  through a selection procedure. Next, individual  $P_t^j$  in  $\mathbf{P}'_t$  which is denoted as  $P_t^j = [m'(\theta_1), m'(\theta_2)]$  is subject to initial constraint (1) and (17):

$$\begin{aligned} m'(\theta_1) &\geq (Bel(\theta_1) = m(\theta_1) = 0) \\ m'(\theta_1) &\leq (Pl(\theta_1) = m(\theta_1) + m(\theta_1 \cup \theta_2) = 0 + 0 = 0); \\ m'(\theta_2) &\geq (Bel(\theta_2) = m(\theta_2) = 1) \\ m'(\theta_2) &\leq (Pl(\theta_2) = m(\theta_2) + m(\theta_2 \cup \theta_1) = 1 + 0 = 1); \end{aligned} \quad (17)$$

From the above inequalities, one sees that only one probability measure  $P_t^S = [m(\theta_1), m(\theta_2)] = [0, 1]$  (where the superscript index  $S$  means *Single*) satisfies this constraint. However because of mechanism of EPT and real-coded generic algorithm (RCGA), the probabilities  $P_t^j$  in population  $\mathbf{P}_t$  which are randomly generated in the interval  $[0, 1]$ , will have a very little chance to be equal to the suitable measure  $[0, 1]$  satisfying the constraints. That is why EPT becomes inefficient in this case which occurs with a probability of  $1/n_{\max}$ , where  $n_{\max}$  denotes the size of population<sup>4</sup>  $\mathbf{P}_t$ . Unfortunately, in TTT decision making problems, such case cannot be avoided because it can really happens.

To circumvent this problem and make EPT approach working in all circumstances, we need to modify a bit the EPT method to generate enough individuals for making selection step efficiently when the bounds of belief interval  $[Bel, Pl]$  take their min and max values  $([0.9, 0.05, 0.05], [0.05, 0.9, 0.05])$ . For achieving this, we propose to enlarge the interval through a parameter  $\lambda$ , and maintain the property of original interval in some degree at the same time. More precisely, the modified belief interval, denoted  $[Bel', Pl']$ , is heuristically computed by a simple thresholding technique as follows:

First, we assume that the original BBA we consider here for FoD  $\Theta = \{\theta_1, \theta_2\}$  is  $[\theta_1, \theta_2, \theta_1 \cup \theta_2] = [a, b, c], (a + b + c) = 1; 0 \leq c \leq 0.1$

Step 1: Let  $m'(\theta_1 \cup \theta_2) = c + \lambda$ ;

Step 2: if  $a > b$

$$m'(\theta_1) = a - \lambda; m'(\theta_2) = b; m'(\theta_1 \cup \theta_2) = c + \lambda; \quad (18)$$

Step 3: if  $a \leq b$

$$m'(\theta_1) = a; m'(\theta_2) = b - \lambda; m'(\theta_1 \cup \theta_2) = c + \lambda; \quad (19)$$

So the value of  $[Bel'(\theta_1), Pl'(\theta_1)]$  and  $[Bel'(\theta_2), Pl'(\theta_2)]$  can be calculated based on Eq.(18),Eq.(19), which are presented as follows:

When  $a > b$ :

$$\begin{cases} Pl'(\theta_1) = m(\theta_1) + m'(\theta_1 \cup \theta_2) = a - \lambda + c + \lambda = a + c; \\ Bel'(\theta_1) = 1 - Pl'(\bar{\theta}_1) = 1 - (b + c + \lambda) = a - \lambda. \end{cases} \quad (20)$$

$$\begin{cases} Pl'(\theta_2) = m(\theta_2) + m'(\theta_1 \cup \theta_2) = b + c + \lambda = b + c + \lambda; \\ Bel'(\theta_2) = 1 - Pl'(\bar{\theta}_2) \\ = 1 - (a - \lambda + c + \lambda) = 1 - (a + c) = b. \end{cases} \quad (21)$$

When  $a \leq b$ :

$$\begin{cases} Pl'(\theta_1) = m(\theta_1) + m'(\theta_1 \cup \theta_2) = a + c + \lambda; \\ Bel'(\theta_1) = 1 - Pl'(\bar{\theta}_1) \\ = 1 - (b - \lambda + c + \lambda) = 1 - (b + c) = a. \end{cases} \quad (22)$$

<sup>4</sup>In our simulation, we did take  $n_{\max} = 1000$ .

$$\begin{cases} Pl'(\theta_2) = m(\theta_2) + m'(\theta_1 \cup \theta_2) = b - \lambda + c + \lambda = b + c; \\ Bel'(\theta_2) = 1 - Pl'(\bar{\theta}_2) = 1 - (a + c + \lambda) = b - \lambda. \end{cases} \quad (23)$$

**Explanation:** Through step 1, one computes the total singleton mass one has in the entire BBA and the threshold value 0.9 allows to evaluate if the percentage of singleton mass is big enough or not. Here, we not only consider the unique extreme case  $m_{target}(\cdot) = [\theta_1, \theta_2, \theta_1 \cup \theta_2] = [0, 1, 0]$ , but also other possible cases such as  $m_{target}(\cdot) = [\theta_1, \theta_2, \theta_1 \cup \theta_2] = [0.0001, 0.9998, 0.0001]$ . Why do we consider the concept of percentage? Actually, the higher percentage of singleton mass, the smaller interval for  $P_t^j$ , in other words, the higher value of  $m(\theta_1 \cup \theta_2)$ , the bigger interval for  $P_t^j$  which can be shown in Eq.(17); The step 2 and step 3 give the way of calculating the updated upper bound of belief interval  $[Bel', Pl']$  and Eq.(20)–Eq.(23) prove that the parameter  $\lambda$  determines the range of the interval; Next, we give two examples to show how the above method works:

#### The pathological case 1 for TTT (using modified EPT)

$$m_{target}(\cdot) = [\theta_1, \theta_2, \theta_1 \cup \theta_2] = [0.0001, 0.9998, 0.0001].$$

Here, the parameter  $\lambda$  is arbitrarily<sup>5</sup> set to 0.4. Then one computes in step 2 the modified plausibility bounds  $Bel'(\theta_1) = 0.0001, Pl'(\theta_1) = 0.0001 + 0.0001 + \lambda = 0.4002$  and  $Bel'(\theta_2) = 0.9998 - 0.4 = 0.5998, Pl'(\theta_2) = 0.9999$ . So we get  $[Bel'(\theta_1), Pl'(\theta_1)] = [0.0001, 0.4002]$  and  $[Bel'(\theta_2), Pl'(\theta_2)] = [0.5998, 0.9999]$ .

Consequently, any Bayesian BBA  $P_t^j = [m'(\theta_1), m'(\theta_2)]$  must be generated according the (modified) compatibility constraints

$$\begin{aligned} m'(\theta_1) &\in [Bel'(\theta_1), Pl'(\theta_1)] = [0.0001, 0.4002] \\ m'(\theta_2) &\in [Bel'(\theta_2), Pl'(\theta_2)] = [0.5998, 0.9999] \end{aligned}$$

#### The pathological case 2 for TTT (using modified EPT)

$$m_{target}(\cdot) = [\theta_1, \theta_2, \theta_1 \cup \theta_2] = [0.45, 0.48, 0.07].$$

Here, the parameter  $\lambda$  is set to 0.2. Then any Bayesian BBA  $P_t^j = [m'(\theta_1), m'(\theta_2)]$  must be generated according the (modified) compatibility constraints

$$\begin{aligned} m'(\theta_1) &\in [Bel'(\theta_1), Pl'(\theta_1)] = [0.45, 0.72] \\ m'(\theta_2) &\in [Bel'(\theta_2), Pl'(\theta_2)] = [0.28, 0.55] \end{aligned}$$

In order to evaluate the influence of the parameter  $\lambda$ , we have reexamined all the pathological cases based on the following procedure:

- 1) The value of parameter  $\lambda$  is taken to five possible values: 0, 0.1, 0.2, 0.3, 0.4, 0.5;
- 2) We randomly generate initial population  $\mathbf{P}_t$  based on  $\lambda$ , which is also subjected to the constraints (12)–(14).

<sup>5</sup>The value of the parameter  $\lambda$  can be chosen to any value in  $[0, 1]$  by the designer for his/her own reason to ensure the alternative interval effectively in modified EPT version.

With this simulation, we can observe in Fig.4 the impact of  $\lambda$  value on the number of  $P_t^j$  in  $\mathbf{P}_t$ . When  $\lambda = 0$  happens <sup>6</sup>, there exists no suitable  $P_t^j$  for case one which demonstrates the necessity to circumvent the pathological case problem. Obviously, the number of  $P_t^j$  increases with the increase of  $\lambda$  value, which efficiently proves the advantage of using the modified EPT approach to make selection step of the evolutionary algorithm more efficient. One point we need to clarify is that the intervals i.e.  $[Bel'(\theta_1), Pl'(\theta_1)]$ ,  $[Bel'(\theta_2), Pl'(\theta_2)]$  induced from parameter  $\lambda$  above aims at guaranteeing enough number of  $P_t^j$  in  $\mathbf{P}_t$  in the implementation of EPT.

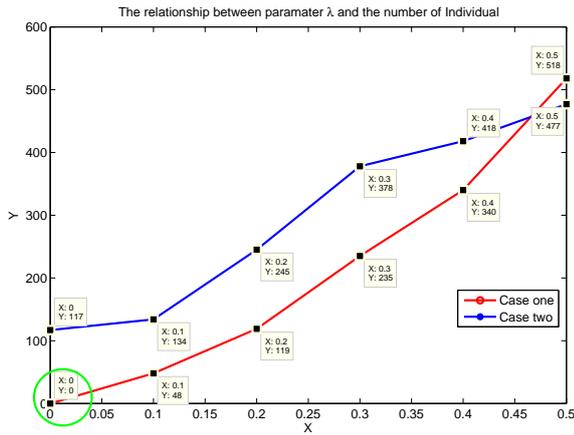

Figure 4: Impact of  $\lambda$  (x-axis) on individuals in  $\mathbf{P}_t$  (y-axis).

3) *Simulation Results of TTT Based on Modified EPT*: Our simulation consists in 100 Monte-Carlo runs and we show in the sequel the averaged performances of EPT and DSMP. The figures 5–8 illustrate the Bayesian BBA’s obtained by DSMP [7] -(part a) and our new EPT method-(part b) based on TTT using PCR6 fusion rule. One sees that regardless of the good classifier  $M_1$  and poor classifier  $M_2$ , EPT is able to track properly the quick changes of target type.

### V. LIMITATION OF EPT

As pointed out by Han et al. in [14], in general it is not enough, nor comprehensive to evaluate the quality of probabilistic transformation of a BBA from only the PIC criterion, even if the chosen PT provides highest PIC value by optimization. Our EPT approach, is not exempt of this problem of course as we can see in the simple example below, where no optimization technique provides useful (robust) solution.

Let’s consider the FoD  $\Theta = \{\theta_1, \theta_2\}$  with the BBA to approximate chosen as follows:

$$m(\theta_1) = 0.10001, m(\theta_2) = 0.10000, m(\theta_1 \cup \theta_2) = 0.79999$$

Based on PIC value optimization using EPT (or any other efficient optimization techniques), we will obtain the Bayesian

<sup>6</sup>which actually the original EPT is applied

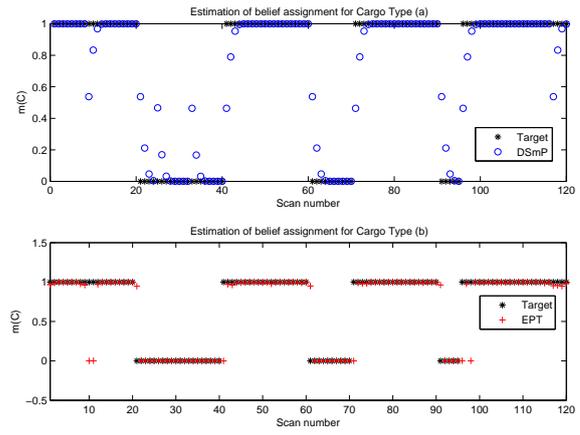

Figure 5: Belief Mass for Cargo Type for  $M_1$ .

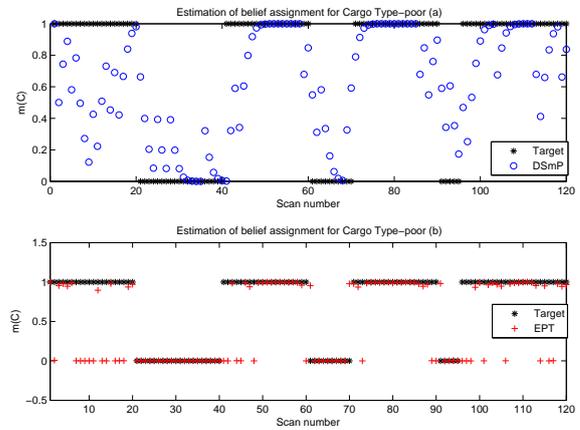

Figure 6: Belief Mass for Cargo Type for  $M_2$ .

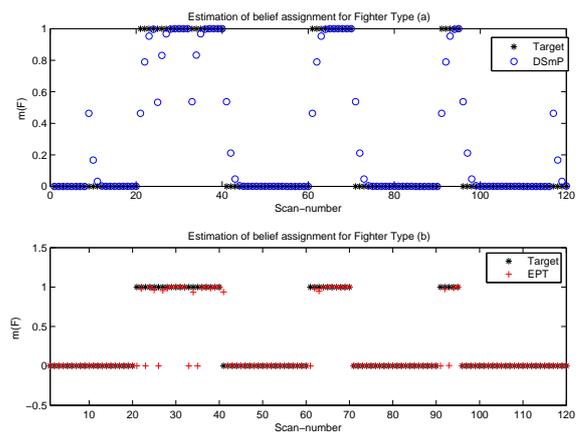

Figure 7: Belief Mass for Fighter Type for  $M_1$ .

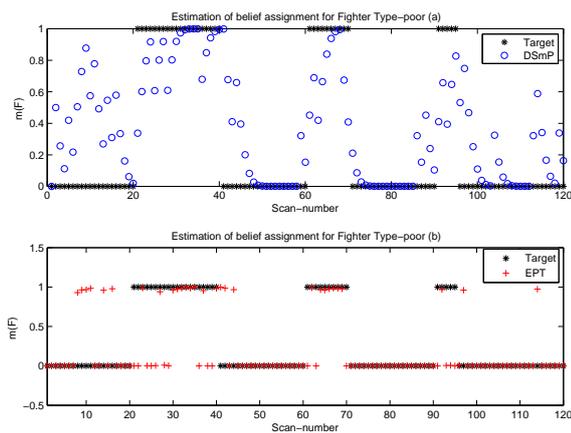

Figure 8: Belief Mass for Fighter Type for  $M_2$ .

BBA  $m(\theta_1, \theta_2) = [0.0001605, 0.9998394]$  with  $PIC = 0.9977$ . This simple example shows that in the original BBA  $m(\theta_1)$  is almost the same as  $m(\theta_2)$  and there is no solid reason to get a very high probability for  $\theta_2$  and a small one for  $\theta_1$  in the Bayesian BBA, even if a highest PIC is reached. Exaggerated high PIC is not always preferred (unreasonable or directly make wrong decisions), which can be seen in Fig.6 and Fig.8, although the PIC should be as high as possible for decision making problems. Therefore, a reasonable compromise must be found between PIC level and also fidelity level of the transformations to the original BBA, which is a theoretical open challenging problem left for further research works.

## VI. CONCLUSION

An evolutionary algorithm for probabilistic transformation (EPT) has been proposed in this paper. It uses the genetic algorithm to obtain Bayesian belief function with highest PIC value. The utility of EPT was verified on a set of three probabilistic transformation cases borrowed from the literature. On these cases, the performance of EPT has been compared to other existing probabilistic transformations. Our results indicate that EPT performs better than others on all problems from PIC increasing standpoint. The shortcomings of original EPT version have been clearly identified on two type tracking problems, and they have been overcome thanks to a modification of belief interval constraints. As future works, we would like to establish more appropriate evaluation criteria and make more comparisons between performances of this EPT approach with other recent proposed evolutionary algorithms. We would also make more investigations on EPT to extend it to work with more than two targets.

**Abstract**—In many applications involving epistemic uncertainties usually modeled by belief functions, it is often necessary to approximate general (non-Bayesian) basic belief assignments (BBAs) to subjective probabilities (called Bayesian BBAs). This necessity occurs if one needs to embed the fusion result in a system based on the probabilistic framework and Bayesian inference (e.g. tracking systems), or if one wants to use classical decision theory to make a decision. There exists already several methods (probabilistic transforms) to approximate any general BBA to a Bayesian BBA. From a fusion standpoint, two approaches are usually adopted: 1) one can approximate at first each BBA in subjective probabilities and use Bayes fusion rule to get the final Bayesian BBA, or 2) one can fuse all the BBAs with a fusion rule, typically Dempster-Shafer's, or PCR6 rules (which is very costly in computations), and convert the combined BBA in a subjective probability measure. The former method is the simplest method but it generates a high loss of information included in original BBAs, whereas the latter is intractable for high dimension problems. This paper presents a new method to achieve this task based on hierarchical decomposition (coarsening) of the frame of discernment, which can be seen as an intermediary approach between the two aforementioned methods. After the presentation of this new method, we show through simulations how it performs with respect to other methods.

**Keywords:** Information fusion, belief functions, DST, DSMT, PCR6 rule, coarsening.

## I. INTRODUCTION

The theory of belief functions, known as Dempster-Shafer Theory (DST) has been developed by Shafer [1] in 1976 from Dempster's works [2]. Belief functions allow to model epistemic uncertainty and they have been already used in many applications since the 1990's [3], mainly those related to expert systems, decision-making support and information fusion. To palliate some limitations of DST, Dezert and Smarandache have proposed an extended mathematical framework of belief functions with new efficient quantitative and qualitative rules of combinations, which is called DSMT (Dezert and Smarandache Theory) in the literature [4], [5] with applications listed in [6]. One of the major drawbacks of DST and DSMT is their high computational complexities, as soon as the fusion space (i.e. frame of discernment - FoD) and the number of sources to combine are large<sup>1</sup>.

<sup>1</sup>DSMT is more complex than DST, and the Proportional Conflict Redistribution rule #6 (PCR6 rule) becomes computationally intractable in the worst case as soon as the cardinality of the Frame of Discernment (FoD) is greater than six.

To reduce the computational cost of operations with belief functions when the number of focal elements is very large, several approaches have been proposed by different authors. Basically, the existing approaches rely either on efficient implementations of computations as proposed for instance in [7], [8], or on approximation techniques of original Basic Belief Assignment (BBA) to combine [9]–[12], or both. In many applications involving epistemic uncertainties usually modeled by belief functions, it is often necessary to approximate general (non-Bayesian) basic belief assignments (BBAs) to subjective probabilities (called Bayesian BBAs). This necessity occurs if one needs to embed the fusion result in a system based on the probabilistic framework and Bayesian inference (e.g. tracking systems), or if one wants to use classical decision theory to make a decision. From a fusion standpoint, two approaches are usually adopted: 1) one can approximate at first each BBA in subjective probabilities and use Bayes fusion rule to get the final Bayesian BBA, or 2) one can fuse all the BBAs with a fusion rule, typically Dempster-Shafer's, or PCR6 rules (which is very costly in computations), and convert the combined BBA in a subjective probability measure. The former method is the simplest method but it generates a high loss of information included in original BBAs, whereas the latter direct method is intractable for high dimension problems. This paper presents a new method to achieve this task based on hierarchical decomposition (coarsening) of the frame of discernment, which can be seen as an intermediary approach between the two aforementioned methods.

This paper presents a new approach to fuse BBAs into a Bayesian BBA in order to reduce computational burden and keep the fusion tractable even for large dimension problems. This method is based on a hierarchical decomposition (coarsening) framework which allows to keep as much as possible information of original BBAs in preserving lower complexity. The main contributions of this paper are:

- 1) the presentation of the FoD bintree decomposition on which will be done the BBAs approximations;
- 2) the presentation of the fusion of approximate BBAs from bintree representation.

This hierarchical structure allows to encompass bintree decomposition and BBAs approximations on it to obtain the final approximate fusionned Bayesian BBA.

This paper is organized as follows. In section II, we recall some basics of DST and DSMT that are relevant to the new method presented in this paper. More details with examples can easily be found in [1], [5]. We will also briefly recall our preliminary works about hierarchical coarsening of FoD. Section III presents the novel hierarchical flexible (adaptive) coarsening method which can be regarded as the extension of our previous works. Two simple examples are given in section IV to illustrate the detailed calculation steps. Simulation experiments are presented in section V to show the rationality of this new approach. Finally, Sect.VI concludes the paper with future works perspectives.

## II. MATHEMATICAL BACKGROUND

This section provides a brief reminder of basics of DST and DSMT, and of original hierarchical coarsening method which are necessary for the presentation and the understanding of the more general flexible coarsening approximate method of section III.

### A. Basics of DST and DSMT

In DST framework, the frame of discernment<sup>2</sup>  $\Theta \triangleq \{\theta_1, \dots, \theta_n\}$  ( $n \geq 2$ ) is a set of exhaustive and exclusive elements (hypotheses) which represent the possible solutions of the problem under consideration and thus Shafer's model assumes  $\theta_i \cap \theta_j = \emptyset$  for  $i \neq j$  in  $\{1, \dots, n\}$ . A basic belief assignment (BBA)  $m(\cdot)$  is defined by the mapping:  $2^\Theta \mapsto [0, 1]$ , verifying  $m(\emptyset) = 0$  and  $\sum_{A \in 2^\Theta} m(A) = 1$ . In DSMT, one can abandon Shafer's model (if Shafer's model doesn't fit with the problem) and refute the principle of the third excluded middle<sup>3</sup>. Instead of defining the BBAs on the power set  $2^\Theta \triangleq (\Theta, \cup)$  of the FoD, the BBAs are defined on the so-called *hyper-power set* (or Dedekind's lattice) denoted  $D^\Theta \triangleq (\Theta, \cup, \cap)$  whose cardinalities follows Dedekind's numbers sequence, see [5], Vol.1 for details and examples. A (generalized) BBA, called a mass function,  $m(\cdot)$  is defined by the mapping:  $D^\Theta \mapsto [0, 1]$ , verifying  $m(\emptyset) = 0$  and  $\sum_{A \in D^\Theta} m(A) = 1$ . DSMT framework encompasses DST framework because  $2^\Theta \subset D^\Theta$ . In DSMT we can take into account also a set of *integrity constraints* on the FoD (if known), by specifying all the pairs of elements which are really disjoint. Stated otherwise, Shafer's model is a specific DSMT model where all elements are known to be disjoint.  $A \in D^\Theta$  is called a focal element of  $m(\cdot)$  if  $m(A) > 0$ . A BBA is called a Bayesian BBA if all of its focal elements are singletons and Shafer's model is assumed, otherwise it is called non-Bayesian [1]. A full ignorance source is represented by the vacuous BBA  $m_v(\Theta) = 1$ . The belief (or credibility) and plausibility functions are respectively defined by  $Bel(X) \triangleq \sum_{Y \in D^\Theta | Y \subseteq X} m(Y)$  and  $Pl(X) \triangleq \sum_{Y \in D^\Theta | Y \cap X \neq \emptyset} m(Y)$ .  $BI(X) \triangleq [Bel(X), Pl(X)]$  is called the belief interval of  $X$ . Its length  $U(X) \triangleq Pl(X) - Bel(X)$  measures the degree of uncertainty of  $X$ .

<sup>2</sup>We use the symbol  $\triangleq$  to mean equals by definition.

<sup>3</sup>The third excluded middle principle assumes the existence of the complement for any elements/propositions belonging to the power set  $2^\Theta$ .

In 1976, Shafer did propose Dempster's rule<sup>4</sup> to combine BBAs in DST framework. DS rule is defined by  $m_{DS}(\emptyset) = 0$  and  $\forall A \in 2^\Theta \setminus \{\emptyset\}$ ,

$$m_{DS}(A) = \frac{\sum_{B, C \in 2^\Theta | B \cap C = A} m_1(B)m_2(C)}{1 - \sum_{B, C \in 2^\Theta | B \cap C = \emptyset} m_1(B)m_2(C)} \quad (1)$$

DS rule formula is commutative and associative and can be easily extended to the fusion of  $S > 2$  BBAs. Unfortunately, DS rule has been highly disputed during the last decades by many authors because of its counter-intuitive behavior in high or even low conflict situations, and that is why many rules of combination have been proposed in the literature to combine BBAs [13]. To palliate DS rule drawbacks, the very interesting PCR6 (Proportional Conflict redistribution rule #6) has been proposed in DSMT and it is usually adopted<sup>5</sup> in recent applications of DSMT. The fusion of two BBAs  $m_1(\cdot)$  and  $m_2(\cdot)$  by the PCR6 rule is obtained by  $m_{PCR6}(\emptyset) = 0$  and  $\forall A \in D^\Theta \setminus \{\emptyset\}$

$$m_{PCR6}(A) = m_{12}(A) + \sum_{B \in D^\Theta \setminus \{A\} | A \cap B = \emptyset} \left[ \frac{m_1(A)^2 m_2(B)}{m_1(A) + m_2(B)} + \frac{m_2(A)^2 m_1(B)}{m_2(A) + m_1(B)} \right] \quad (2)$$

where  $m_{12}(A) = \sum_{B, C \in D^\Theta | B \cap C = A} m_1(B)m_2(C)$  is the conjunctive operator, and each element  $A$  and  $B$  are expressed in their disjunctive normal form. If the denominator involved in the fraction is zero, then this fraction is discarded. The general PCR6 formula for combining more than two BBAs altogether is given in [5], Vol. 3. We adopt the generic notation  $m_{12}^{PCR6}(\cdot) = PCR6(m_1(\cdot), m_2(\cdot))$  to denote the fusion of  $m_1(\cdot)$  and  $m_2(\cdot)$  by PCR6 rule. PCR6 is not associative and PCR6 rule can also be applied in DST framework (with Shafer's model of FoD) by replacing  $D^\Theta$  by  $2^\Theta$  in Eq. (2).

### B. Hierarchical coarsening for fusion of Bayesian BBAs

Here, we briefly recall the principle of hierarchical coarsening of FoD to reduce the computational complexity of PCR6 combination of original Bayesian BBAs. The fusion of original non-Bayesian BBAs will be presented in the next section.

This principle was called *rigid grouping* in our previous works [17]–[19]. The goal of this coarsening is to replace the original (refined) Frame of Discernment (FoD)  $\Theta$  by a set of coarsened ones to make the computation of PCR6 rule tractable. Because we consider here only Bayesian BBA to combine, their focal elements are only singletons of the FoD  $\Theta \triangleq \{\theta_1, \dots, \theta_n\}$ , with  $n \geq 2$ , and we assume Shafer's model of the FoD  $\Theta$ .

A coarsening of the FoD  $\Theta$  means to replace it with another FoD less specific of smaller dimension  $\Omega = \{\omega_1, \dots, \omega_k\}$  with  $k < n$  from the elements of  $\Theta$ . This can be done in many ways depending the problem under consideration. Generally, the elements of  $\Omega$  are singletons of  $\Theta$ , and disjunctions of

<sup>4</sup>We use DS index to refer to Dempster-Shafer's rule (DS rule) because Shafer did really promote Dempster's rule in his milestone book [1].

<sup>5</sup>PCR6 rule coincides with PCR5 when combining only two BBAs [5].

elements of  $\Theta$ . For example, if  $\Theta = \{\theta_1, \theta_2, \theta_3, \theta_4\}$ , then the possible coarsened frames built from  $\Theta$  could be, for instance,  $\Omega = \{\omega_1 = \theta_1, \omega_2 = \theta_2, \omega_3 = \theta_3 \cup \theta_4\}$ , or  $\Omega = \{\omega_1 = \theta_1 \cup \theta_2, \omega_2 = \theta_3 \cup \theta_4\}$ , etc. When dealing with Bayesian BBAs, the projection<sup>6</sup>  $m^\Omega(\cdot)$  of the original BBA  $m^\Theta(\cdot)$  is simply obtained by taking

$$m^\Omega(\omega_i) = \sum_{\theta_j \subseteq \omega_i} m^\Theta(\theta_j) \quad (3)$$

The hierarchical coarsening process (or rigid grouping) is a simple dichotomous approach of coarsening obtained as follows:

- If  $n = |\Theta|$  is an even number:

The disjunction of the  $n/2$  first elements  $\theta_1$  to  $\theta_{n/2}$  of  $\Theta$  define the element  $\omega_1$  of  $\Omega$ , and the last  $n/2$  elements  $\theta_{n/2+1}$  to  $\theta_n$  of  $\Theta$  define the element  $\omega_2$  of  $\Omega$ , that is

$$\Omega \triangleq \{\omega_1 = \theta_1 \cup \dots \cup \theta_{n/2}, \omega_2 = \theta_{n/2+1} \cup \dots \cup \theta_n\}$$

and based on (3), one has

$$m^\Omega(\omega_1) = \sum_{j=1, \dots, n/2} m^\Theta(\theta_j) \quad (4)$$

$$m^\Omega(\omega_2) = \sum_{j=n/2+1, \dots, n} m^\Theta(\theta_j) \quad (5)$$

For example, if  $\Theta = \{\theta_1, \theta_2, \theta_3, \theta_4\}$ , and one considers the Bayesian BBA  $m^\Theta(\theta_1) = 0.1$ ,  $m^\Theta(\theta_2) = 0.2$ ,  $m^\Theta(\theta_3) = 0.3$  and  $m^\Theta(\theta_4) = 0.4$ , then  $\Omega = \{\omega_1 = \theta_1 \cup \theta_2, \omega_2 = \theta_3 \cup \theta_4\}$  and  $m^\Omega(\omega_1) = 0.1 + 0.2 = 0.3$  and  $m^\Omega(\omega_2) = 0.3 + 0.4 = 0.7$ .

- If  $n = |\Theta|$  is an odd number:

In this case, the element  $\omega_1$  of the coarsened frame  $\Omega$  is the disjunction of the  $[n/2 + 1]$ <sup>7</sup> first elements of  $\Theta$ , and the element  $\omega_2$  is the disjunction of other elements of  $\Theta$ . That is

$$\Omega \triangleq \{\omega_1 = \theta_1 \cup \dots \cup \theta_{[n/2+1]}, \omega_2 = \theta_{[n/2+1]+1} \cup \dots \cup \theta_n\}$$

and based on (3), one has

$$m^\Omega(\omega_1) = \sum_{j=1, \dots, [n/2+1]} m^\Theta(\theta_j) \quad (6)$$

$$m^\Omega(\omega_2) = \sum_{j=[n/2+1]+1, \dots, n} m^\Theta(\theta_j) \quad (7)$$

For example, if  $\Theta = \{\theta_1, \theta_2, \theta_3, \theta_4, \theta_5\}$ , and one considers the Bayesian BBA  $m^\Theta(\theta_1) = 0.1$ ,  $m^\Theta(\theta_2) = 0.2$ ,  $m^\Theta(\theta_3) = 0.3$ ,  $m^\Theta(\theta_4) = 0.3$  and  $m^\Theta(\theta_5) = 0.1$ , then  $\Omega = \{\omega_1 = \theta_1 \cup \theta_2 \cup \theta_3, \omega_2 = \theta_4 \cup \theta_5\}$  and  $m^\Omega(\omega_1) = 0.1 + 0.2 + 0.3 = 0.6$  and  $m^\Omega(\omega_2) = 0.3 + 0.1 = 0.4$ .

Of course, the same coarsening applies to all original BBAs  $m_s^\Theta(\cdot)$ ,  $s = 1, \dots, S$  of the  $S > 1$  sources of evidence to work with less specific BBAs  $m_s^\Omega(\cdot)$ ,  $s = 1, \dots, S$ . The less specific

<sup>6</sup>For clarity and convenience, we put explicitly as upper index the FoD of which the belief mass refers.

<sup>7</sup>The notation  $[x]$  means the integer part of  $x$ .

BBAs (called coarsened BBAs by abuse of language) can then be combined with PCR6 rule of combination according to formula (2). This dichotomous coarsening method is repeated iteratively  $l$  times as schematically represented by a bintree<sup>8</sup>. The last step of this hierarchical process is to calculate the combined (Bayesian) BBA of all focal elements according to the connection weights of the bintree structure, where the number of iterations (or layers)  $l$  of the tree depends on the cardinality  $|\Theta|$  of the original FoD  $\Theta$ . Specifically, the assignment of each focal element is updated according to the connection weights of link paths from root to terminal nodes. This principle is illustrated in details in the following example.

**Example 1:** Let's consider  $\Theta = \{\theta_1, \theta_2, \theta_3, \theta_4, \theta_5\}$ , and the following three Bayesian BBAs

Focal elem.	$m_1^\Theta(\cdot)$	$m_2^\Theta(\cdot)$	$m_3^\Theta(\cdot)$
$\theta_1$	0.1	0.4	0
$\theta_2$	0.2	0	0.1
$\theta_3$	0.3	0.1	0.5
$\theta_4$	0.3	0.1	0.4
$\theta_5$	0.1	0.4	0

The hierarchical coarsening and fusion of BBAs is obtained from the following steps:

**Step 1:** We define the bintree structure based on iterative half split of FoD as shown in Fig. 1.

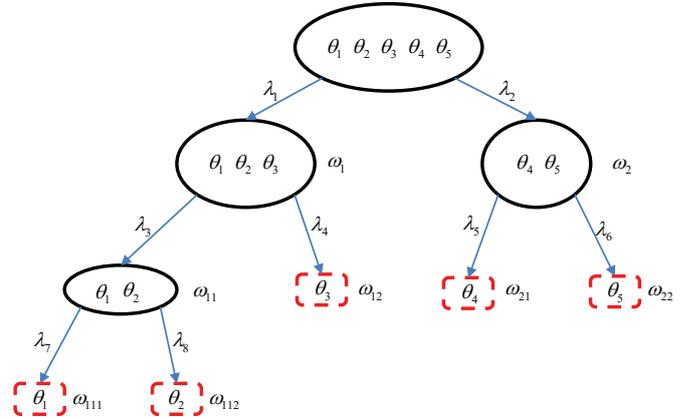

Figure 1: Fusion of Bayesian BBAs using bintree coarsening for Example 1.

The connecting weights are denoted as  $\lambda_1, \dots, \lambda_8$ . The elements of the frames  $\Omega_l$  are defined as follows:

- At layer  $l = 1$ :  $\Omega_1 = \{\omega_1 \triangleq \theta_1 \cup \theta_2 \cup \theta_3, \omega_2 \triangleq \theta_4 \cup \theta_5\}$
- At layer  $l = 2$ :

$$\Omega_2 = \{\omega_{11} \triangleq \theta_1 \cup \theta_2, \omega_{12} \triangleq \theta_3, \omega_{21} \triangleq \theta_4, \omega_{22} \triangleq \theta_5\}$$

- At layer  $l = 3$ :  $\Omega_3 = \{\omega_{111} \triangleq \theta_1, \omega_{112} \triangleq \theta_2\}$

<sup>8</sup>Here we consider bintree only for simplicity, which means that the coarsened frame  $\Omega$  consists of two elements only. Of course a similar method can be used with tri-tree, quad-tree, etc.

**Step 2:** The BBAs of elements of the (sub-)frames  $\Omega_l$  are obtained as follows:

- At layer  $l = 1$ , we use (6)-(7) because  $|\Theta| = 5$  is an odd number. Therefore, we get

Focal elem.	$m_1^{\Omega_1}(\cdot)$	$m_2^{\Omega_1}(\cdot)$	$m_3^{\Omega_1}(\cdot)$
$\omega_1 \triangleq \theta_1 \cup \theta_2 \cup \theta_3$	0.6	0.5	0.6
$\omega_2 \triangleq \theta_4 \cup \theta_5$	0.4	0.5	0.4

- At layer  $l = 2$ : We work with the two subframes  $\Omega_{21} \triangleq \{\omega_{11}, \omega_{12}\}$  and  $\Omega_{22} \triangleq \{\omega_{21}, \omega_{22}\}$  of  $\Omega_2$  with the BBAs:

Focal elem.	$m_1^{\Omega_{21}}(\cdot)$	$m_2^{\Omega_{21}}(\cdot)$	$m_3^{\Omega_{21}}(\cdot)$
$\omega_{11} \triangleq \theta_1 \cup \theta_2$	$\frac{1}{2}$	$\frac{4}{5}$	$\frac{1}{6}$
$\omega_{12} \triangleq \theta_3$	$\frac{1}{2}$	$\frac{1}{5}$	$\frac{5}{6}$
Focal elem.	$m_1^{\Omega_{22}}(\cdot)$	$m_2^{\Omega_{22}}(\cdot)$	$m_3^{\Omega_{22}}(\cdot)$
$\omega_{21} \triangleq \theta_4$	$\frac{3}{4}$	$\frac{1}{5}$	1
$\omega_{22} \triangleq \theta_5$	$\frac{1}{4}$	$\frac{4}{5}$	0

These mass values are obtained by the proportional redistribution of the mass of each focal element with respect to the mass of its parent focal element in the bin tree. For example, the value  $m_2^{\Omega_{21}}(\omega_{11}) = 4/5$  is derived by taking

$$m_2^{\Omega_{21}}(\omega_{11}) = \frac{m_2^\Theta(\theta_1) + m_2^\Theta(\theta_2)}{m_2^\Theta(\theta_1) + m_2^\Theta(\theta_2) + m_2^\Theta(\theta_3)} = \frac{0.4}{0.5} = \frac{4}{5}$$

Other mass values are computed similarly using this proportional redistribution method.

- At layer  $l = 3$ : We use again the proportional redistribution method which gives us

Focal elem.	$m_1^{\Omega_3}(\cdot)$	$m_2^{\Omega_3}(\cdot)$	$m_3^{\Omega_3}(\cdot)$
$\omega_{111} \triangleq \theta_1$	$\frac{1}{3}$	1	0
$\omega_{112} \triangleq \theta_2$	$\frac{2}{3}$	0	1

**Step 3:** The connection weights  $\lambda_i$  are computed from the assignments of coarsening elements. In each layer  $l$ , we fuse sequentially<sup>9</sup> the three BBAs using PCR6 formula (2). More precisely, we compute at first  $m_{12}^{PCR6, \Omega_l}(\cdot) = PCR6(m_1^{\Omega_l}(\cdot), m_2^{\Omega_l}(\cdot))$  and then  $m_{(12)3}^{PCR6, \Omega_l}(\cdot) = PCR6(m_{12}^{PCR6, \Omega_l}(\cdot), m_3^{\Omega_l}(\cdot))$ . Hence, we obtain the following connecting weights in the bintree:

- At layer  $l = 1$ :

$$\lambda_1 = m_{(12)3}^{PCR6, \Omega_1}(\omega_1) = 0.6297$$

$$\lambda_2 = m_{(12)3}^{PCR6, \Omega_1}(\omega_2) = 0.3703$$

- At layer  $l = 2$ :

$$\lambda_3 = m_{(12)3}^{PCR6, \Omega_{21}}(\omega_{11}) = 0.4137$$

$$\lambda_4 = m_{(12)3}^{PCR6, \Omega_{21}}(\omega_{12}) = 0.5863$$

$$\lambda_5 = m_{(12)3}^{PCR6, \Omega_{22}}(\omega_{21}) = 0.8121$$

$$\lambda_6 = m_{(12)3}^{PCR6, \Omega_{22}}(\omega_{22}) = 0.1879$$

<sup>9</sup>Because PCR6 fusion is not associative, we should apply the general PCR6 formula to get best results. Here we use sequential fusion to reduce the computational complexity even if the fusion result is approximate.

- At layer  $l = 3$ :

$$\lambda_7 = m_{(12)3}^{PCR6, \Omega_3}(\omega_{111}) = 0.3103$$

$$\lambda_8 = m_{(12)3}^{PCR6, \Omega_3}(\omega_{112}) = 0.6897$$

**Step 4:** The final assignment of belief mass to the elements of original FoD  $\Theta$  are calculated using the product of the connection weights of link paths from root (top) node to terminal nodes (leaves). We finally get the following *resulting combined and normalized* Bayesian BBA

$$m^\Theta(\theta_1) = \lambda_1 \cdot \lambda_3 \cdot \lambda_7 = 0.6297 \cdot 0.4137 \cdot 0.3103 = 0.0808$$

$$m^\Theta(\theta_2) = \lambda_1 \cdot \lambda_3 \cdot \lambda_8 = 0.6297 \cdot 0.4137 \cdot 0.6897 = 0.1797$$

$$m^\Theta(\theta_3) = \lambda_1 \cdot \lambda_4 = 0.6297 \cdot 0.5863 = 0.3692$$

$$m^\Theta(\theta_4) = \lambda_2 \cdot \lambda_5 = 0.3703 \cdot 0.8121 = 0.3007$$

$$m^\Theta(\theta_5) = \lambda_2 \cdot \lambda_6 = 0.3703 \cdot 0.1879 = 0.0696$$

### III. NEW HIERARCHICAL FLEXIBLE COARSENING METHOD

Contrary to the (rigid) hierarchical coarsening method presented in section II, in our new flexible coarsening approach the elements  $\theta_i$ ,  $i = 1, \dots, n$  in FoD  $\Theta$  will not be half split to build coarsening focal elements  $\omega_j$ ,  $j = 1, \dots, k$  of the FoD  $\Omega_l$ . In the hierarchical flexible (adaptive) coarsening method, the elements  $\theta_i$  chosen to belong to the same group are determined using the consensus information drawn from the BBAs provided by the sources. Specifically, the degrees of disagreement between the provided sources on decisions  $(\theta_1, \theta_2, \dots, \theta_n)$  are first calculated using the belief-interval based distance  $d_{BI}$  [16], [20] to obtain *disagreement vector*. Then, the k-means algorithm is applied for clustering elements  $\theta_i$ ,  $i = 1, \dots, n$  based on the corresponding value in consensus vector. It is worth noting that values of disagreement reflect the preferences of independent sources of evidence for the same focal element. If they are small, it means that all sources have a consistent opinion and these elements should be clustered in the same group. Conversely, if disagreement values are large, it means that the sources have strong disagreement on these focal elements, and these focal elements need to be clustered in another group.

#### A. Calculating the disagreement vector

Let us consider several BBAs  $m_s^\Theta(\cdot)$ , ( $s = 1, \dots, S$ ) defined on same FoD  $\Theta$  of cardinality  $|\Theta| = n$ . The specific BBAs  $m_{\theta_i}(\cdot)$ ,  $i = 1, \dots, n$  entirely focused on  $\theta_i$  are defined by  $m_{\theta_i}(\theta_i) = 1$ , and for  $X \neq \theta_i$   $m_{\theta_i}(X) = 0$ . The disagreement of opinions of two sources about  $\theta_i$  is defined as the  $L_1$ -distance between the  $d_{BI}$  distances of the BBAs  $m_s^\Theta(\cdot)$ ,  $s = 1, 2$  to  $m_{\theta_i}(\cdot)$ , which is expressed by

$$D_{12}(\theta_i) \triangleq |d_{BI}(m_1^\Theta(\cdot), m_{\theta_i}(\cdot)) - d_{BI}(m_2^\Theta(\cdot), m_{\theta_i}(\cdot))| \quad (8)$$

The disagreement of opinions of  $S \geq 3$  sources about  $\theta_i$ , is defined as

$$D_{1-S}(\theta_i) \triangleq \frac{1}{2} \sum_{i=1}^S \sum_{j=1}^S |d_{BI}(m_i^\Theta(\cdot), m_{\theta_i}(\cdot)) - d_{BI}(m_j^\Theta(\cdot), m_{\theta_i}(\cdot))| \quad (9)$$

where  $d_{BI}$  distance is defined by<sup>10</sup> [20]

$$d_{BI}^E(m_1, m_2) \triangleq \sqrt{n_c \cdot \sum_{i=1}^{2^n-1} [d^I(BI_1(\theta_i), BI_2(\theta_i))]^2} \quad (10)$$

Here,  $n_c = 1/2^{n-1}$  is the normalization constant and  $d^I([a, b], [c, d])$  is the Wasserstein's distance defined by  $d^I([a, b], [c, d]) = \sqrt{[\frac{a+b}{2} - \frac{c+d}{2}]^2 + \frac{1}{3}[\frac{b-a}{2} - \frac{d-c}{2}]^2}$ . And  $BI(\theta_i) = [Bel(\theta_i), Pl(\theta_i)]$ .

The disagreement vector  $\mathbf{D}_{1-S}$  is defined by

$$\mathbf{D}_{1-S} \triangleq [D_{1-S}(\theta_1), \dots, D_{1-S}(\theta_n)] \quad (11)$$

### B. Clustering focal elements

Once  $\mathbf{D}_{1-S}$  is derived, a clustering algorithm is used to coarsen focal elements according to their corresponding values in  $\mathbf{D}_{1-S}$ . In this paper, we have used the k-means algorithm<sup>11</sup> to cluster focal elements. For each source  $s = 1, \dots, S$ , the mass assignments of focal elements in two<sup>12</sup> different clusters are added up according to formulas (12)–(13).

$$m_s^\Omega(\omega_1) = \sum_{\theta_i \in \omega_1} m^\Theta(\theta_i) \quad (12)$$

$$m_s^\Omega(\omega_2) = \sum_{\theta_j \in \omega_2} m^\Theta(\theta_j) \quad (13)$$

### C. Combination of the BBAs

Based on the disagreement vector and k-means algorithm, a new adaptive bintree structure based on this flexible coarsening decomposition is obtained (see example in the next section) and the elements in FoD  $\Theta$  are grouped more reasonably in each layer of the decomposition. Once the adaptive bintree structure is derived, other steps (multiplications of link weights) can be implemented which are identical to hierarchical (rigid) coarsening method presented in section II to get the final combined Bayesian BBA.

### D. Summary of the method

The fusion method of BBAs to get a combined Bayesian BBA based on hierarchical flexible decomposition of the FoD consists of the four steps below illustrated in Fig. 2.

- **Step 1 (pre-processing):** At first, all input BBAs to combine are approximated to Bayesian BBAs with DSMT transform.
- **Step 2 (disagreement vector):**  $\mathbf{D}_{1-S}(\cdot)$  is calculated using  $d_{BI}$  distances to estimate the degree of disagreement of BBAs  $m_1^\Theta, \dots, m_S^\Theta$  on potential decisions  $\theta_1, \dots, \theta_n$ .
- **Step 3 (adaptive bintree):** The adaptive bintree decomposition of the FoD  $\Theta$  is obtained using k-Means algorithm to get elements of subframes  $\Omega_l$ .
- **Step 4 (assignments and connection weights):** For each source  $m_s^\Theta(\cdot)$  to combine, the mass assignment of

<sup>10</sup>For simplicity, we assume Shafer's model so that  $|2^\Theta| = 2^n$ , otherwise the number of elements in the summation of (10) should be  $|D^\Theta| - 1$  with another normalization constant  $n_c$ .

<sup>11</sup>which is implemented in Matlab<sup>TM</sup>

<sup>12</sup>because we use here the bisection decomposition.

each element of subframe  $\Omega_l$  is computed by (12)–(13). The weight of links between two layers of the bintree decomposition are obtained with PCR6 rule<sup>13</sup>.

- **Step 5 (fusion):** The final result (combined Bayesian BBA) is computed by the product of weights of link paths from root to terminal nodes.

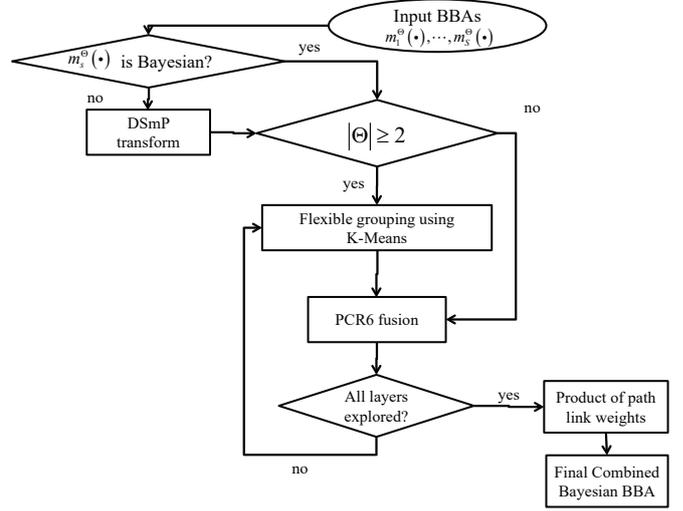

Figure 2: Hierarchical flexible decomposition of FoD for fusion.

## IV. TWO SIMPLE EXAMPLES

### A. Example 1 (fusion of Bayesian BBAs)

Let us revisit example 1 presented in section II-B. It can be verified in applying formula (9) that the disagreement vector  $\mathbf{D}_{1-3}$  for this example is equal to

$$\mathbf{D}_{1-3} = [0.4085, 0.2156, 0.3753, 0.2507, 0.4086]$$

The derivation of  $D_{1-3}(\theta_1)$  is given below for convenience.

$$\begin{aligned} D_{1-3}(\theta_1) &= |d_{BI}(m_1^\Theta(\cdot), m_{\theta_1}(\theta_1)) - d_{BI}(m_2^\Theta(\cdot), m_{\theta_1}(\theta_1))| \\ &\quad + |d_{BI}(m_2^\Theta(\cdot), m_{\theta_1}(\theta_1)) - d_{BI}(m_3^\Theta(\cdot), m_{\theta_1}(\theta_1))| \\ &\quad + |d_{BI}(m_1^\Theta(\cdot), m_{\theta_1}(\theta_1)) - d_{BI}(m_3^\Theta(\cdot), m_{\theta_1}(\theta_1))| \\ &= 0.4085. \end{aligned}$$

Based on the disagreement vector and k-means algorithm, a new adaptive bintree structure is obtained and shown in Fig. 3. Compared to Fig. 1, the elements in FoD  $\Theta$  are grouped more reasonably. In vector  $\mathbf{D}_{1-3}$ ,  $\theta_1$  and  $\theta_5$  lie in similar degree of disagreement so that they are put in the same group. Similarly for  $\theta_2$  and  $\theta_4$ . However, element  $\theta_3$  seems *weird*, which is put alone at the beginning of flexible coarsening. Once this adaptive bintree decomposition is obtained, other steps can be implemented which are identical to hierarchical coarsening method of section II to get the final combined BBA.

The flexible coarsening and fusion of BBAs is obtained from the following steps:

<sup>13</sup>general formula preferred, or applied sequentially to reduce complexity.

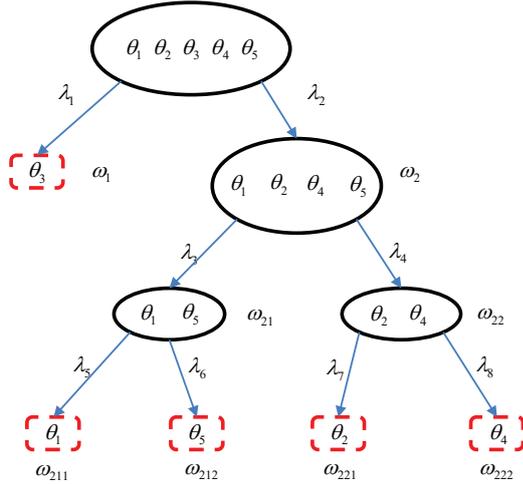

Figure 3: Example 1: Flexible bintree decomposition of FoD.

**Step 1:** According to Fig.3, the elements of the frames  $\Omega_l$  are defined as follows:

- At layer  $l = 1$ :  $\Omega_1 = \{\omega_1 \triangleq \theta_3, \omega_2 \triangleq \theta_1 \cup \theta_2 \cup \theta_4 \cup \theta_5\}$
- At layer  $l = 2$ :  $\Omega_2 = \{\omega_{21} \triangleq \theta_1 \cup \theta_5, \omega_{22} \triangleq \theta_2 \cup \theta_4\}$
- At layer  $l = 3$ :  $\Omega_3 = \{\omega_{211} \triangleq \theta_1, \omega_{212} \triangleq \theta_5, \omega_{221} \triangleq \theta_2, \omega_{222} \triangleq \theta_4\}$

**Step 2:** The BBAs of elements of the (sub-)frames  $\Omega_l$  are obtained as follows:

- At layer  $l = 1$ , we use (12)-(13) and we get

Focal elem.	$m_1^{\Omega_1}(\cdot)$	$m_2^{\Omega_1}(\cdot)$	$m_3^{\Omega_1}(\cdot)$
$\omega_1 \triangleq \theta_3$	0.3	0.1	0.5
$\omega_2 \triangleq \theta_1 \cup \theta_2 \cup \theta_4 \cup \theta_5$	0.7	0.9	0.5

- At layer  $l = 2$ : We use again the proportional redistribution method which gives us:

Focal elem.	$m_1^{\Omega_2}(\cdot)$	$m_2^{\Omega_2}(\cdot)$	$m_3^{\Omega_2}(\cdot)$
$\omega_{21} \triangleq \theta_1 \cup \theta_5$	$\frac{3}{7}$	$\frac{4}{9}$	$\frac{1}{5}$
$\omega_{22} \triangleq \theta_2 \cup \theta_4$	$\frac{4}{7}$	$\frac{5}{9}$	$\frac{4}{5}$

- At layer  $l = 3$ : We work with the two subframes  $\Omega_{31} \triangleq \{\omega_{211}, \omega_{212}\}$  and  $\Omega_{32} \triangleq \{\omega_{221}, \omega_{222}\}$  of  $\Omega_3$  with the BBAs

Focal elem.	$m_1^{\Omega_{31}}(\cdot)$	$m_2^{\Omega_{31}}(\cdot)$	$m_3^{\Omega_{31}}(\cdot)$
$\omega_{211} \triangleq \theta_1$	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$
$\omega_{212} \triangleq \theta_5$	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$
Focal elem.	$m_1^{\Omega_{32}}(\cdot)$	$m_2^{\Omega_{32}}(\cdot)$	$m_3^{\Omega_{32}}(\cdot)$
$\omega_{221} \triangleq \theta_2$	$\frac{2}{3}$	0	$\frac{1}{3}$
$\omega_{222} \triangleq \theta_4$	$\frac{3}{5}$	1	$\frac{4}{5}$

**Step 3:** The connection weights  $\lambda_i$  are computed from the assignments of coarsening elements. Hence, we obtain the following connecting weights in the bintree:

- At layer  $l = 1$ :

$$\lambda_1 = 0.2226; \quad \lambda_2 = 0.7774.$$

- At layer  $l = 2$ :

$$\lambda_3 = 0.2200; \quad \lambda_4 = 0.7800.$$

- At layer  $l = 3$ :

$$\lambda_5 = 0.5; \quad \lambda_6 = 0.5; \quad \lambda_7 = 0.0669; \quad \lambda_8 = 0.9331.$$

**Step 4:** We finally get the following *resulting combined and normalized Bayesian BBA*

$$m^\Theta(\cdot) = \{0.0855, 0.0406, 0.2226, 0.5658, 0.0855\}.$$

**B. Example 2 (with non-Bayesian BBAs)**

**Example 1bis:** Let's consider  $\Theta = \{\theta_1, \theta_2, \theta_3, \theta_4, \theta_5\}$ , and the following BBAs given by

Focal elem.	$m_1^\Theta(\cdot)$	$m_2^\Theta(\cdot)$	$m_3^\Theta(\cdot)$
$\theta_1$	0.1	0.4	0
$\theta_2$	0.2	0	0
$\theta_3$	0.3	0.05	0
$\theta_4$	0.03	0.05	0
$\theta_5$	0.1	0.04	0
$\theta_1 \cup \theta_2$	0.1	0.04	0
$\theta_2 \cup \theta_3 \cup \theta_5$	0	0.02	0.1
$\theta_3 \cup \theta_4$	0.02	0.1	0.2
$\theta_1 \cup \theta_5$	0.1	0.3	0.2
$\Theta$	0.05	0	0.5

**Step 1 (Pre-Processing):** All these three BBAs are transformed into Bayesian BBAs with DSMP transform and the generated BBAs are illustrated as

Focal elem.	$m_1^\Theta(\cdot)$	$m_2^\Theta(\cdot)$	$m_3^\Theta(\cdot)$
$\theta_1$	0.1908	0.7127	0.2000
$\theta_2$	0.2804	0	0.1334
$\theta_3$	0.3387	0.1111	0.2333
$\theta_4$	0.0339	0.1	0.2000
$\theta_5$	0.1562	0.0761	0.2333

It can be verified in applying formula (9) that the disagreement vector  $\mathbf{D}_{1-3}$  for this example is equal to

$$\mathbf{D}_{1-3} = [0.5385, 0.3632, 0.3453, 0.2305, 0.2827]$$

**Step 2:** According to the clustering algorithm, the elements of the frames  $\Omega_l$  are defined as follows:

- At layer  $l = 1$ :  $\Omega_1 = \{\omega_1 \triangleq \theta_1, \omega_2 \triangleq \theta_2 \cup \theta_3 \cup \theta_4 \cup \theta_5\}$
- At layer  $l = 2$ :  $\Omega_2 = \{\omega_{21} \triangleq \theta_2 \cup \theta_3, \omega_{22} \triangleq \theta_4 \cup \theta_5\}$
- At layer  $l = 3$ :  $\Omega_3 = \{\omega_{211} \triangleq \theta_2, \omega_{212} \triangleq \theta_3, \omega_{221} \triangleq \theta_4, \omega_{222} \triangleq \theta_5\}$

**Step 3:** The BBAs of elements of the (sub-)frames  $\Omega_l$  are obtained as follows:

- At layer  $l = 1$ , we use (12)-(13) and we get

Focal elem.	$m_1^{\Omega_1}(\cdot)$	$m_2^{\Omega_1}(\cdot)$	$m_3^{\Omega_1}(\cdot)$
$\omega_1 \triangleq \theta_1$	0.1908	0.7127	0.2000
$\omega_2 \triangleq \theta_2 \cup \theta_3 \cup \theta_4 \cup \theta_5$	0.8092	0.2873	0.8000

- At layer  $l = 2$ : We use again the proportional redistribution method which gives us:

Focal elem.	$m_1^{\Omega_2}(\cdot)$	$m_2^{\Omega_2}(\cdot)$	$m_3^{\Omega_2}(\cdot)$
$\omega_{21} \triangleq \theta_2 \cup \theta_3$	0.7651	0.3867	0.4584
$\omega_{22} \triangleq \theta_4 \cup \theta_5$	0.2349	0.6133	0.5416

- At layer  $l = 3$ : We work with the two subframes  $\Omega_{31} \triangleq \{\omega_{211}, \omega_{212}\}$  and  $\Omega_{32} \triangleq \{\omega_{221}, \omega_{222}\}$  of  $\Omega_3$  with the BBAs:

Focal elem.	$m_1^{\Omega_{31}}(\cdot)$	$m_2^{\Omega_{31}}(\cdot)$	$m_3^{\Omega_{31}}(\cdot)$
$\omega_{211} \triangleq \theta_2$	0.4529	0	0.3638
$\omega_{212} \triangleq \theta_3$	0.5471	1	0.6362
Focal elem.	$m_1^{\Omega_{32}}(\cdot)$	$m_2^{\Omega_{32}}(\cdot)$	$m_3^{\Omega_{32}}(\cdot)$
$\omega_{221} \triangleq \theta_4$	0.1783	0.5679	0.4616
$\omega_{222} \triangleq \theta_5$	0.8217	0.4321	0.5384

**Step 4:** The connection weights  $\lambda_i$  are computed from the assignments of coarsening elements. Hence, we obtain the following connecting weights in the bintree:

- At layer  $l = 1$ :

$$\lambda_1 = 0.2345; \quad \lambda_2 = 0.7655.$$

- At layer  $l = 2$ :

$$\lambda_3 = 0.5533; \quad \lambda_4 = 0.4467.$$

- At layer  $l = 3$ :

$$\lambda_5 = 0.1606; \quad \lambda_6 = 0.8394;$$

$$\lambda_7 = 0.3349; \quad \lambda_8 = 0.6651.$$

**Step 5:** We finally get the following *resulting combined and normalized Bayesian BBA*

$$m^\ominus(\cdot) = \{0.2345, 0.0681, 0.3555, 0.1145, 0.2274\}.$$

## V. SIMULATION RESULTS AND PERFORMANCES

### A. Flexible Grouping of Singletons

1) *Similarity*:<sup>14</sup> Assuming that  $\Theta = \{\theta_1, \theta_2, \theta_3, \theta_4, \theta_5, \theta_6, \theta_7, \theta_8, \theta_9, \theta_{10}, \theta_{11}, \theta_{12}, \theta_{13}, \theta_{14}, \theta_{15}\}$  and first, we randomly generate 2 BBAs, denoted as  $m_1^\ominus(\cdot)$  and  $m_2^\ominus(\cdot)$ , which can be seen in Table I.

Table I: BBAs for Two Sources  $m_1^\ominus(\cdot)$  and  $m_2^\ominus(\cdot)$

	$\theta_1$	$\theta_2$	$\theta_3$	$\theta_4$	$\theta_5$
$m_1^\ominus(\cdot)$	0.1331	0.0766	0.0175	0.0448	0.0229
$m_2^\ominus(\cdot)$	0.1020	0.0497	0.1094	0.0612	0.0612
	$\theta_6$	$\theta_7$	$\theta_8$	$\theta_9$	$\theta_{10}$
$m_1^\ominus(\cdot)$	0.1142	0.0023	0.2254	0.1583	3.4959e-04
$m_2^\ominus(\cdot)$	0.0069	0.0070	0.0128	0.0833	0.0338
	$\theta_{11}$	$\theta_{12}$	$\theta_{13}$	$\theta_{14}$	$\theta_{15}$
$m_1^\ominus(\cdot)$	0.0075	0.0514	0.1121	0.0314	0.0021
$m_2^\ominus(\cdot)$	0.1180	0.1202	0.1351	0.0686	0.0309

In order to fully verify the similarity between hierarchical flexible coarsening method and PCR6 in DSMT, a new strict

<sup>14</sup>Similarity represents the approximate degree between fusion results using flexible coarsening and PCR6.

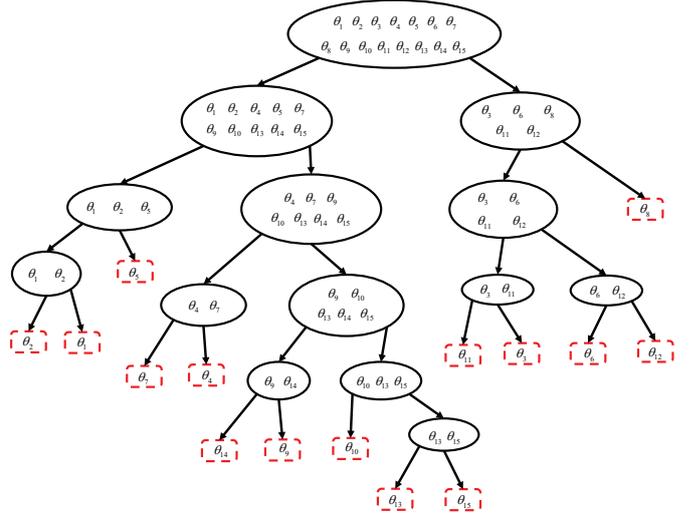

Figure 4: Structure of Hierarchical Flexible Coarsening.

distance metric between two BBAs, denoted  $d_{BI}^E$ , was recently proposed in [20], [16] and it will be used in this paper.

In this paper, we regard  $d_{BI}^E$  as one criteria for evaluating the degree of similarity between the fusion results obtained from flexible coarsening and PCR6.

Based on (8) and (10), the disagreement vector  $\mathbf{D}(\cdot)$  is obtained:

$$\mathbf{D}(\cdot) = (0.0032, 0.0020, 0.0290, 0.0092, 0.0147, 0.0228, \\ 0.0059, 0.0537, 0.0154, 0.0131, 0.0338, 0.0235, \\ 0.0118, 0.0145, 0.0120).$$

Thus, bintree structure of hierarchical flexible coarsening is illustrated in Fig. 4 and the similarity between fusion results of hierarchical flexible coarsening and PCR6 is 0.9783. And the similarity between hierarchical coarsening method and PCR6 is 0.9120. In particular, terminal nodes (the red small box in Fig. 4) of flexible grouping are not in accordance with the original order  $\theta_1, \theta_2, \dots, \theta_{15}$ . This is quite different compared to original hierarchical coarsening method.

From the point of view of statistics, 100 BBAs are randomly generated to be fused with three methods: hierarchical flexible coarsening, hierarchical coarsening and also PCR6. Comparisons are made in Fig. 5, which show the superiority of our new approach proposed in this paper (Average value of new method is 97% and the old method is 93.5%).

### B. Flexible Grouping of Conflicting Focal Elements

Assuming that there are five sources of evidence  $m_1^\ominus(\cdot), m_2^\ominus(\cdot), m_3^\ominus(\cdot), m_4^\ominus(\cdot), m_5^\ominus(\cdot)$ , and the restricted hype-power set  $D^\ominus = \{\theta_1, \theta_2, \theta_3, \theta_4, \theta_5, \theta_6, \theta_7, \theta_8, \theta_9, \theta_{10}, \theta_1 \cap \theta_2, \theta_5 \cap \theta_6 \cap \theta_7, \theta_1 \cap \theta_5 \cap \theta_9 \cap \theta_{10}\}$ . And then we randomly generate 1000 BBAs for each source to calculate the similarity using (10). From Fig. 6, we can find that hierarchical flexible coarsening method can also maintain high degree of similarity which performs better than hierarchical coarsening.

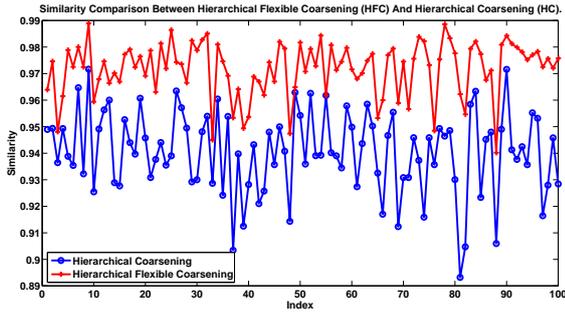

Figure 5: Comparisons Between HFC and HC (Only Singletons).

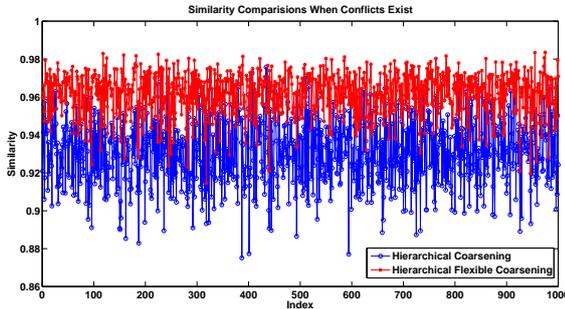

Figure 6: Comparisons Between HFC and HC (Singletons and Conflicting Focal Elements).

C. Flexible Grouping of Uncertain and Hybrid Focal Elements

We can also deal with uncertain and hybrid focal elements. Assuming that there are also five sources of evidence  $m_1^\ominus(\cdot), m_2^\ominus(\cdot), m_3^\ominus(\cdot), m_4^\ominus(\cdot), m_5^\ominus(\cdot)$  and  $D_1^\ominus = \{\theta_1, \theta_2, \theta_3, \theta_4, \theta_5, \theta_6, \theta_7, \theta_8, \theta_9, \theta_{10}, \theta_1 \cup \theta_2, \theta_5 \cup \theta_6 \cup \theta_7, \theta_1 \cup \theta_5 \cup \theta_9 \cup \theta_{10}\}$ ;  $D_2^\ominus = \{\theta_1, \theta_2, \theta_3, \theta_4, \theta_5, \theta_6, \theta_7, \theta_8, \theta_9, \theta_{10}, \theta_2 \cap \theta_4 \cup \theta_6, \theta_1 \cup \theta_3 \cap \theta_5 \cup \theta_7 \cap \theta_9\}$ <sup>15</sup>. And then we respectively and randomly generate 1000 BBAs for these two cases  $D_1^\ominus$  and  $D_2^\ominus$ . Finally, we calculate the average similarity degree of HFC and HC with PCR6 in Table II, which illustrates HFC performs better than old method. However, there exist the extra time cost of HFC compared to HC due to the clustering steps in coarsening process.

Table II: Similarity Comparisons

	Hierarchical Flexible Coarsening	Hierarchical Coarsening
$D_1^\ominus$	98%	91%
$D_2^\ominus$	97%	93%

VI. CONCLUSION AND PERSPECTIVES

A novel hierarchical flexible approximate method in DSMT is proposed here. Compared to original hierarchical coarsen-

<sup>15</sup>In this case,  $D_1^\ominus$  represents uncertain focal elements and  $D_2^\ominus$  represents hybrid focal elements.

ing, flexible strategy guarantees higher similarity with PCR6 rules in fusion process. Besides, whether focal elements in hyper power set are singletons, conflicting focal elements, uncertain or even hybrid focal elements, the new method works well. In the future work, we will focus on the general framework of hierarchical coarsening, which could generate final non-Bayesian BBAs in order to avoid loss of information. Furthermore, other advantages or disadvantages of our proposed methods such as computational efficiency and time consumption need to be further investigated.

**Abstract**—In many applications involving epistemic uncertainties usually modeled by belief functions, it is often necessary to approximate general (non-Bayesian) basic belief assignments (BBAs) to subjective probabilities (called Bayesian BBAs). This necessity occurs if one needs to embed the fusion result in a system based on the probabilistic framework and Bayesian inference (e.g. tracking systems), or if one needs to make a decision in the decision making problems. In this paper, we present a new fast combination method, called modified rigid coarsening (MRC), to obtain the final Bayesian BBAs based on hierarchical decomposition (coarsening) of the frame of discernment. Regarding this method, focal elements with probabilities are coarsened efficiently to reduce computational complexity in the process of combination by using disagreement vector and a simple dichotomous approach. In order to prove the practicality of our approach, this new approach is applied to combine users' soft preferences in recommender systems (RSs). Additionally, in order to make a comprehensive performance comparison, the proportional conflict redistribution rule #6 (PCR6) is regarded as a baseline in a range of experiments. According to the results of experiments, MRC is more effective in accuracy of recommendations compared to original Rigid Coarsening (RC) method and comparable in computational time.

**Keywords:** Recommender system, DSMT, PCR6.

## I. INTRODUCTION

The theory of belief functions, known as Dempster-Shafer Theory (DST) was developed by Shafer [1] in 1976 from Dempster's works [2]. Belief functions allow one to model epistemic uncertainty [3] and they have been already used in many applications since the 1990's [4], mainly those relevant to expert systems, decision-making support and information fusion. To palliate some limitations (such as high computational complexity) of DST, Dezert and Smarandache proposed an extended mathematical framework of belief functions with new efficient quantitative and qualitative rules of combinations, which was called DSMT (Dezert and Smarandache Theory) in literature [5], [6] with applications listed in [7]. One of the major drawbacks of DST and DSMT is their high computational complexities, on condition that the fusion space (i.e. frame of discernment – FoD) and the number of sources to combine are large. DSMT is more complex than DST, and the Proportional Conflict Redistribution rule #6 (PCR6 rule) becomes computationally intractable in the worst case as soon

as the cardinality of the Frame of Discernment (FoD) is greater than six.

To reduce the computational cost of operations with belief functions when the number of focal elements is very large, several approaches have been proposed by different authors. Basically, the existing approaches rely either on efficient implementations of computations as proposed for instance in [8], [9], or on approximation techniques of original Basic Belief Assignment (BBA) to combine [10]–[14], or both. From a fusion standpoint, two approaches are usually adopted: 1) one can approximate at first each BBA in subjective probabilities and use Bayes fusion rule to get the final Bayesian BBA [11], [12], or 2) one can fuse all the BBAs with a fusion rule, typically Dempster-Shafer's, or proportional conflict redistribution rule #6 (PCR6) rules (which is very costly in computations), and convert the combined BBA in a subjective probability measure [10], [14]. The former method is the simplest method but it generates a high loss of information included in the original BBAs, whereas the latter method is intractable for high dimension issues.

This paper presents a new combination method, called modified rigid coarsening (MRC), to get the final Bayesian BBAs based on hierarchical decomposition (coarsening) of the frame of discernment, which can be seen as an intermediary approach between the two aforementioned methods. This hierarchical structure allows to encompass bintree decomposition and mass of coarsening FoD on it. To prove the practicality of our proposed method, MRC is applied to combine users' preferences so as to provide the suitable recommendation for RSs. This paper is an extended version of our preliminary work on original rigid coarsening (RC) published in [15]. In this paper, more detailed analyses of this new combination method are provided. More importantly, this innovative method is also applied into the real application. These are all added values (contributions) of this paper.

The main contributions of this paper are:

- 1) the presentation of the FoD bintree decomposition on which will be done the BBAs approximations;
- 2) user preferences in Recommender Systems (RSs) are modeled by DSMT-Modeling Function.

In order to measure the efficiency and effectiveness of the MRC, it is integrated in the RSs based on DSMT and compared to traditional methods in the experiments. The results show that regarding the accuracy of recommendations, MRC is extremely close to classical PCR6; and the computational time of MRC can be obviously superior to that of PCR6.

The remainder of this paper is organized as follows. In section II, we review relevant prior work on DST and DSMT first. In section III, MRC is presented. In section IV, a recommendation system based on DSMT, that employs MRC to combine users' preferences, is shown. In section V, we evaluate our proposed algorithm based on two public datasets: Movielens and Flixster. Finally, we conclude and discuss future work.

## II. MATHEMATICAL BACKGROUND

This section provides a brief reminder of the basics of DST and DSMT, which is necessary for the presentation and understanding of the more general MRC of Section III.

In DST framework, the frame of discernment<sup>1</sup>  $\Theta \triangleq \{\theta_1, \dots, \theta_n\}$  ( $n \geq 2$ ) is a set of exhaustive and exclusive elements (hypotheses) which represents the possible solutions of the problem under consideration and thus Shafer's model assumes  $\theta_i \cap \theta_j = \emptyset$  for  $i \neq j$  in  $\{1, \dots, n\}$ . A basic belief assignment (BBA)  $m(\cdot)$  is defined by the mapping:  $2^\Theta \mapsto [0, 1]$ , verifying  $m(\emptyset) = 0$  and  $\sum_{A \in 2^\Theta} m(A) = 1$ . In DSMT, one can abandon Shafer's model (if Shafer's model doesn't fit with the problem) and refute the principle of the third excluded middle. The third excluded middle principle assumes the existence of the complement for any elements/propositions belonging to the power set  $2^\Theta$ . Instead of defining the BBAs on the power set  $2^\Theta \triangleq (\Theta, \cup)$  of the FoD, the BBAs are defined on the so-called *hyper-power set* (or Dedekind's lattice) denoted  $D^\Theta \triangleq (\Theta, \cup, \cap)$  whose cardinalities follows Dedekind's numbers sequence, see [6], Vol.1 for details and examples. A (generalized) BBA, called a mass function,  $m(\cdot)$  is defined by the mapping:  $D^\Theta \mapsto [0, 1]$ , verifying  $m(\emptyset) = 0$  and  $\sum_{A \in D^\Theta} m(A) = 1$ . The DSMT framework encompasses DST framework because  $2^\Theta \subset D^\Theta$ . In DSMT, we can take into account also a set of *integrity constraints* on the FoD (if known), by specifying all the pairs of elements which are really disjoint. Stated otherwise, Shafer's model is a specific DSMT model where all elements are deemed to be disjoint.  $A \in D^\Theta$  is called a focal element of  $m(\cdot)$  if  $m(A) > 0$ . A BBA is called a Bayesian BBA if all of its focal elements are singletons and Shafer's model is assumed, otherwise it is called non-Bayesian [1]. A full ignorance source is represented by the vacuous BBA  $m_v(\Theta) = 1$ . The belief (or credibility) and plausibility functions are respectively defined by  $Bel(X) \triangleq \sum_{Y \in D^\Theta | Y \subseteq X} m(Y)$  and  $Pl(X) \triangleq \sum_{Y \in D^\Theta | Y \cap X = \emptyset} m(Y)$ .  $BI(X) \triangleq [Bel(X), Pl(X)]$  is called the belief interval of  $X$ . Its length  $U(X) \triangleq Pl(X) - Bel(X)$  measures the degree of uncertainty of  $X$ .

<sup>1</sup>Here, we use the symbol  $\triangleq$  to mean equals by definition.

In 1976, Shafer did propose Dempster's rule and we use DS index to refer to Dempster-Shafer's rule (DS rule) because Shafer did really promote Dempster's rule in his milestone book [1]) to combine BBAs in DST framework. DS rule is defined by  $m_{DS}(\emptyset) = 0$  and  $\forall A \in 2^\Theta \setminus \{\emptyset\}$ ,

$$m_{DS}(A) = \frac{\sum_{B,C \in 2^\Theta | B \cap C = A} m_1(B)m_2(C)}{1 - \sum_{B,C \in 2^\Theta | B \cap C = \emptyset} m_1(B)m_2(C)}. \quad (1)$$

The DS rule formula is commutative and associative and can be easily extended to the fusion of  $S > 2$  BBAs. Unfortunately, DS rule has been highly disputed during the last decades by many authors because of its counter-intuitive behavior in high or even low conflict situations, and that is why many rules of combination were proposed in literature to combine BBAs [16]. To palliate DS rule drawbacks, the very interesting PCR6 was proposed in DSMT and it is usually adopted (PCR6 rule coincides with PCR5 when combining only two BBAs [6]) in recent applications of DSMT. The fusion of two BBAs  $m_1(\cdot)$  and  $m_2(\cdot)$  by the PCR6 rule is obtained by  $m_{PCR6}(\emptyset) = 0$  and  $\forall A \in D^\Theta \setminus \{\emptyset\}$

$$m_{PCR6}(A) = m_{12}(A) + \sum_{B \in D^\Theta \setminus \{A\} | A \cap B = \emptyset} \left[ \frac{m_1(A)^2 m_2(B)}{m_1(A) + m_2(B)} + \frac{m_2(A)^2 m_1(B)}{m_2(A) + m_1(B)} \right]. \quad (2)$$

where  $m_{12}(A) = \sum_{B,C \in D^\Theta | B \cap C = A} m_1(B)m_2(C)$  is the conjunctive operator, and each element A and B are expressed in their disjunctive normal form. If the denominator involved in the fraction is zero, then this fraction is discarded. The general PCR6 formula for combining more than two BBAs altogether is given in [6], Vol. 3. We adopt the generic notation  $m_{12}^{PCR6}(\cdot) = PCR6(m_1(\cdot), m_2(\cdot))$  to denote the fusion of  $m_1(\cdot)$  and  $m_2(\cdot)$  by PCR6 rule. PCR6 is not associative and PCR6 rule can also be applied in DST framework (with Shafer's model of FoD) by replacing  $D^\Theta$  by  $2^\Theta$  in (2).

## III. MODIFIED RIGID COARSENING FOR FUSION OF BAYESIAN BBAS

Here, we introduce the principle of MRC of FoD to reduce the computational complexity of PCR6 combination of original Bayesian BBAs. Considering the case of non-Bayesian BBAs, it requires decoupling all non-singletons in these BBAs in advance. The fusion of original nonBayesian BBAs needs to be decoupled by using DSMT in advance, which will be explained in Section IV.

### A. Rigid coarsening

This proposal was initially called *rigid coarsening (RC)* in our previous works [17]–[19] and currently improved in our recent work [15]. The goal of this coarsening is to replace the original (refined) FoD  $\Theta$  by a set of coarsened ones to make computation of the PCR6 rule tractable. Because we consider here only Bayesian BBA to combine, their focal

elements are only singletons of the FoD  $\Theta \triangleq \{\theta_1, \dots, \theta_n\}$ , with  $n \geq 2$ , and we assume Shafer's model of the FoD  $\Theta$ . A coarsening of the FoD  $\Theta$  means to replace it with another FoD less specific of smaller dimension  $\Omega = \{\omega_1, \dots, \omega_k\}$  with  $k < n$  from the elements of  $\Theta$ . This can be done in many ways depending the problem under consideration. Generally, the elements of  $\Omega$  are singletons of  $\Theta$ , and disjunctions of elements of  $\Theta$ . For example, if  $\Theta = \{\theta_1, \theta_2, \theta_3, \theta_4\}$ , then a possible coarsened frame built from  $\Theta$  could be, for instance,  $\Omega = \{\omega_1 = \theta_1, \omega_2 = \theta_2, \omega_3 = \theta_3 \cup \theta_4\}$ , or  $\Omega = \{\omega_1 = \theta_1 \cup \theta_2, \omega_2 = \theta_3 \cup \theta_4\}$ , etc.

**Definition 1:** When dealing with Bayesian BBAs, the projection<sup>2</sup>  $m^\Omega(\cdot)$  of the original BBA  $m^\Theta(\cdot)$  is simply obtained by taking

$$m^\Omega(\omega_i) = \sum_{\theta_j \in \omega_i} m^\Theta(\theta_j). \quad (3)$$

The rigid coarsening process is a simple dichotomous approach of coarsening obtained as follows:

- If  $n = |\Theta|$  is an even number:

The disjunction of the  $n/2$  first elements  $\theta_1$  to  $\theta_{\frac{n}{2}}$  of  $\Theta$  define the element  $\omega_1$  of  $\Omega$ , and the last  $n/2$  elements  $\theta_{\frac{n}{2}+1}$  to  $\theta_n$  of  $\Theta$  define the element  $\omega_2$  of  $\Omega$ , that is

$$\Omega \triangleq \{\omega_1 = \theta_1 \cup \dots \cup \theta_{\frac{n}{2}}, \omega_2 = \theta_{\frac{n}{2}+1} \cup \dots \cup \theta_n\}$$

and based on (3), one has

$$m^\Omega(\omega_1) = \sum_{j=1, \dots, \frac{n}{2}} m^\Theta(\theta_j), \quad (4)$$

$$m^\Omega(\omega_2) = \sum_{j=\frac{n}{2}+1, \dots, n} m^\Theta(\theta_j). \quad (5)$$

For example, if  $\Theta = \{\theta_1, \theta_2, \theta_3, \theta_4\}$ , and one considers the Bayesian BBA  $m^\Theta(\theta_1) = 0.1$ ,  $m^\Theta(\theta_2) = 0.2$ ,  $m^\Theta(\theta_3) = 0.3$  and  $m^\Theta(\theta_4) = 0.4$ , then  $\Omega = \{\omega_1 = \theta_1 \cup \theta_2, \omega_2 = \theta_3 \cup \theta_4\}$  and  $m^\Omega(\omega_1) = 0.1 + 0.2 = 0.3$  and  $m^\Omega(\omega_2) = 0.3 + 0.4 = 0.7$ .

- If  $n = |\Theta|$  is an odd number:

In this case, the element  $\omega_1$  of the coarsened frame  $\Omega$  is the disjunction of the<sup>3</sup>  $[n/2 + 1]$  first elements of  $\Theta$ , and the element  $\omega_2$  is the disjunction of other elements of  $\Theta$ . That is

$$\Omega \triangleq \{\omega_1 = \theta_1 \cup \dots \cup \theta_{[\frac{n}{2}+1]}, \omega_2 = \theta_{[\frac{n}{2}+1]+1} \cup \dots \cup \theta_n\}$$

and based on (3), one has

$$m^\Omega(\omega_1) = \sum_{j=1, \dots, [\frac{n}{2}+1]} m^\Theta(\theta_j), \quad (6)$$

<sup>2</sup>For clarity and convenience, we put explicitly as upper index the FoD for which the belief mass refers.

<sup>3</sup>The notation  $[x]$  means the integer part of  $x$  first elements of  $\Theta$

$$m^\Omega(\omega_2) = \sum_{j=[\frac{n}{2}+1]+1, \dots, n} m^\Theta(\theta_j). \quad (7)$$

For example, if  $\Theta = \{\theta_1, \theta_2, \theta_3, \theta_4, \theta_5\}$ , and one considers the Bayesian BBA  $m^\Theta(\theta_1) = 0.1$ ,  $m^\Theta(\theta_2) = 0.2$ ,  $m^\Theta(\theta_3) = 0.3$ ,  $m^\Theta(\theta_4) = 0.3$  and  $m^\Theta(\theta_5) = 0.1$ , then  $\Omega = \{\omega_1 = \theta_1 \cup \theta_2 \cup \theta_3, \omega_2 = \theta_4 \cup \theta_5\}$  and  $m^\Omega(\omega_1) = 0.1 + 0.2 + 0.3 = 0.6$  and  $m^\Omega(\omega_2) = 0.3 + 0.1 = 0.4$ .

Of course, the same coarsening strategy applies to all original BBAs  $m_s^\Theta = (\cdot)$ ,  $s = 1, \dots, S$  of the  $S > 1$  sources of evidence to work with less specific BBAs  $m_s^\Omega = (\cdot)$ ,  $s = 1, \dots, S$ . The less specific BBAs (called coarsened BBAs by abuse of language) can then be combined with the PCR6 rule of combination according to formula (2). This dichotomous coarsening method is repeated iteratively  $l$  times as schematically represented by a bintree. Here, we consider bintree only for simplicity, which means that the coarsened frame  $\Omega$  consists of two elements only. Of course a similar method can be used with tri-tree, quad-tree, etc. The last step of this hierarchical process is to calculate the combined (Bayesian) BBA of all focal elements according to the connection weights of the bintree structure, where the number of layers  $l$  of the tree depends on the cardinality  $|\Theta|$  of the original FoD  $\Theta$ . Specifically, the mass of each focal element is updated depending on the connection weights of link paths from root to terminal nodes. This principle is illustrated in details in the following example.

**Example 1:** Let's consider  $\Theta = \{\theta_1, \theta_2, \theta_3, \theta_4, \theta_5\}$ , and the following three Bayesian BBAs can be seen in Table I:

Table I  
THREE BAYESIAN BBAs FOR EXAMPLE 1.

Focal elements	$m_1^\Theta(\cdot)$	$m_2^\Theta(\cdot)$	$m_3^\Theta(\cdot)$
$\theta_1$	0.1	0.4	0
$\theta_2$	0.2	0	0.1
$\theta_3$	0.3	0.1	0.5
$\theta_4$	0.3	0.1	0.4
$\theta_5$	0.1	0.4	0

The rigid coarsening and fusion of BBAs is deduced from the following steps:

**Step 1:** We define the bintree structure based on iterative half split of FoD as shown in Fig 1.

The connecting weights are denoted as  $\lambda_1, \dots, \lambda_8$ . The elements of the frames  $\Omega_l$  are defined as follows:

- At layer  $l = 1$  :  $\Omega_1 = \{\omega_1 \triangleq \theta_1 \cup \theta_2 \cup \theta_3, \omega_2 \triangleq \theta_4 \cup \theta_5\}$
- At layer  $l = 2$  :  $\Omega_2 = \{\omega_{11} \triangleq \theta_1 \cup \theta_2, \omega_{12} \triangleq \theta_3, \omega_{21} = \theta_4, \omega_{22} = \theta_5\}$
- At layer  $l = 3$  :  $\Omega_3 = \{\omega_{111} \triangleq \theta_1, \omega_{112} \triangleq \theta_2\}$

**Step 2:** The BBAs of elements of the (sub-) frames  $\Omega_l$  are obtained as follows:

- At layer  $l = 1$ , we use Eqs (6) and (7) because  $|\Theta| = 5$  is an odd number. Therefore, we get the BBAs in Table II:
- At layer  $l = 2$ : We work with the two subframes  $\Omega_{21} \triangleq \{\omega_{11}, \omega_{12}\}$  and  $\Omega_{22} \triangleq \{\omega_{21}, \omega_{22}\}$  of  $\Omega_2$  with the

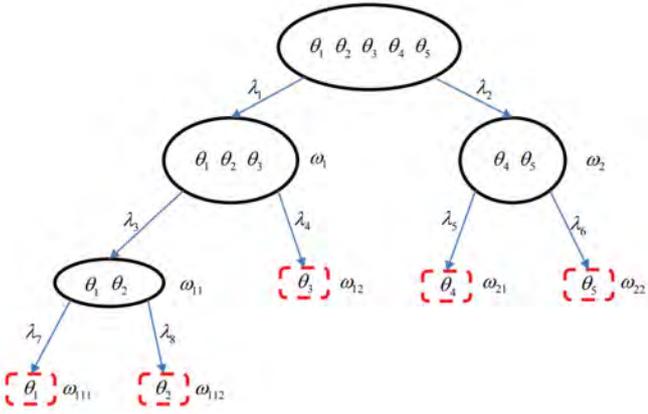

Figure 1. Fusion of Bayesian BBAs using bintree coarsening for Example 1.

Table II  
THE BBAs OF ELEMENTS OF THE SUB-FRAMES  $\Omega_1$  FOR EXAMPLE 1.

Focal elements	$m_1^\Theta(\cdot)$	$m_2^\Theta(\cdot)$	$m_3^\Theta(\cdot)$
$\omega_1 \triangleq \theta_1 \cup \theta_2 \cup \theta_3$	0.6	0.6	0.6
$\omega_2 \triangleq \theta_4 \cup \theta_5$	0.4	0.5	0.4

BBAs in Tables III and IV:

Table III  
THE BBAs OF ELEMENTS OF THE SUB-FRAMES  $\Omega_{21}$  FOR EXAMPLE 1.

Focal elements	$m_1^{\Omega_{21}}(\cdot)$	$m_2^{\Omega_{21}}(\cdot)$	$m_3^{\Omega_{21}}(\cdot)$
$\omega_{11} \triangleq \theta_1 \cup \theta_2$	$\frac{1}{2}$	$\frac{4}{5}$	$\frac{1}{6}$
$\omega_{12} \triangleq \theta_3$	$\frac{1}{2}$	$\frac{1}{5}$	$\frac{5}{6}$

Table IV  
THE BBAs OF ELEMENTS OF THE SUB-FRAMES  $\Omega_{22}$  FOR EXAMPLE 1.

Focal elements	$m_1^{\Omega_{22}}(\cdot)$	$m_2^{\Omega_{22}}(\cdot)$	$m_3^{\Omega_{22}}(\cdot)$
$\omega_{21} \triangleq \theta_4$	$\frac{3}{4}$	$\frac{1}{5}$	1
$\omega_{22} \triangleq \theta_5$	$\frac{1}{4}$	$\frac{4}{5}$	0

These mass values are obtained by the proportional redistribution of the mass of each focal element with respect to the mass of its parent focal element in the bin tree. For example,  $m_2^{\Omega_{21}}(\omega_{11}) = 4/5$  is derived by taking

$$m_2^{\Omega_{21}}(\omega_{11}) = \frac{m_2^\Theta(\theta_1) + m_2^\Theta(\theta_2)}{m_2^\Theta(\theta_1) + m_2^\Theta(\theta_2) + m_2^\Theta(\theta_3)} = \frac{0.4}{0.5} = \frac{4}{5}$$

Other masses of coarsening focal elements are computed similarly using this proportional redistribution method.

- At layer  $l = 3$ : We use again the proportional redistribution method which gives us the BBAs of the sub-frames  $\Omega_3$  in Table V:

Table V  
THE BBAs OF ELEMENTS OF THE SUB-FRAMES  $\Omega_3$  FOR EXAMPLE 1.

Focal elements	$m_1^{\Omega_3}(\cdot)$	$m_2^{\Omega_3}(\cdot)$	$m_3^{\Omega_3}(\cdot)$
$\omega_{111} \triangleq \theta_1$	$\frac{1}{3}$	1	0
$\omega_{112} \triangleq \theta_2$	$\frac{2}{3}$	0	1

**Step 3:** The connection weights  $\lambda_i$  are computed from the assignments of coarsening. In each layer  $l$ , we fuse sequentially the three BBAs using PCR6 formula (2). Because PCR6 fusion is not associative, we should apply the general PCR6 formula to get best results. Here we use sequential fusion to reduce the computational complexity even if the fusion result is approximate. More precisely, we compute at first  $m_{12}^{PCR6, \Omega_l}(\cdot) = PCR6(m_1^{\Omega_l}(\cdot), m_2^{\Omega_l}(\cdot))$  and  $m_{(12)3}^{PCR6, \Omega_l}(\cdot) = PCR6(m_{12}^{\Omega_l}(\cdot), m_3^{\Omega_l}(\cdot))$ . Hence, we obtain the following connecting weights in the bintree:

- At layer  $l = 1$ :

$$\lambda_1 = m_{(12)3}^{PCR6, \Omega_1}(\omega_1) = 0.6297$$

$$\lambda_2 = m_{(12)3}^{PCR6, \Omega_1}(\omega_2) = 0.3703$$

- At layer  $l = 2$ :

$$\lambda_3 = m_{(12)3}^{PCR6, \Omega_{21}}(\omega_{11}) = 0.4137$$

$$\lambda_4 = m_{(12)3}^{PCR6, \Omega_{21}}(\omega_{12}) = 0.5863$$

$$\lambda_5 = m_{(12)3}^{PCR6, \Omega_{22}}(\omega_{21}) = 0.8121$$

$$\lambda_6 = m_{(12)3}^{PCR6, \Omega_{22}}(\omega_{22}) = 0.1879$$

- At layer  $l = 3$ :

$$\lambda_7 = m_{(12)3}^{PCR6, \Omega_3}(\omega_{111}) = 0.3103$$

$$\lambda_8 = m_{(12)3}^{PCR6, \Omega_3}(\omega_{112}) = 0.6897$$

**Step 4:** The final assignments of elements in original FoD  $\Theta$  are calculated using the product of the connection weights of link paths from root (top) node to terminal nodes (leaves). We eventually get the *combined and normalized* Bayesian BBA:

$$m^\Theta(\theta_1) = \lambda_1 \cdot \lambda_3 \cdot \lambda_7 = 0.6297 \cdot 0.4137 \cdot 0.3103 = 0.0808$$

$$m^\Theta(\theta_2) = \lambda_1 \cdot \lambda_3 \cdot \lambda_8 = 0.6297 \cdot 0.4137 \cdot 0.6897 = 0.1797$$

$$m^\Theta(\theta_3) = \lambda_1 \cdot \lambda_4 = 0.6297 \cdot 0.5863 = 0.3692$$

$$m^\Theta(\theta_4) = \lambda_2 \cdot \lambda_5 = 0.3703 \cdot 0.8121 = 0.3007$$

$$m^\Theta(\theta_5) = \lambda_2 \cdot \lambda_6 = 0.3703 \cdot 0.1879 = 0.0696$$

### B. Modified rigid coarsening

One of the issues with RC described in the previous section is that *no extra self-information of focal elements is embedded into the coarsening process*. In this paper, the elements  $\theta_i$  selected to belong to the same group are determined using the consensus information drawn from the BBAs provided by the sources. Specifically, the degrees of disagreement between the provided sources on decisions  $(\theta_1, \theta_2, \dots, \theta_n)$  are first calculated using the belief-interval based distance  $d_{BI}$  [20] to obtain *disagreement vector*. And then all focal elements in FoD are sorted in an ascending order. Finally, the simple dichotomous approach is utilized to hierarchical coarsen those **Re-sorted** focal elements.

**Calculating the disagreement vector.** Let us consider several BBAs  $m_s^\ominus(\cdot), (s = 1, \dots, S)$  defined on same FoD  $\ominus$  of cardinality  $|\ominus| = n$ . The specific BBAs  $m_{\theta_i}(\cdot), i = 1, \dots, n$  entirely focused on  $\theta_i$  are defined by  $m_{\theta_i}(\theta_i) = 1$ , and for  $X \neq \theta_i, m_{\theta_i}(X) = 0$ .

**Definition 2:** The disagreement of opinions of two sources about  $\theta_i$  is defined as the  $L_1$ -distance between the  $d_{BI}$  distances of the BBAs  $m_s^\ominus(\cdot), s = 1, 2$  to  $m_{\theta_i}(\cdot)$ , which is expressed by

$$D_{12}(\theta_i) \triangleq |d_{BI}(m_1^\ominus(\cdot), m_{\theta_i}(\cdot)) - d_{BI}(m_2^\ominus(\cdot), m_{\theta_i}(\cdot))|. \quad (8)$$

**Definition 3:** The disagreement of opinions of  $S \geq 3$  sources about  $\theta_i$ , is defined as

$$D_{1-S}(\theta_i) \triangleq \frac{1}{2} \sum_{i=1}^S \sum_{j=1}^S |d_{BI}(m_i^\ominus(\cdot), m_{\theta_i}(\cdot)) - d_{BI}(m_j^\ominus(\cdot), m_{\theta_i}(\cdot))|. \quad (9)$$

where  $d_{BI}$  distance is defined by [20]. For simplicity, we assume Shafer's model so that  $|2^\ominus| = 2^n$ , otherwise the number of elements in the summation of (10) should be  $|D^\ominus| - 1$  with another normalization constant  $n_c$ .

$$d_{BI}^E(m_1, m_2) \triangleq \sqrt{n_c \cdot \sum_{i=1}^{2^n-1} [d^I(BI_1(\theta_i), BI_2(\theta_i))]^2}. \quad (10)$$

Here,  $n_c = 1/2^{n-1}$  is the normalization constant and  $d^I([a, b], [c, d])$  is the Wasserstein's distance defined by  $d^I([a, b], [c, d]) = \sqrt{[\frac{a+b}{2} - \frac{c+d}{2}]^2 + \frac{1}{3}[\frac{b-a}{2} - \frac{d-c}{2}]^2}$ , and  $BI(\theta_i) = [Bel(\theta_i), Pl(\theta_i)]$ .

The disagreement vector  $D_{1-S}$  is defined by

$$D_{1-S} \triangleq [D_{1-S}(\theta_1), \dots, D_{1-S}(\theta_n)]. \quad (11)$$

**Modified rigid coarsening by using the disagreement vector.** Once  $D_{1-S}$  is derived, all focal elements  $\{\theta_1, \theta_2, \dots, \theta_n\}$  are sorted according to their corresponding values in  $D_{1-S}$ .

Let us revisit example 1 presented in the previous subsection. It can be verified in applying formula (9) that the disagreement vector  $D_{1-3}$  for this example is equal to

$$D_{1-3} = [0.4085, 0.2156, 0.3753, 0.2507, 0.4086]$$

The derivation of  $D_{1-3}(\theta_1)$  is given below for convenience:

$$\begin{aligned} D_{1-3} &= |d_{BI}(m_1^\ominus(\cdot), m_{\theta_1}(\theta_1)) - d_{BI}(m_2^\ominus(\cdot), m_{\theta_1}(\theta_1))| \\ &+ |d_{BI}(m_2^\ominus(\cdot), m_{\theta_1}(\theta_1)) - d_{BI}(m_3^\ominus(\cdot), m_{\theta_1}(\theta_1))| \\ &+ |d_{BI}(m_1^\ominus(\cdot), m_{\theta_1}(\theta_1)) - d_{BI}(m_3^\ominus(\cdot), m_{\theta_1}(\theta_1))| \\ &= 0.4085. \end{aligned}$$

Based on the disagreement vector, a new bintree structure is obtained and shown in Fig 2.

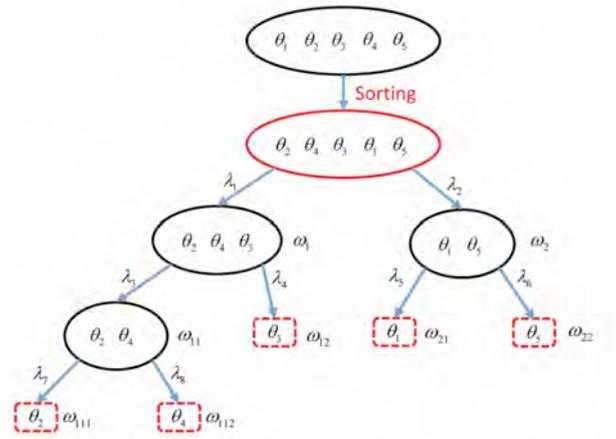

Figure 2. Fusion of Bayesian BBAs using MRC for Example 1.

Compared with Fig 1, the elements in FoD  $\ominus$  are grouped more reasonably. In vector  $D_{1-3}$ ,  $\theta_1$  and  $\theta_5$  lie in similar degree of disagreement so that they are put in the same group. Similarly for  $\theta_2$  and  $\theta_4$ . However, element  $\theta_3$  seems *weird*, which is put alone in the process of coarsening. Once this new bintree decomposition is obtained, other steps can be implemented which are identical to rigid coarsening in section to get the final combined BBA.

**Step 1:** According to Fig 2, the elements of the frames  $\Omega_l$  are defined as follows:

- At layer  $l = 1$ :

$$\Omega_1 = \{\omega_1 \triangleq \theta_2 \cup \theta_4 \cup \theta_3, \omega_2 \triangleq \theta_1 \cup \theta_5\}.$$

- At layer  $l = 2$ :

$$\Omega_2 = \{\omega_{11} \triangleq \theta_2 \cup \theta_4, \omega_{12} \triangleq \theta_3, \omega_{21} \triangleq \theta_1, \omega_{22} \triangleq \theta_5\}.$$

- At layer  $l = 3$ :

$$\Omega_3 = \{\omega_{111} \triangleq \theta_2, \omega_{112} \triangleq \theta_4\}.$$

**Step 2:** The BBAs of elements of the (sub-) frames  $\Omega_l$  are obtained as follows:

- At layer  $l = 1$ , we use (6) and (7) and we get Table VI

Table VI

 THE BBAS OF ELEMENTS OF THE SUB-FRAMES  $\Omega_1$  USING MRC FOR EXAMPLE 1.

Focal elements	$m_1^{\Omega_1}(\cdot)$	$m_2^{\Omega_1}(\cdot)$	$m_3^{\Omega_1}(\cdot)$
$\omega_1 \triangleq \theta_2 \cup \theta_4 \cup \theta_3$	0.8	0.2	1.0
$\omega_2 \triangleq \theta_1 \cup \theta_5$	0.2	0.8	0.0

- At layer  $l = 2$ , We use again the proportional redistribution method which gives us Tables VII and VIII. Here, masses of  $\omega_{21}, \omega_{22}$  in  $m_3^{\Omega_{22}}(\cdot)$  are not considered because the mass of their parent focal element ( $m_3^{\Omega_1}(\omega_2)$ ) in bintree is 0.

Table VII

 THE BBAS OF ELEMENTS OF THE SUB-FRAMES  $\Omega_{21}$  USING MRC FOR EXAMPLE 1.

Focal elements	$m_1^{\Omega_{21}}(\cdot)$	$m_2^{\Omega_{21}}(\cdot)$	$m_3^{\Omega_{21}}(\cdot)$
$\omega_{11} \triangleq \theta_2 \cup \theta_4$	$\frac{5}{8}$	$\frac{1}{2}$	$\frac{1}{2}$
$\omega_{12} \triangleq \theta_3$	$\frac{3}{8}$	$\frac{1}{2}$	$\frac{1}{2}$

Table VIII

 THE BBAS OF ELEMENTS OF THE SUB-FRAMES  $\Omega_{22}$  USING MRC FOR EXAMPLE 1.

Focal elements	$m_1^{\Omega_{22}}(\cdot)$	$m_2^{\Omega_{22}}(\cdot)$	$m_3^{\Omega_{22}}(\cdot)$
$\omega_{21} \triangleq \theta_1$	$\frac{1}{2}$	$\frac{1}{2}$	-
$\omega_{22} \triangleq \theta_5$	$\frac{1}{2}$	$\frac{1}{2}$	-

- At layer  $l = 3$ , We work with the two subframes of  $\Omega_3$ , that is  $\Omega_3 \triangleq \{\omega_{111}, \omega_{112}\}$ , with the BBAs in Table IX.

Table IX

 THE BBAS OF ELEMENTS OF THE SUB-FRAMES  $\Omega_3$  USING MRC FOR EXAMPLE 1.

Focal elements	$m_1^{\Omega_3}(\cdot)$	$m_2^{\Omega_3}(\cdot)$	$m_3^{\Omega_3}(\cdot)$
$\omega_{111} \triangleq \theta_2$	$\frac{2}{5}$	0.0	$\frac{1}{5}$
$\omega_{112} \triangleq \theta_4$	$\frac{3}{5}$	1.0	$\frac{4}{5}$

**Step 3:** The connection weights  $\lambda_i$  are computed from the assignments of coarsening elements. Hence, we obtain the following connecting weights in the bintree:

- At layer  $l = 1$ :  $\lambda_1 = 0.8333$ , and  $\lambda_2 = 0.1667$ .
- At layer  $l = 2$ :  $\lambda_3 = 0.5697$ ,  $\lambda_4 = 0.4303$ ,  $\lambda_5 = 0.5000$ , and  $\lambda_6 = 0.5000$ .
- At layer  $l = 3$ :  $\lambda_7 = 0.0669$ , and  $\lambda_8 = 0.9331$ .

**Step 4:** We finally get the following *combined and normalized* Bayesian BBA

$$m^\Theta(\cdot) = \{0.0833, 0.0318, 0.3586, 0.4430, 0.0834\}.$$

### C. Summary of the proposed method

The fusion method of BBAs to get a combined Bayesian BBA based on hierarchical decomposition of the FoD consists of several steps (**Algorithm 1**) illustrated in Fig 3.

### Algorithm 1: Modified Rigid Coarsening Method

---

**Input :** All original BBAs  
 $m_1^\Theta(\cdot), \dots, m_s^\Theta(\cdot), s = 1, 2, \dots, s$

**Output:** The final combined BBA  $m^\Theta(\cdot)$

- 1 **if** Compound focal elements in  
 $\Theta : \theta_i \cup \theta_j \neq \emptyset$  or  $\theta_i \cap \theta_j \neq \emptyset$  **then**
- 2     Probabilistic transformation:  
 $DSmP(m_1^\Theta(\cdot)), DSmP(m_2^\Theta(\cdot)), \dots, DSmP(m_s^\Theta(\cdot))$
- 3 **end**
- 4 **for**  $i \leq n$  **do**
- 5     **for**  $s \leq S$  **do**
- 6         Calculate  $D_{1-S}(\theta_i) \triangleq$   
 $\frac{1}{2} \sum_{i=1}^S \sum_{j=1}^S |d_{BI}(m_i^\Theta(\cdot), m_{\theta_i}(\cdot)) - d_{BI}(m_j^\Theta(\cdot), m_{\theta_j}(\cdot))|$
- 7     **end**
- 8 **end**
- 9 **for**  $i \leq n$  **do**
- 10     Sorting  $D_{1-S}(\theta_i)$  in an ascending order.
- 11 **end**
- 12 **while**  $|\Theta| \geq 2$  **do**
- 13     **if**  $n$  is an even number **then**
- 14          $m^{\Omega_i}(\omega_1) = \sum_{j=1, \dots, \frac{n}{2}} m^\Theta(\theta_j)$ ;
- 15          $m^{\Omega_i}(\omega_2) = \sum_{j=\frac{n}{2}+1, \dots, n} m^\Theta(\theta_j)$ ;
- 16     **else**
- 17          $m^{\Omega_i}(\omega_1) = \sum_{j=1, \dots, \lfloor \frac{n}{2} \rfloor + 1} m^\Theta(\theta_j)$ ;
- 18          $m^{\Omega_i}(\omega_2) = \sum_{j=\lfloor \frac{n}{2} \rfloor + 1 + 1, \dots, n} m^\Theta(\theta_j)$ ;
- 19     **end**
- 20     Then connection weights  $\lambda$  is calculated:  
 $PCR6(m^{\Omega_i}(\omega_1), m^{\Omega_i}(\omega_2))$
- 21 **end**
- 22 **foreach** focal element  $\theta_i, i \in 1, \dots, n$  **do**
- 23      $m^\Theta(\theta_i)$  equals to the product of path link weights  
 from root to terminal nodes.
- 24 **end**

---

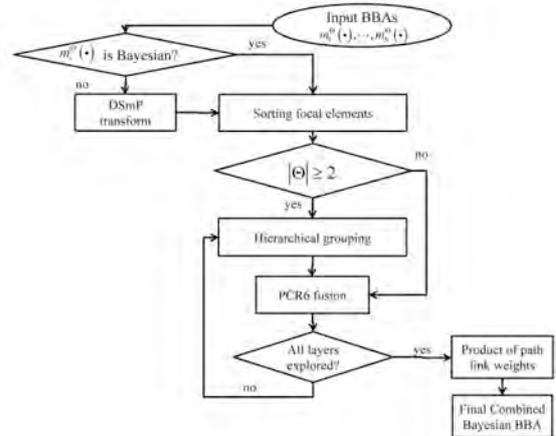

Figure 3. Modified rigid coarsening of FoD for fusion.

It is worth noting that when the given BBAs are not Bayesian, the first step is to use the existing Probabilistic Transformation (PT) to transform them to Bayesian BBAs. In order to use the proposed combination method in the RSs, modified rigid coarsening is mathematically denoted as  $\oplus$  in the following sections.

*D. Simulation considering accuracy and computational efficiency*

- Accuracy:

Assuming that the FoD is

$$\Theta = \{\theta_1, \theta_2, \theta_3, \theta_4, \theta_5, \theta_6, \theta_7, \theta_8, \theta_9, \theta_{10}, \theta_{11}, \theta_{12}, \theta_{13}, \theta_{14}, \theta_{15}, \theta_{16}, \theta_{17}, \theta_{18}, \theta_{19}, \theta_{20}\}$$

then 1000 BBAs are randomly generated to be fused with three methods: modified rigid coarsening, rigid coarsening and also PCR6. And then distances of fusion results are computed using  $d_{BI}$  between two pairs: modified rigid coarsening and PCR6; rigid coarsening and PCR6. Comparisons are made in Fig 4, which show the superiority of our new approach proposed in this paper (The average value of the approximation of modified rigid coarsening is **97.5%** and original rigid coarsening is **94.5%**). Here, similarity represents the approximate degree between fusion results using hierarchical approximate method (both rigid and modified rigid coarsening) and PCR6.

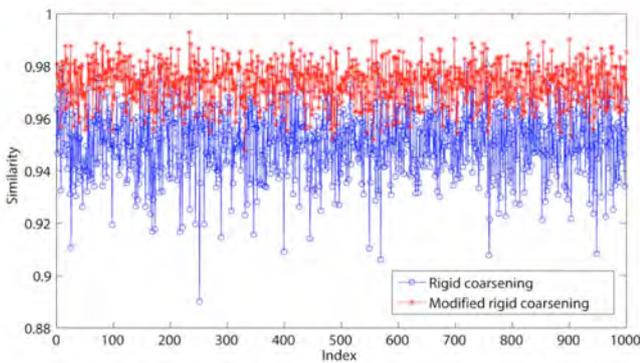

Figure 4. Accuracy comparisons between MRC and PCR6 (Only Singletons).

- Computational efficiency:

As we mentioned before, another advantage of the hierarchical combination method is the computational efficiency. Here, two experiments are conducted (*All experiments are implemented on a PC with I3 CPU, Integrated graphics chipsets and 4G DDR*): 1) the number of singletons is unchanged while the number of BBAs to be fused is increasing; 2) the number of BBAs is unchanged while the number of singletons in FoD is increasing. The results are illustrated in Fig 5 and 6. From experiment 1, all these three methods (classical PCR6, rigid coarsening and also modified rigid coarsening) calculate quickly (**less than 1.2s**) even the number of BBAs

increases from 100 to 1000. However, such situation deteriorates when the number of focal elements increases. In Fig 6, when the number of focal elements increases to 500, time consumption of three combinations is: PCR6: 20.6857s; modified rigid coarsening: 7.3320s; rigid coarsening: 5.9748s. This phenomenon also proves that it is reasonable to map original FoD to the coarsening FoD, with the aim of reducing the number of focal elements at the time of fusion. But in any case, computing efficiency of rigid coarsening or modified rigid coarsening is still better than PCR6. On the other hand, modified rigid coarsening makes a significant improvement (accuracy) at the expense of parts of the computational efficiency.

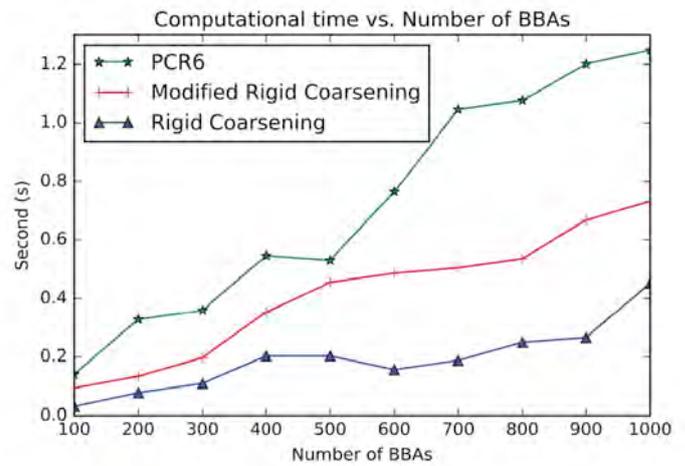

Figure 5. Efficiency comparisons between MRC, RC and PCR6 (With the number of BBAs increasing).

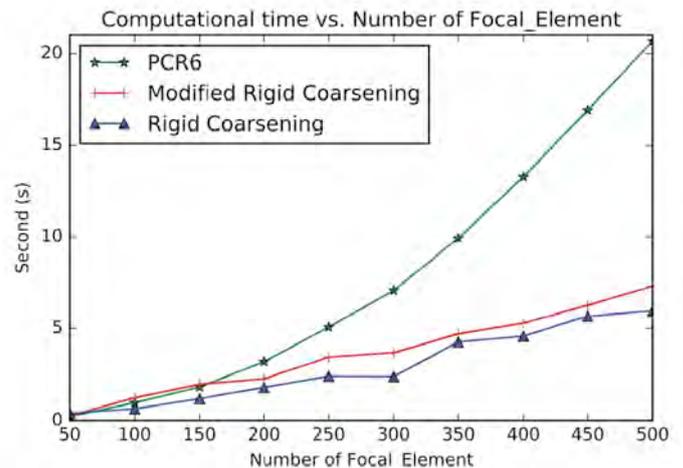

Figure 6. Efficiency comparisons between MRC, RC and PCR6 (With the number of focal elements increasing).

#### IV. A RECOMMENDER SYSTEM INTEGRATING WITH HIERARCHICAL COARSENING COMBINATION METHOD

In today's e-commerce, online providers often recommend proper goods or services to each consumer based on their personal opinions or preferences [21], [22]. However, it is a tough task to provide appropriate recommendation which may confront several difficulties. One difficulty is that users' preferences are usually characterized as uncertain, imprecise or incomplete [23], [24], which cannot be used directly in RSs. Besides, it is easy to understand that when the more information about user preferences are, the more accurate prediction of RSs will be [25], [26]. But, the problem is that which method we adopt to integrate multi-source uncertain information?

As a general framework for information fusion, DST can not only model uncertain information, but also provide an efficient way to combine multi-source information. These mentioned features make this theory a wide range of applications [27]–[29], especially in RSs [23], [25], [30]–[32]. According to DST, users' comments on products in RSs are described by using mass functions and rules of combination method are used frequently in order to provide appropriate recommendation.

As mentioned in previous sections, both the performances of combination rules in DST or in DSMT suffer from computational complex which is obviously ignored in [23], [25]. Thus, in this paper, modified rigid coarsening method is applicable to combine the imprecise users' preferences in RSs. First, we are required to introduce the relevant knowledge of RSs. Actually, almost all characteristics of RSs have been introduced in [23], [25], [30]–[32].

First, we give the corresponding representation of the mathematical notation in RSs based on DSMT. RSs usually contain two objects: *Users*, *Items*. A set of  $M$  users and a set containing  $N$  items is respectively denoted by  $\mathbf{U} = \{U_1, U_2, \dots, U_M\}$  and  $\mathbf{I} = \{I_1, I_2, \dots, I_N\}$ . Besides, we assume that users can give the corresponding ratings to the items, which include  $L$  rating levels ( $\Theta = \{\theta_1, \theta_2, \dots, \theta_L\}$ ). Here,  $L$  preference levels means multi-level evaluation results. For example, four-levels of user evaluation on the product are *Excellent*, *Good*, *Fair*, *Poor*.  $r_{i,k}$  means a rating of user  $U_i$  on item  $I_k$  and a rating matrix  $\mathbf{R} = r_{i,k}$  comprises all the ratings of users on items. It should be noted that  $r_{i,k}$  is originally modeled as a mass function  $m_{i,k} : D^\Theta \rightarrow [0, 1]$ . Additionally, let  $\mathbf{I}_i^R$  and  $\mathbf{U}_k^R$  denote the set of items rated by user  $U_i$  and the set of users having rated item  $I_k$ , respectively.

Contextual information can often be summarized into several genres that significantly affect user's rating of items. Normally, we represent contextual information by a set containing  $P$  genres, denoted by  $\mathbf{S} = \{S_1, S_2, \dots, S_P\}$ . And each genre  $S_p$ , with  $1 \leq p \leq P$  contains at most  $Q$  groups, denoted by  $S_p = \{g_{p,1}, g_{p,2}, \dots, g_{p,q}, \dots, g_{p,Q}\}$ ,  $1 \leq q \leq Q$ . For a genre  $S_p \in \mathbf{S}$ , a user  $U_i \in \mathbf{U}$  can be interested in several groups and also an item  $I_i \in \mathbf{I}$  can belong to one or some groups of this genre, which can be seen in Fig 7.

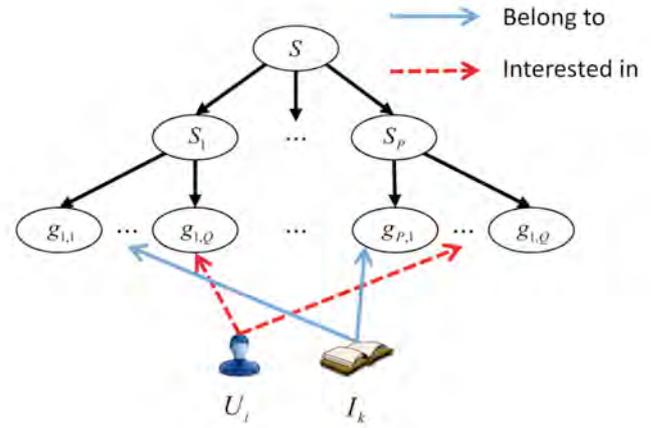

Figure 7. Contextual information.

**Definition 4:** In order to facilitate such expression, two functions  $\kappa(\cdot)$  and  $\varphi(\cdot)$  are defined to determine the groups in which user  $U_i$  is interested and the groups to which item  $I_k$  belongs, respectively:

$$\kappa_p : U_i \mapsto \kappa_p(U_i) \subseteq S_p \quad (12)$$

$$\varphi_p : I_k \mapsto \varphi_p(I_k) \subseteq S_p \quad (13)$$

Generally, the main steps of a recommendation system is illustrated in Fig 8.

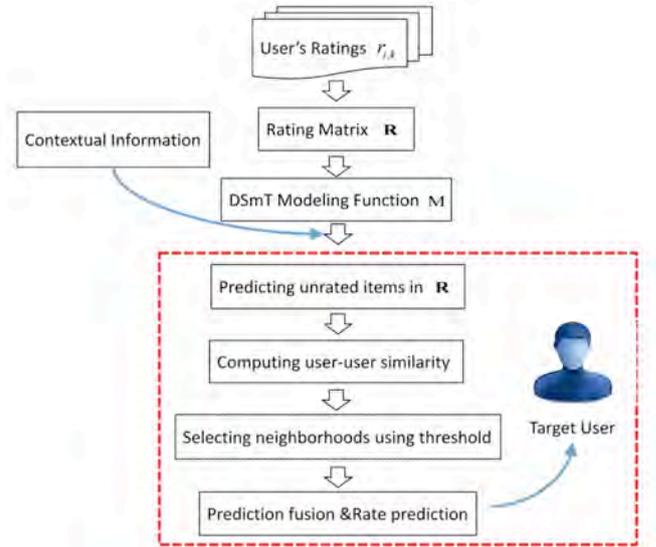

Figure 8. General process of recommendations.

The functional blocks of Fig. 8 are as follows:

1) DSMT-Modeling Function

Regarding the DS-partial probability models proposed in [23], the existing ratings  $r_{i,k}$ , of user  $U_i$  on item  $I_k$ , are

modeled by DSMT-modeling function  $M(\cdot)$  in order to transform such hard ratings into the corresponding soft ratings represented as  $m_{i,k}$  as below:

**Definition 5:**

$$m_{i,k} = \begin{cases} \alpha_{i,k}(1 - \sigma_{i,k}), & \text{for } A = \theta_l; \\ \frac{1}{2}\alpha_{i,k}\sigma_{i,k}, & \text{for } A = B; \\ \frac{1}{2}\alpha_{i,k}\sigma_{i,k}, & \text{for } A = C; \\ 1 - \alpha_{i,k}, & \text{for } A = \Theta; \\ 0, & \text{otherwise.} \end{cases} \quad (14)$$

with

$$B = \begin{cases} \theta_1 \cup \theta_2, & \text{if } l = 1; \\ \theta_{L-1} \cup \theta_L, & \text{if } l = L; \\ \theta_{l-1} \cup \theta_l \cup \theta_{l+1}, & \text{otherwise.} \end{cases}$$

$$C = \begin{cases} \theta_1 \cup \theta_2, & \text{if } l = 1; \\ \theta_{L-1} \cup \theta_L, & \text{if } l = L; \\ (\theta_{l-1} \cap \theta_l, \theta_l \cap \theta_{l+1}), & \text{otherwise.} \end{cases}$$

where  $\alpha_{i,l} \in [0, 1]$  and  $\sigma_{i,k}$  are a trust factor and a dispersion factor, respectively [23].

Referring to the partial probability model analysis in [23], we also give the corresponding user profiles which can be seen in Fig 9.

Figure 9. DSMT modeling function.

Compared to [23], the difference is that we not only consider the union  $n$  (black and gray rectangle), but also consider the intersection (red rectangle) of the hard ratings, which is also the distinction between DS theory and DSMT theory.

**Lemma 1:** Referring to Definition 5, we can also generate the relative refined BBA in the framework of DS theory:

$$m_{i,k}^{Refined} = \begin{cases} \alpha_{i,k}(1 - \sigma_{i,k}), & \text{for } A = \theta_l; \\ \alpha_{i,k}\sigma_{i,k}, & \text{for } A = B; \\ 1 - \alpha_{i,k}, & \text{for } A = \Theta; \\ 0, & \text{otherwise.} \end{cases} \quad (15)$$

with

$$B = \begin{cases} \theta_1 \cup \theta_2, & \text{if } l = 1; \\ \theta_{L-1} \cup \theta_L, & \text{if } l = L; \\ \theta_{l-1} \cup \theta_l \cup \theta_{l+1}, & \text{otherwise.} \end{cases}$$

where  $\alpha_{i,k} \in [0, 1]$  and  $\sigma_{i,k}$  are a trust factor and a dispersion factor, respectively [23].

After soft ratings are generated, DSMP [33] is applied to decouple non-Bayesian  $m_{i,k}$ , since the hierarchical fusion algorithm is currently just available for Bayesian BBAs.

**Definition 6:** DSMP is a new generalized pignistic transformation defined by  $DSMP_\varepsilon(\emptyset) = 0$  and for any singleton  $\theta_i \in \Theta$  by

$$DSMP_\varepsilon(\theta_i) \triangleq m(\theta_i) + (m(\theta_i) + \varepsilon) \times \sum_{A \in 2^\Theta, \theta_N \subset A, |A| \geq 2} \frac{m(A)}{\sum_{B \in 2^\Theta, B \subset A, |B|=1} m(B) + \varepsilon \cdot |A|} \quad (16)$$

As shown in [33], DSMP makes a remarkable improvement compared with BetP and CuzzP, since a more judicious redistribution of the ignorance masses to the singletons has been adopted by DSMP.  $\varepsilon$  is a small positive number, typically  $\varepsilon = 0.001$ .

2) Predicting unrated items:

Assuming that users who are keen on the similar groups tend to have common preferences. In this RS, it is necessary to predict the unrated items first. Considering a group  $g_{p,q} \in S_p$  with  $g_{p,q} \in \varphi(I_k)$ , every soft rating,  $m_{i,k}$ , of user  $U_i$ , who is keen on group  $g_{p,q}$ , on item  $I_k$  is regarded as a block of common preference for group  $g_{p,q}$ . Thus,  $G_{m_{p,q,k}} : D^\Theta \rightarrow [0, 1]$  which represents all users' group preferences on item  $I_k$  regarding group  $g_{p,q}$ , is computed as follows

$$G_{m_{p,q,k}} = \bigoplus_{\{j | I_k \in I_j^R, g_{p,q} \in \kappa_p(U_j), g_{p,q} \in \varphi_p(I_k)\}} m_{j,k} \quad (17)$$

Supposing that item  $I_k$  has not been rated by user  $U_i$ , it usually contains three steps to generate unprovided rating  $r_{i,k}$  of user  $U_i$  which are shown as below

- Step one: Considering a concept  $S_p$ , for each group  $g_{p,q} \in \kappa_p(U_i) \cap \varphi_p(I_k)$ , it is assumed that all users' group preferences on item  $I_k$  regarding group  $g_{p,q}$  imply common preference of  $U_i$  on  $I_k$  regarding group  $g_{p,q}$ . Furthermore, this group preference is regarded as a piece of user  $U_i$ 's concept preference on item  $I_k$  regarding concept  $S_p$ . Therefore, concept

preference of user  $U_i$  on item  $I_k$  regarding concept  $S_p$ , denoted by mass function  $S_{m_{p,q,k}} : D^\Theta \rightarrow [0, 1]$ , can be computed as below

$$S_{m_{p,q,k}} = \bigoplus_{\{q|g_{p,q} \in \kappa_p(U_j), g_{p,q} \in \varphi_p(I_k)\}} G_{m_{p,q,k}}. \quad (18)$$

- Step two: If there exists at least one common group in concept  $S_p$  which item  $I_k$  belongs to and also user  $U_i$  is interested in, then  $U_i$ 's concept preference on item  $I_k$  regarding concept  $S_p$  is regarded as a piece of context preference. Therefore, this user's contextual preference on item  $I_k$ , denoted by mass function  $S_{m_{i,k}} : D^\Theta \rightarrow [0, 1]$ , is achieved as follows

$$S_{m_{i,k}} = \bigoplus_{p=1, \dots, P} S_{m_{p,i,k}}. \quad (19)$$

- Step three: Context preference of  $U_i$  on item  $I_k$  is assigned to unprovided rating  $\bar{m}_{i,k}$  as below

$$\bar{m}_{i,k} = S_{m_{i,k}}. \quad (20)$$

So far, all unprovided ratings are predicted in this RS. Subsequently, user-user similarities are computed depending on both provided and predicted ratings in the following steps.

### 3) Computing user-user similarities:

Here, we use the distance measure proposed in [34] to calculate distances between two users  $U_i$  and  $U_j$  with  $i \neq j$ , which is defined as below

$$D(U_i, U_j) = \sum_{k=1}^N \left( \ln \max_{\theta \in \Theta} \frac{m_{j,k}(\theta)}{m_{i,k}(\theta)} - \ln \min_{\theta \in \Theta} \frac{m_{j,k}(\theta)}{m_{i,k}(\theta)} \right), \quad (21)$$

where  $m_{i,k}$  and  $m_{j,k}$  are the soft ratings of user  $U_i$  and user  $U_j$  on item  $I_k$  respectively. Afterwards, the degree of similarity between  $U_i$  and  $U_j$ , denoted by  $s_{i,j}$ , is calculated as follows

$$s_{i,j} = e^{-\gamma \times D(U_i, U_j)}, \text{ where } \gamma \in (0, \infty). \quad (22)$$

Obviously, if the value of  $s_{i,j}$  is high, it means the user  $U_i$  and user  $U_j$  are very close, and vice versa. Eventually, a mathematical matrix  $\mathbf{S} = \{s_{i,j} | U_i, U_j \in \mathbf{U}, i \neq j\}$  is employed to represent the similarities among all users.

### 4) Selecting neighbors based on user-user similarities:

Taking into account an active user  $U_i$ , for each unrated item  $I_k$  by user  $U_i$ , a set containing  $K$  nearest neighborhoods, denoted by  $\mathfrak{R}_{i,k}$ , is chosen by using the method proposed in [35]. Two simple steps of this method are shown below

- Step one: the process of such selection depends on two criteria: 1. Those users who rated  $I_k$  and 2. The corresponding user-user similarities with user  $U_i$  are equal or greater than the threshold  $\tau$ .  $\mathfrak{R}_{i,k}$  denotes the selected set, which is acquired as follows:

$$\mathfrak{R}_{i,k} = \{U_j \in \mathbf{U} | I_k \in \mathbf{I}_j^R, s_{i,j} \geq \tau\}. \quad (23)$$

- Step two: all of members in  $\mathfrak{R}_{i,k}$  is descending sorted by  $s_{i,j}$  and top  $K$  members are selected as the neighborhood set  $\mathfrak{R}_{i,k}$ .

### 5) Estimating ratings according to neighborhoods:

Supposing that item  $I_k$  has not been rated by user  $U_i$ . The predicted rating of  $U_i$  on item  $I_k$  is denoted as  $\hat{m}_{i,k}$ . Thus,  $\hat{m}_{i,k}$  is calculated according to the ratings of user  $U_i$ 's nearest users. Mathematically,  $\hat{m}_{i,k}$  is given as below

$$\hat{m}_{i,k} = m_{i,k} \oplus \tilde{m}_{i,k}, \quad (24)$$

where  $\tilde{m}_{i,k}$  is the mass regarding the neighborhoods' whole preference in the set Eq (23) on item  $I_k$ . Considering user  $U_i \in \mathfrak{R}_{i,k}$ , and supposing that  $s_{i,j}$  is the similarity between user  $U_i$  and user  $U_j$ . We use a discount rate  $1 - s_{i,j}$  to discount the rating of user  $U_j$  on item  $I_k$ .

Therefore,  $\tilde{m}_{i,k}$  is:

$$\tilde{m}_{i,k} = \bigoplus_{\{j | U_j \in \mathfrak{R}_{i,k}\}} \dot{m}_{j,k}^{s_{i,j}}, \quad (25)$$

where

$$\dot{m}_{j,k}^{s_{i,j}} = \begin{cases} s_{i,j} \times m_{j,k}(A), & \text{for } A \subset \Theta; \\ s_{i,j} \times m_{j,k}(\Theta) + (1 - s_{i,j}), & \text{for } A = \Theta. \end{cases}$$

### 6) Generating recommendations:

In order to generate appropriate recommendations for the candidate user  $U_i$ , predicted ratings of  $U_i$  on all unprovided items are sorted, and then based on the sorted list, the appropriate recommendations are generated.

## V. EXPERIMENTS

To evaluate the performance of modified rigid coarsening in precision of recommendation and computational time, original rigid coarsening method and also classical PCR6 combination method are selected to be regarded as baselines. Besides, we use DS-MAE [23] to measure the precision of recommendations.

**Definition 7:** DS-MAE is mathematically given as follows

$$DS - MAE(\theta_j) = \frac{1}{|D_j|} \sum_{(i,k) \in D_j, \theta_i \in \Theta} |\hat{m}_{i,k}(\theta_j) - M(\theta_j)|, \quad (26)$$

where  $D_j$  is the testing set identifying the user-item pairs whose true rating is  $\theta_j \in \Theta$ .

Those specific users' interested information about genres is unknown. Thus, we define a rule that if a user has rated an item then this user is interested in all genres to which the item belongs.

#### 1) Experiment One:

Movielens<sup>4</sup> is a movie recommendation dataset widely used for benchmarking process. There are nearly 100,000 hard ratings on 19 different types of movies

<sup>4</sup><http://grouplens.org/datasets/movielens>

(Action, Comedy, and so on). The domain of such rating given in Movielens includes 5 levels, denoted as  $\Theta = \{1, 2, 3, 4, 5\}$ . At the same time, each user is required to evaluate at least 20 movies, so as to ensure adequate rating information. The relevant parameters used in RSs are set:  $\gamma = 10^{-4}$  and  $\forall(i, k)\{\alpha_{i,k}, \sigma_{i,k}\} = \{0.9, 2/3\}$ . However, Setting parameter  $\tau$  to be a fixed value is obviously unreasonable because the similarity between two users is quite different when using different combination methods. Hence, in this paper, the value of parameter  $\tau$  will not be set in advance. Instead, it is determined based on the similarity in matrix  $S$ . Specifically, the highest value of top 30% in  $S$  is selected for  $\tau$ .

Additionally, we adopt the robust strategy of 10-fold cross validation to conduct experiments, which is widely applied in experimental verification. Specific steps are as follows: original ratings in Movielens are first randomly divided into 10-folds and the experiments are thus carried out 10 times: in each sub-experiment, nine tenths of the ratings are chosen as training data and the remaining ratings are regarded as testing data. It's worth noting that all results illustrated in the following experiments are the average values of 10 times.

The figure 10 demonstrates the values of overall DS-MAE varying with changing neighborhood size  $K$ . And the smaller values of DS-MAE indicate the better ones. As can be seen in Fig 10, with  $K \leq 70$  performances of the three methods increase sharply as well as being the same as each other. With  $K \geq 70$ , performances of both methods become stable. Especially, performance of modified rigid coarsening method is very close to classical PCR6 rules. However, original rigid coarsening is slightly worse than the other two algorithms.

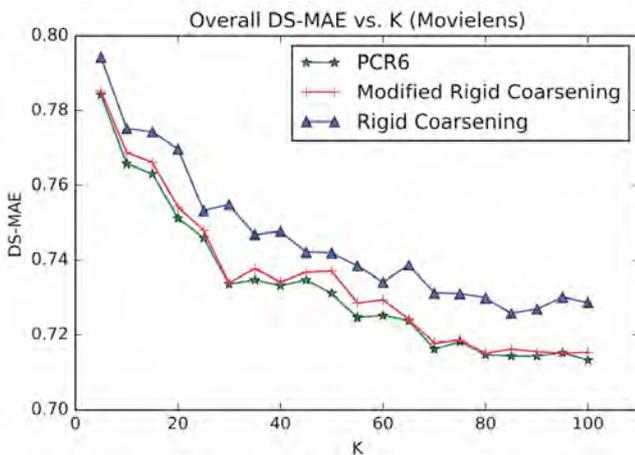

Figure 10. Overall DS-MAE between three combination methods. (Movielens).

The figure 11 depicts the computational time varying with changing neighborhood size  $K$ . In this figure, the time taken by hierarchical coarsening combination methods (both rigid coarsening and modified rigid coarsening method) is quite faster compared to classical PCR6. Besides, modified rigid coarsening is relatively slower than original rigid coarsening. All these results illustrate that modified rigid coarsening method sacrifices some of the computational efficiency, in exchange for upgrading the accuracy of approximation.

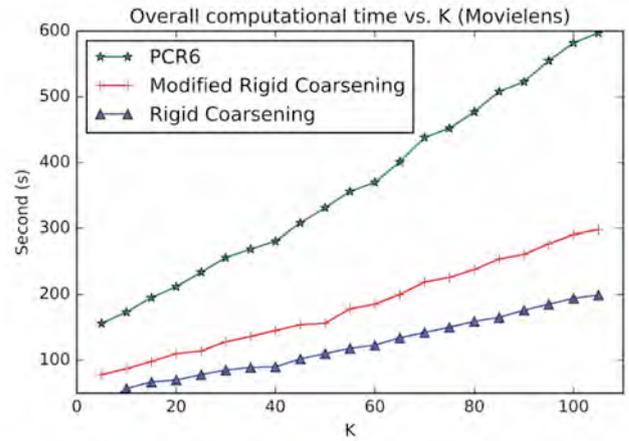

Figure 11. Overall computational time between three combination methods. (Movielens).

## 2) Experiment Two:

Flixster<sup>5</sup> is a classical recommendation dataset which nearly contains 535013 hard ratings on 19 different types of movies (Drama, Comedy, and so on). The domain of such rating given in Flixster includes 10 levels, denoted as  $\Theta = \{0.5, 1.0, 1.5, 2.0, 2.5, 3.0, 3.5, 4.0, 4.5, 5.0\}$ . At the same time, each user is required to evaluate at least 15 movies, so as to ensure adequate rating information. The relevant parameters used in RSs are set:  $\gamma = 10^{-4}$  and  $\forall(i, k)\{\alpha_{i,k}, \sigma_{i,k}\} = \{0.9, 2/3\}$ . However, Setting parameter  $\tau$  to be a fixed value is obviously unreasonable because the similarity between two users is quite different when using different combination methods. Hence, in this paper, the value of parameter  $\tau$  will not be set in advance. Instead, it is determined based on the similarity in matrix  $S$ . Specifically, the highest value of top 50% in  $S$  is selected for  $\tau$ .

The figure 12 demonstrates the values of overall DS-MAE varying with changing neighborhood size  $K$ . And the smaller values of DS-MAE indicate the better ones. As can be seen in Fig 12 we can get a similar result to the previous data set (Movielens). Especially, perfor-

<sup>5</sup><http://datasets.syr.edu/datasets/Flixster.html>

mance of modified rigid coarsening method is in the middle of the comparison methods. However, original rigid coarsening is worse than the other two algorithms.

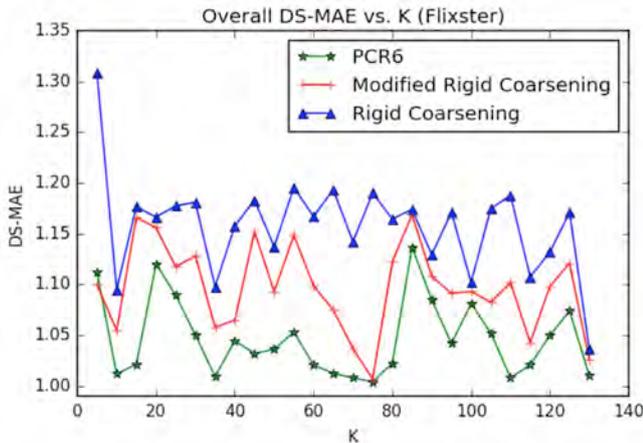

Figure 12. Overall DS-MAE between three combination method. (Flixster).

The figure 13 depicts the computational time varying with changing neighborhood size  $K$ . From this figure, we can also get the same conclusion that the time taken by hierarchical coarsening combination methods (both rigid coarsening and modified rigid coarsening method) is quite faster compared to classical PCR6.

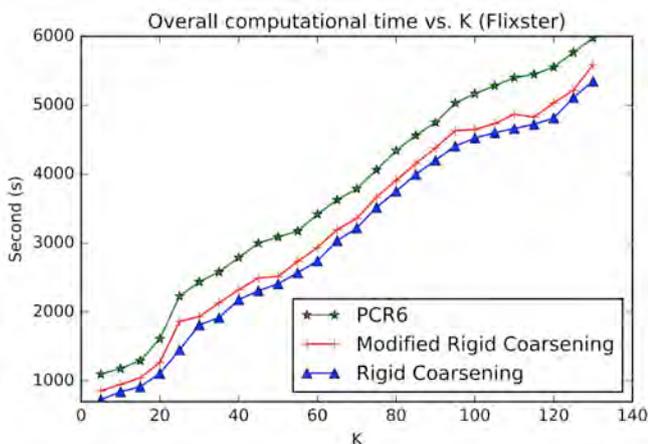

Figure 13. Overall computational time between three combination methods. (Flixster).

## VI. CONCLUSION

In this paper, we propose a new combination method, called modified rigid coarsening method. This new method can map the original refined FoD to the new coarsening FoD in the process of combination. Compared to traditional fusion method PCR6 in DS<sub>m</sub>T, this approach can not only reduce computational complexity, but also ensure high approximation accuracy. Besides, in order to verify the practicality of our

approach, we apply this approach to fuse soft ratings in RSs. To be specific, user preferences are first transformed by DS<sub>m</sub>T-partial probability model to accurately represent uncertain information. Then, information about user preferences from different sources can be easily combined. In the future work, more helpful information will be mined to discern focal element in FoD so as to improve the accuracy of approximation and more data sets will be applied.

## ACKNOWLEDGMENT

This work was supported in part by the National Natural Science Foundation of China under Grant 61573097, 91748106, in part by Key Laboratory of Integrated Automation of Process Industry (PAL-N201704), in part by the Qing Lan Project and Six Major Top-talent Plan, and in part by the Priority Academic Program Development of Jiangsu Higher Education Institutions. The authors thank the reviewers and editors for giving valuable comments, which are very helpful for improving this manuscript.

**Abstract**—To prevent disastrous consequences imputed to levee breakage, assessment methodologies have to be improved. Geophysical and geotechnical investigation methods are usually used to make such assessments. However, the effective combination of these two specific types of data remains a challenge. We propose the fusion of geophysical and geotechnical data by means of Belief Functions. Here we demonstrate our approach on a synthetic case study including geophysical (electrical resistivity) and geotechnical (cone-bearing) data and by implementing Smets and PCR5 normalization rules. This new data combination approach allows the characterization of horizontal interfaces and of a geological structure initially hidden by the effects of a highly conductive body.

**Keywords:** data fusion, belief functions, geophysical data, geotechnical data, experimental test bench, electrical resistivity tomography.

## I. INTRODUCTION

Fluvial levees are elevated partitions between channels and floodplains [1], built for flood protection. These structures are considered as hazardous and may fail, leading to disastrous consequences such as human and material loss and economic disasters. Levee assessment acknowledged methodologies usually include geotechnical and geophysical investigation methods [2]. While geotechnical investigation methods are intrusive, they provide quite accurate and punctual information. Conversely, geophysical methods are non-intrusive and provide physical information on large volumes of subsoil with high output (according to the chosen method and acquisition mode) and potentially significant uncertainties. These associated uncertainties can particularly be attributed to the indirect and integrating nature of the methods as well as to the non-uniqueness of inverse problems solution. One of the important issues when assessing levees is the combination of geotechnical and geophysical data [3]. Furthermore, one should take into consideration their respective imprecisions, uncertainties and contrasting spatial distributions. We suggest the use of Belief Functions (BFs) and combination rules to merge geotechnical (cone bearing) and geophysical (electrical resistivity) data. Our data fusion methodology is being optimized and tested on both

real and synthetic data. In this paper, we aim to demonstrate the potential of this methodology by means of a synthetic study that exemplifies a simplified levee case study. Indeed, we show the ability of combined geotechnical (cone bearing) and geophysical (electrical resistivity) data to discriminate three type of geological materials in the presence of a conductive anomaly, which has a significant bias effect on the geophysical data. The reader can refer to the theoretical basis of BFs, introduced by Shafer [4]. The use of BFs needs: (1) to select a common frame of discernment (FoD) of the considered problem, (2) to determine the masses of belief or Basic Belief Assignments (BBAs) from available data (geotechnical and geophysical), and (3) to choose a rule of combination.

## II. FOD AND BBAs CONSTRUCTION

For the addressed levee assessment issue, we consider three classes of distinct materials  $\theta_1$ ,  $\theta_2$  and  $\theta_3$ . Since the FoD,  $\Theta$ , must consist of a set of exclusive and exhaustive hypotheses, we will be using a fourth class  $\theta_4$  to cover the physical characteristics of materials not included in the three first sets. Thus we use  $\Theta = \{\theta_1, \theta_2, \theta_3, \theta_4\}$ . The construction of the BBAs for each data source consists in assigning each data type (geophysical and geotechnical) to  $\Theta$ .

## III. CONSTRUCTION FROM GEOPHYSICAL DATA - ELECTRICAL RESISTIVITY VALUES

Since electrical resistivity (ER) tomography is one of the most widely used methods for levee investigation, we propose the use of ER as geophysical data. As a framework to exemplify a fluvial levee problematic we consider two soil layers: an upper resistive layer ( $10^3 \Omega.m$ ) standing for sands [5] and a subjacent and more conductive one ( $10 \Omega.m$ ) standing for a clayey layer starting at 6 m depth. An inhomogeneity ( $10^2 \Omega.m$ ) standing for a silty lens of about 1.3 m high and 40.5 m wide is positioned at 7 m depth (Figure 1.a). We then associate ER classes of specific soils (split into ranges of ER in  $\Omega.m$ ) to  $\Theta$  so that:  $\theta_1 = [5, 20]$ ,  $\theta_2 = [50, 2 \cdot 10^2]$ ,  $\theta_3 = [5 \cdot 10^2, 2 \cdot 10^3]$  and  $\theta_4 = [0.2, 5[ \cup ]20, 50[ \cup ]2 \cdot 10^2, 5 \cdot 10^2[ \cup ]2 \cdot 10^3, 5 \cdot 10^3]$ .

We finally place a very small ( $0.5 \times 0.5\text{m}$ ) and highly conductive body ( $10^{-6} \Omega\cdot\text{m}$ ) centered at 1.35 m depth (represented in green in Figure 1.a), that could be considered as a metallic pipe. Even though this body is small in the  $XY$  plane, it might have an elongated shape in the  $Z$  direction. We use Res2Dmod free software [6] to simulate noiseless data acquisition from the chosen resistivity model (Figure 1.a) and then use the Res2Dinv software (ver. 3.71.118) [7] to get the inverted ER section as one would obtain from the processing of survey data (Figure 1.b).

The discrimination between sands and clays is obvious while the distinction of the silty lens is not. Indeed, the conductive local body generates resistive artefacts close to its position and a very large and conductive artifact deeper in the subsoil, hiding the presence of the silty lens. The image given by the inverted ER (Figure 1.b) strongly departs from the true model (Figure 1.a). We finally use the Res2dinv discretization grid for the BBA  $m_1(\cdot)$  corresponding to each event of  $2^\Theta$  (each event of  $\Theta$  plus their possible unions and the empty set). The values of the masses are set using the Wasserstein distances [8] between (a) an inverted ER value  $\pm$  its uncertainty, issued from the Res2dinv result, and (b) the interval corresponding to each event, so as each cell of the grid gets a normalized BBA.

#### IV. CONSTRUCTION FROM GEOTECHNICAL DATA - CONE-BEARING VALUES

We use artificial cone bearing values (expressed in MPa) as geotechnical data. These physical values could have been obtained from a cone penetrometer test (CPT) investigation campaign. Indeed, CPT campaigns are widely used to investigate embankment levees [2]. We simulate a data acquisition from four boreholes with an interspacing of 20 m, drilled to 17 m depth with a vertical acquisition every 50 cm (dashed lines in Figure 1.a). Two of the boreholes happen to go through the silty lens. We assign intervals of cone bearing values (in MPa) to  $\Theta$  so that:  $\theta_1 = [2, 8]$ ,  $\theta_2 = [20, 80]$ ,  $\theta_3 = [2 \cdot 10^2, 8 \cdot 10^2]$  and  $\theta_4 = [0.1, 2 \cup] 8, 20 \cup] 80, 2 \cdot 10^2 \cup] 8 \cdot 10^2, 10^3]$ . These intervals can be associated to specific soil types [9] such as clays for low values, silty soils for intermediate values and sands for higher ones. We assume a mass of belief equal to 1 in the borehole and impose an exponential lateral decrease of the trust in the data (following the mean horizontal scale of fluctuation of about 50 m proposed by Phoon and Kulhawy [10]). The geotechnical grid depends on the distance between the boreholes and the vertical sampling. Thus, for each cell, a second BBA  $m_2(\cdot)$  is proposed, entering in the fusion process

#### V. COMBINATION OF BBAS AND PRELIMINARY RESULTS

We suggest the use of a fusion mesh containing all the meshes from both the geophysical and geotechnical grids so that we avoid data interpolation that might lead to unnecessary data alteration. The data merging consists in combining  $m_1(\cdot)$  and  $m_2(\cdot)$  assigned to each cell of the grid. While many rules of BBA combination have been proposed, in this work we

focus on two of them: Smets' rule [11] and the Proportional Conflict Redistribution rule no. 5 (PCR5) [12]. Smets' rule (conjunctive rule under an open-world assumption) allows the quantification of the conflict level of our two information sources (geotechnical and geophysical sources) represented by (Eq. 1):

$$m_{12}(\emptyset) = \sum_{X_1, X_2 \subseteq \Theta | X_1 \cap X_2 = \emptyset} m_1(X_1)m_2(X_2) \quad (1)$$

Thanks to the latter rule, we are able to point out the conflictual zones in the vicinity of: the horizontal interfaces, the silty lens, the local very conductive body and the resistive and conductive artifacts (in red, Figure 2.a). The fusion, following Dempster-Shafer's rule (Eq. 2) (closed world assumption) [4] with the PCR5 normalization [12] (Figure 2.c) is fairly close to the true model we used (Figure 1.a). This normalization allows the spreading of the conflict masses  $m_{12}(\emptyset)$  to other events of  $2^\Theta$ .

$$m_{12}^{\text{DS}}(A) = \frac{1}{1 - m_{12}(\emptyset)} \sum_{X_1, X_2 \subseteq \Theta | X_1 \cap X_2 = A} m_1(X_1)m_2(X_2) \quad (2)$$

It exhibits a quite clear view of the interface between sands and clays and allows the visualization of the silty lens despite the blind zone generated by the conductive anomaly (Figure 1.b). As a decision-making support, we propose to display the events having the highest belief masses (Figure 2.a and 2.c) and their associated degrees of belief (Figure 2.b and 2.d).

Via our procedure, even though the highly conductive anomaly (that can be associated to a metallic pipe) is not clearly detected and characterized, Figure 2.a still points out a conflictual zone around the position of that anomaly. Unfortunately, we still have incorrect material type determination on the 19 first horizontal meters and 15 last horizontal meters about the sand/clay interface because of the wrong ER values proposed by the inverted geophysical model (Figure 1.b). In the future, this kind of under-determination may be minimized by reconsidering the way to decrease the lateral trust of the geotechnical data.

#### VI. CONCLUSION

The use of BFs for the fusion of geophysical and geotechnical investigation data is promising. Indeed, it enables to highlight the presence of an interface between two geological media much more precisely than the geophysical method alone, using Res2Dinv. Furthermore, it enables the reliable estimation of the complete extension of a lens with intermediate ER and cone bearing values, even though the effects of a local and highly conductive body (that can be associated to a transversal metallic pipe) hides the geological lens. Without normalization, Smets' combination rule easily spotlights the conflicting zones. Such information could also be precious during an investigation campaign, indicating zones where survey has to be strengthened.

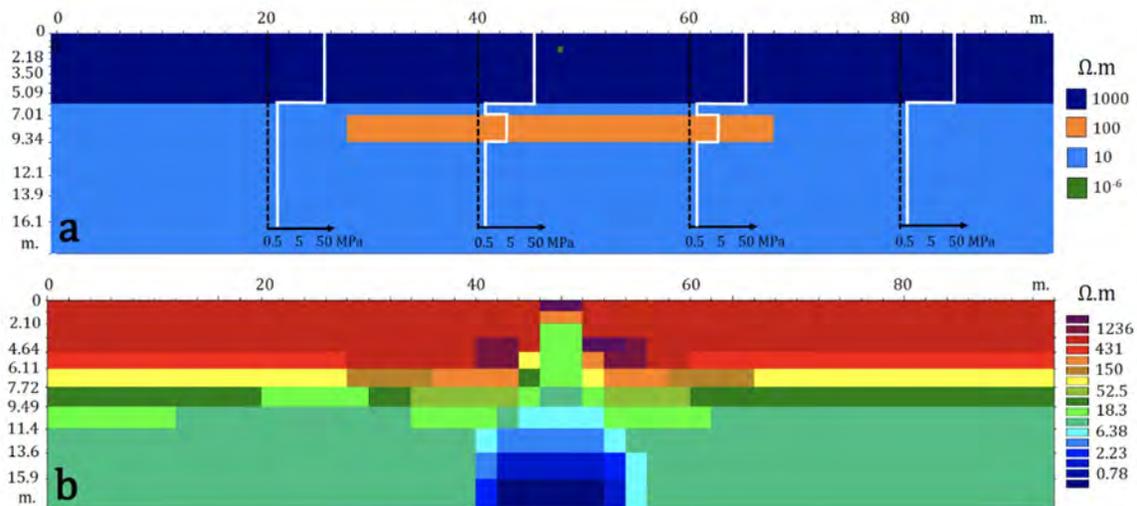

Fig. 1. 2D section of subsoil displaying a) true ER with borehole positions in dashed lines and associated cone bearing values in white and b) inverted ER model displayed in model data blocks with RMS error = 1.11%.

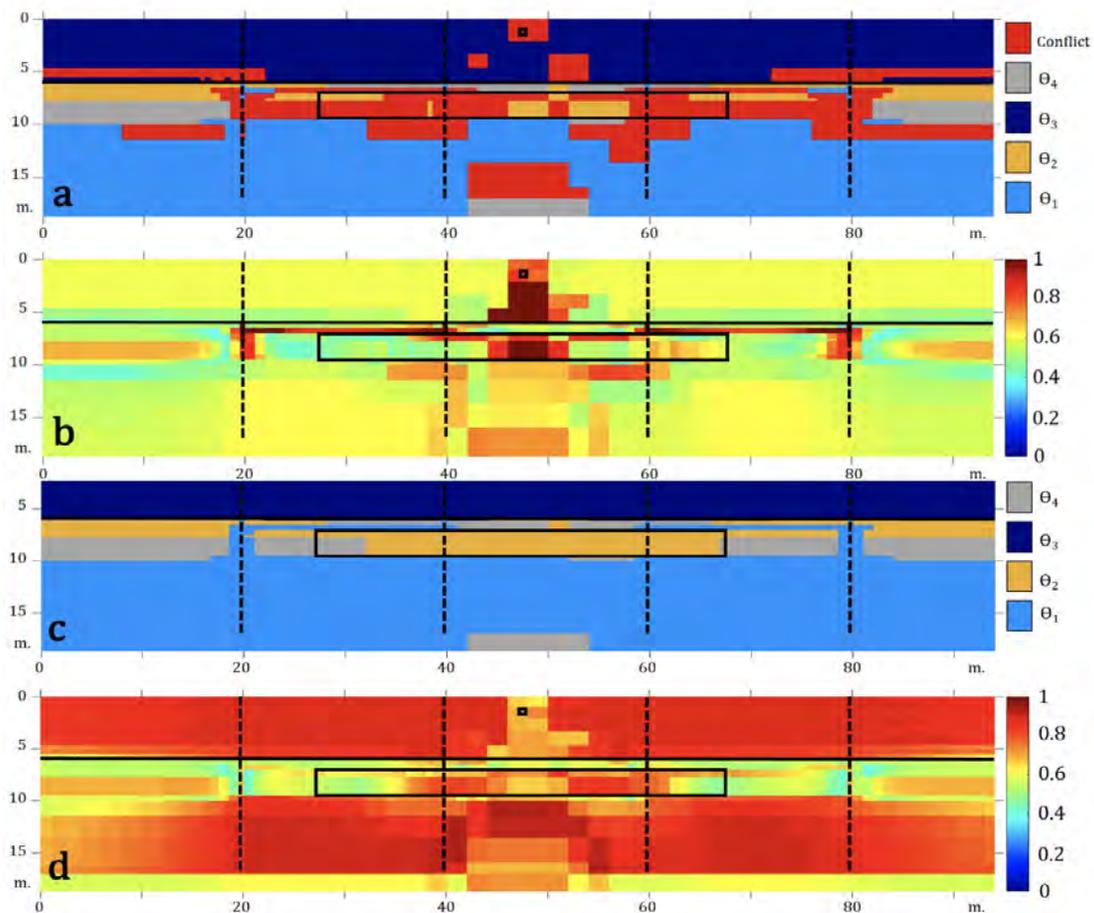

Fig. 2. Data merging with Smets (a, b) and PCR5 normalization rule (c, d). (b) and (d) represent the BBAs associated to the most plausible events respectively presented in (a) and (c). The black lines stand for the interfaces and the inhomogeneities fixed in the model (Figure 1.a) while the dashed lines stand for the borehole positions.

This will be in the heart of further studies in order to be able to propose the most pertinent positions for geotechnical boreholes thanks to belief functions and combination rules, therewith to improve fluvial levee assessment. This algorithm will also be employed using real data acquired on a scale model as well as on a levee in order to propose a 3D modelling.

**Abstract**—This paper presents a study on human perception of the heading on the base of motion and form visual cues integration. The authors examine how human age influences this process. Because the visual stimuli are in general uncertain, or in some cases even conflicting, the process of combination is estimated on the base on the well known Normalized Conjunctive Consensus fusion rule, as well as on the base of the more efficient Dezert-Smarandache Theory (DSMT) of plausible and paradoxical reasoning, and more precisely on the probabilistic Proportional Conflict Redistribution rule no.5 defined within it. The main goal is focused on how these fusion rules succeed to model consistent and adequate predictions about both individuals' behavior, and age-contingent groups of individuals.

**Keywords:** vision, heading perception, form cue, motion cue, cues combination, DSMT, probabilistic proportional redistribution rule no.5, normalized conjunctive rule.

## I. INTRODUCTION

Form and motion information are closely linked and continuously interacting in the human visual system, which takes the advantage to utilize both of these visual characteristics (or so called cues) to make decisions about human heading perception [1] described via the respective rapid eye movement (so called saccades) towards the object of interest position. The cooperation between the form and motion cues becomes very useful and even necessary, when: (i) each cue (motion, form) alone does not supply sufficient information to estimate the proper and accurate heading, or/and, (ii) the uncertainty, associated with the utilized visual cues and the possible conflicts between them influence negatively the process of decision making. The last case relates closely to the effect of the age-related changes throughout the life cycle and to deterioration in the cognitive processes, and consequently in visual information processing due to a variety of factors like cell death, cognitive de-differentiation, increase of internal noise in the visual system. As a result, the contrast sensitivity, self-motion perception, as well as eye movement characteristics are deteriorated in the elderly [2], [3], [4]. To overcome all these difficulties one needs to combine and utilize in an effective way both

of cues in order to achieve inferences, more informative and potentially more accurate than if they were obtained by means of a single cue. Integration of information from multiple sources (cues) in a single modality increases the precision of perceptual performance. Such a claim recently has been supported by a list of neurobiological studies, like [5], [6], [7], and also neurophysiological findings exist about neurons responding to both form and motion in some cortical sites (including early visual areas and extrastriate areas) [8], [9].

Inspired and based on these important biological findings of the cue combination effectiveness, the aim of this paper is to investigate how humans integrate motion and form information in the process of decision making about heading direction. The authors will focus on how the human age influences this process, and also whether the human visual system is enable to adapt during the life cycle in order to exploit all available information, providing a sensible and meaningful decision about the problem under concern. In our study we simulate only the directional flow occurring during the forward motion of the observer and not the changes in speed or size of the moving objects that accompanied it. The researcher team will compare human cue combination performance with modelled combination performance, based on particular fusion rules. In the presented study the authors will apply and compare the performances of the following fusion rules: the Normalized Conjunctive Consensus (NCC), and the very recent probabilistic Proportional Conflict Redistribution rule no.5 (pPCR5) defined within DSMT. The novelty of our study consists in applying especially this novel pPCR5 fusion rule to model the human process of form and motion cues integration.

This paper is organized as follows. In section II we briefly present the form and motion combination process, and the principles of the used fusion rules, applied to model the human cue integration. Section III is devoted to the experimental strategy, methods, procedures, stimulus, apparatus, and also

subjects participating in the experiments. The results obtained are described and analysed in Section IV. Conclusions are made in Section V.

## II. FUSION RULES FOR MODELLING VISUAL CUE COMBINATION

Various fusion rules exist in the literature to deal with uncertain or even conflicting evidence based on different mathematical models and on different methods for transferring the conflicting mass onto the sensible hypotheses about the problem under consideration. The classical one is Bayesian inference [10], [11] which deals with probabilistic information. The main idea of Bayesian inference is to obtain the most reliable estimate of the state of the world on the base of independent cues combination, i.e. the estimate in which the variance of the resulting combined cue is minimized. But being very sensitive to the sources with the bigger means, it could neglect part of available information, which is not adequate and reliable behavior in cases of conflicting visual cues combination. Bayesian inference has some difficulties to apply, related to the requirements of measurements' statistics and knowledge about the a priori information. Dempster-Shafer Theory (DST) [12], [13] was the first theory for combining uncertain information expressed as basic belief assignments with Dempster's rule. Although appealing in modelling the epistemic uncertainty this theory shows very questionable and controversial results in cases of high (and even low) conflicting sources of evidence [14], [15], [16], [17].

To overcome all these limitations of DST, Dezert-Smarandache Theory of Plausible and Paradoxical Reasoning was developed [18].

DSMT works for any model, which fits adequately with the true nature of the fusion problem under consideration. It is a general mathematical framework for managing and solving problems of uncertain, highly conflicting, imprecise knowledge representation and fusion, and decision making procedures, based on vague, imprecise models for a wide class of static or dynamic fusion problems.

### A. Normalized Conjunctive Consensus rule

The Normalized Conjunctive Consensus (NCC) rule is used to combine simultaneously assumed independent visual cues. In the case considered in our paper, the information obtained by the available form and motion cues is characterized by Gaussian likelihood functions with given means  $\mu_i, i = 1, 2, \dots$  and standard deviations  $\sigma_i, i = 1, 2, \dots$ , defining the uncertainty encountered in data. In case of two independent cues with one-dimensional Gaussian distributions  $p_1(x) = \frac{1}{\sigma_1\sqrt{2\pi}} \exp -\frac{1}{2}\left(\frac{x-\mu_1}{\sigma_1}\right)^2$  and  $p_2(x) = \frac{1}{\sigma_2\sqrt{2\pi}} \exp -\frac{1}{2}\left(\frac{x-\mu_2}{\sigma_2}\right)^2$ , the combined distribution based on NCC rule becomes:

$$p_{NCC}(x) = \frac{1}{\sigma_{NCC}\sqrt{2\pi}} \exp -\frac{1}{2}\left(\frac{x-\mu_{NCC}}{\sigma_{NCC}}\right)^2, \quad (1)$$

where  $\sigma_{NCC}^2 = \frac{\sigma_1^2\sigma_2^2}{\sigma_1^2+\sigma_2^2}$  and  $\mu_{NCC} = \sigma_{NCC}^2\left(\frac{\mu_1}{\sigma_1^2} + \frac{\mu_2}{\sigma_2^2}\right)$ .

It is characterized with a mean, biased toward the function with the bigger of the two means, similarly to Bayesian estimator. It is optimal, i.e. minimizes the variance of the error estimation, when the original distributions have close mean values. When both cues are in conflict, however, (characterized with distant distributions), NCC rule leads to neglecting part of the available information, because the source with the bigger mean is weighted more heavily. In this case it is reasonable to keep the original distributions in the fused probability density function until it is possible to make reliable decision. This has been done by pPCR5 fusion rule defined in DSMT.

### B. Probabilistic Proportional Conflict Redistribution rule no.5

The general principle of all Proportional Conflict Redistribution rules [18], Vol.3 is to: 1) calculate the conjunctive consensus between sources of evidence (different visual cues) 2) calculate the total or partial conflicting masses; 3) redistribute the conflicting mass (total or partial) proportionally on non-empty sets involved in the model according to all integrity constraints. The recently proposed non-Bayesian probabilistic Proportional Conflict Redistribution rule no.5 (pPCR5) [18] is based on the discrete Proportional Conflict Redistribution rule no.5 [18], Vol.3, for combining discrete basic belief assignments. For completeness, we will discuss in brief the main idea behind the discrete PCR5. It comes from the necessity to deal with both uncertain and conflicting information, transferring partial or total conflicting masses proportionally only to non-empty sets involved in the particular conflict and proportionally to their individual masses. Basic belief assignment (bba) represents the knowledge, provided by particular source of information about its belief in the true state of the problem under consideration. Given a frame of hypotheses  $\Theta = \{\theta_1, \dots, \theta_n\}$ , and the so called power set  $2^\Theta = \{\emptyset, \theta_1, \dots, \theta_n, \theta_1 \cup \theta_2, \dots, \theta_1 \cup \theta_2 \cup \dots \cup \theta_n\}$ , on which the combination is defined, the general basic belief assignment is defined as a mapping  $m_s(\cdot) : 2^\Theta \rightarrow [0, 1]$ , associated with the given source of information s, such that:  $m_s(\emptyset) = 0$  and  $\sum_{X \in 2^\Theta} m_s(X) = 1$ . The quantity  $m_s(X)$  represents the mass of belief exactly committed to X. Under Shafer's model assumption of the frame  $\Theta$  (requiring all the hypotheses to be exclusive and exhaustive), the PCR5 combination rule for only two sources of information is defined as:  $m_{PCR5}(\emptyset) = 0$  and  $\forall X \in 2^\Theta \setminus \{\emptyset\}$

$$m_{PCR5}(X) = m_{12}(X) + \sum_{\substack{Y \in 2^\Theta \setminus \{X\} \\ X \cap Y = \emptyset}} \left[ \frac{m_1(X)^2 m_2(Y)}{m_1(X) + m_2(Y)} + \frac{m_2(X)^2 m_1(Y)}{m_2(X) + m_1(Y)} \right]. \quad (2)$$

All sets involved in the formula are in canonical form. The quantity  $m_{12}(X)$  corresponds to the conjunctive consensus, i.e:  $m_{12}(X) = \sum_{\substack{X_1, X_2 \in 2^\Theta \\ X_1 \cap X_2 = X}} m_1(X_1) m_2(X_2)$ . All denominators are different from zero. If a denominator is zero, that fraction is discarded. No matter how big or small the conflicting mass is, PCR5 mathematically does a proper redistribution of the conflicting mass. It is because PCR5 goes backwards

on the tracks of the conjunctive rule and redistributes the partial conflicting masses only to the sets involved in the conflict and proportionally to their masses put in the conflict, considering the conjunctive normal form of the partial conflict. PCR5 is quasi-associative and preserves the neutral impact of the vacuous belief assignment. The probabilistic PCR5 (pPCR5) is an extension of discrete PCR5 version to its continuous probabilistic counterpart. Basic belief assignment, involved in discrete PCR5 rule is extended to densities of probabilities of random variables. For two independent sources of information with given Gaussian distributions  $p_1(x)$  and  $p_2(x)$ , the obtained combined result becomes [18]:

$$p_{pPCR5}(x) = p_1(x) \int \frac{p_1(x)p_2(y)}{p_1(x) + p_2(y)} dy + p_2(x) \int \frac{p_2(x)p_1(y)}{p_2(x) + p_1(y)} dy. \quad (3)$$

The behavior of pPCR5 fusion rule in comparison to NCC rule (1) could be characterized by two cases below:

**Case 1:** both densities  $p_1(x)$  and  $p_2(x)$  are close (Fig.1-case 1). The combined density acts as an amplifier of the information by reducing the variance. Here pPCR5 acts as NCC fusion rule.

**Case 2:** the densities  $p_1(x)$  and  $p_2(x)$  are distant (Fig.1-case 2). Then the combined density keeps both original densities (not merging both densities into only one unimodal Gaussian density as NCC rule does), avoiding to neglect a part of the available information.

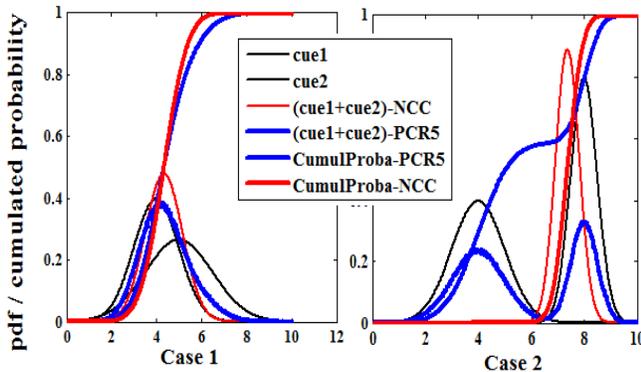

Figure 1. Performance of pPCR5 fusion rule vs. NCC rule.

This new (from a theoretical point of view) property is very interesting and it presents advantages for practical applications as it will be shown in our particular research. Application of pPCR5 fusion rule assures robustness to the potential errors and allows taking more reliable and adequate decisions in the process of integration of different cues in visual perception.

### III. EXPERIMENTS

#### A. Stimuli

The stimuli consisted of 50 dots. The dot patterns occupied an area of 15 angular degrees. The stimuli were

generated beforehand and contained 100 frames (except the static condition). Each frame lasted 33 msec. The lifetime of the dots was 3 frames, thus on every frame one-third of the dots were randomly re-positioned. For the motion and the combined condition the velocity of the dots was 4 degrees of arc/sec. The stimuli were radial patterns with a focus (center) positioned eccentrically to the middle of the screen. The center of the patterns defined by the orientation of the pairs or the trajectories of the dots could take 7 values to the left or to the right of the midpoint of the screen: 0.67 to 4.67 degrees of arc in steps of 0.67 degrees of arc. Ten different exemplars of patterns for each center and condition were generated. The dots subtended 0.2 degrees of arc.

#### B. Experimental conditions

Four different experimental conditions were performed:

- **Static (form) condition** The experimental stimuli (Fig.2) consist of dots pairs separated by 2 degrees of arc. The orientation of the virtual lines connecting the dots in 18 pairs intersected in a common point considered the center of the patterns, while the rest 7 pairs had random orientation.
- **Motion condition** In this experiment (Fig.3) 36 points had trajectories that intersected at a common point, while the rest 14 dots had random trajectories.
- **Flicker condition** In this condition (Fig.4) a sequence of random static patterns was presented. As in the static condition the orientation of 18 pairs of dots, separated by 2 degrees of arc pointed to a common center while the rest 7 pairs had different orientation. The sequential presentation of the static patterns created illusory motion, but the trajectories of the apparent motion were random.
- **Combined condition** In this experiment (Fig.5) 18 pairs of dots moved along trajectories towards a common center. The orientation of these pairs was along the motion trajectory. The rest 7 pairs had random trajectories, but again, the orientation defined by the pairs was along the trajectory of motion.

The figures 2-5 correspond to a single frame from the four experimental conditions. The four conditions of the experiment differ by the relative contribution and the order of temporal and spatial integration. In the static conditions the observers needed to find the correspondence of the dots to a pair and to globally integrate this information in order to find the focus of the radial pattern. In the flicker condition on every frame the observers had to integrate the spatial information from the pairs of dots but they could benefit from temporal integration of the sequential patterns that would be equivalent to the presence of a larger number of dot pairs. In the motion conditions the observers had to temporally integrate the displacement of dots in the sequential frames in order to determine their trajectory of motion and to integrate this information in space to determine the focus of the radial pattern. In the combined condition the observers had redundant information as both the trajectory of dot motion and the orientation of the dot pairs provided similar information.

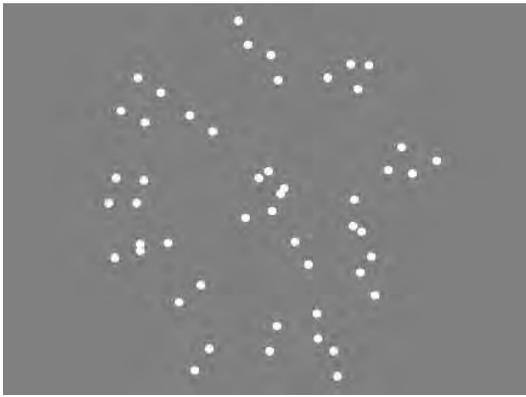

Figure 2. Static Condition.

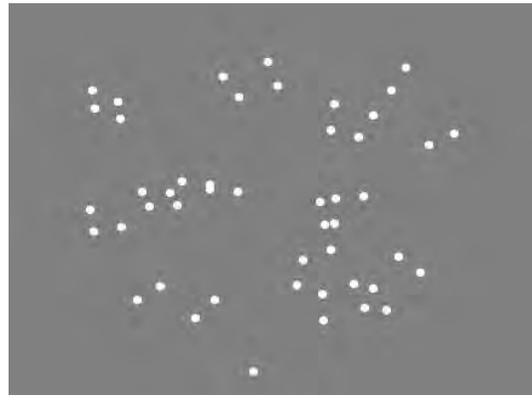

Figure 4. Flicker Condition.

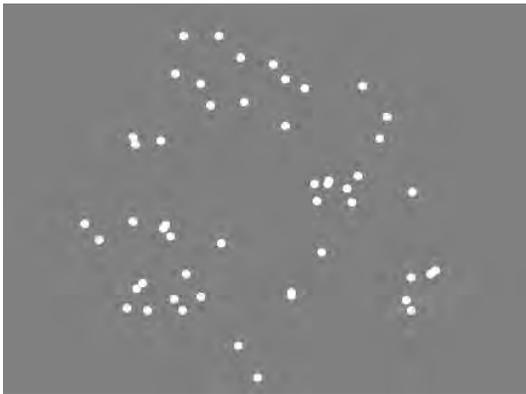

Figure 3. Motion Condition.

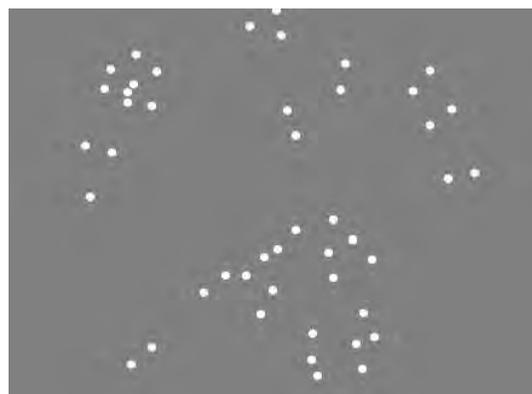

Figure 5. Combined Condition.

### C. Experimental Procedure

The subject sat at 57 cm from the monitor screen. The stimuli were presented on a gray screen with mean luminance  $50 \text{ cd/m}^2$ . Each stimulus presentation was preceded by a warning signal. A red fixation point with size of 0.8 degrees of arc appeared in the center of the screen for 500 msec. The stimuli were presented simultaneously with the disappearance of the fixation point. The Subjects performed a single-stimulus two-alternative force choice task. They had to continue looking at the position where the fixation point was presented until making a decision where the center of the pattern was (left or right relative to the fixation point). At this moment the subject had to move his/her eyes towards the position of the perceived center and to press the left or the right mouse button depending on whether the perceived center appeared to the left or to the right from the fixation point. If the subject could not make a decision during the 3.3 sec of the stimulus presentation (100 frames), the stimulus disappeared and the screen remained gray until the subject made a response.

### D. Method

The method of constant stimuli was used. Each condition was presented in a separate block consisting of 10 presentations for each position of the pattern center (a total of 140 presentations, 7 positions for a center shifted to the left and

7 positions for a center shifted to the right). The order of stimulus presentation was random. Each Subject took part in at least two experiments with 4 blocks for each of the 4 experimental conditions. All conditions were presented in a random order in a single day. The duration of each block depended on the subject performance, but the experiment did not exceed 1 hour. The eye movements of the subjects were registered with Jazz-novo multisensor measurement system (Ober Consulting Sp. z o.o) [20].

### E. Apparatus

The stimuli were presented on a 20.1 inch NEC MultiSync LCD monitor with NvidiaQuadro 900XGL graphic board at a refresh rate of 60 Hz and screen resolution 1280/1024 pixels. The experiments were controlled by a custom program developed under Visual C++ and OpenGL.

### F. Subjects

The subjects participating in the experiments are divided in three age groups: young (aged from 20 to 34 years), middle (aged 35 to 55 years) and elderly (aged 57 to 84 years). They did not have a whole training session, but they were given examples of stimuli to check whether they understood the task and to get an idea of the stimuli in a given condition.

#### IV. PERFORMANCE EVALUATION OF AGE-RELATED OBSERVERS GROUPS

The experimental goal of our study is directed to characterize the human heading perception influenced by: (i) form information only (ii) motion information only (iii) flicker information, i.e temporal integration of form information (iv) combined form and motion information. The question is if people rely and base their responses on a single source of information, or on combined one, and also which type of information utilized is more informative in the decision process. The participants belong to three age groups: Young, Middle aged, and Old. Hence, also the influence of human age on the assessment of heading perception will be evaluated. The evaluation is made on the base of experimental psychometric functions, obtained for all different experimental conditions and for each subject in all age-contingent groups. The psychometric function reflects the dependence between a given physical quantity (in this case, the pattern shift from the middle of the screen) and the proportion of subjects' responses of a given type, in our case "the proportion of responses "Center to the right".

- **Evaluation of heading perception in Young observers group**

The comparison of the performance in the static, motion and flicker conditions show that in Young group only 2 out of 10 observers have best performance for the static condition, 4 observers effectively utilized the motion information showing best performance in this case, and 4 out of 10 observers show best performance in the flicker condition. For 4 out of 10 observers the null hypothesis of equal psychometric functions for both motion and flicker information could not be rejected, i.e they could be considered as equivalent. These results suggest that the young observers effectively integrate the available information in time. The contribution of the information available in each of these three conditions to the performance of the combined condition differs. Only 1 out of 10 subjects relies mainly on motion, 1 - on the information available in the flicker condition, while 7 out of 10 combined effectively the independent sources of information available in the static and motion condition. The performance of averaged (on the base of 10 subjects in the group) young subject is shown on Fig.6.

For the averaged young subject the psychometric curves associated with static, motion, and flicker information are not distant and the null hypothesis that they do not differ could not be rejected.

- **Evaluation of heading perception in Middle aged observers group**

In this age-related group only 1 out of 6 subjects shows

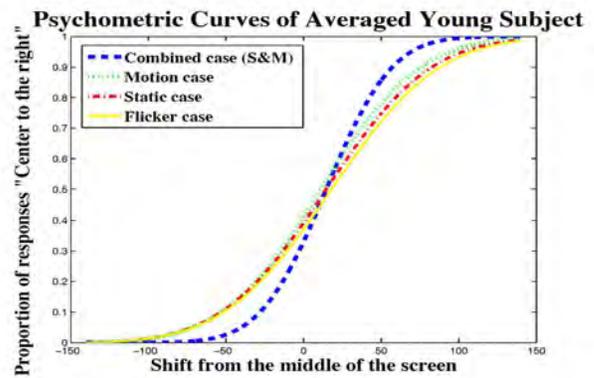

Figure 6. Psychometric Curves of Averaged Young Subject.

better performance in the static condition and 1 out of 6 observers - in the flicker condition. For 1 out of 6 observers the null hypotheses of equal psychometric functions for both motion and static information could not be rejected. For 4 out of 6 observers the null hypothesis for equal psychometric functions for motion and flicker conditions could not be rejected too. As general, the results suggest a small effect of the static information. The results for 4 out of 6 observers show that the results in the combined condition could be successfully predicted based on the performance of the static and motion conditions. The performance of averaged middle aged subject is shown on Fig.7.

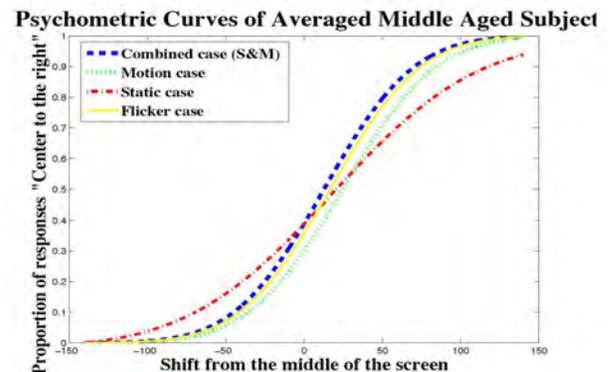

Figure 7. Psychometric Curves of Averaged Middle aged Subject.

The averaged middle aged observer does not rely mainly on the static information. For him the combined and flicker condition do not differ significantly.

- **Evaluation of heading perception in Old observers group**

The obtained results in Old-age group show that 3 out of 10 observers show best performance in the static, 3 out of 10 - in motion, and 4 out of 10 in the flicker condition. The null hypothesis for equal psychometric

functions is valid for: 1 out of 10 for motion and static condition, and for 2 out of 10 - for motion and flicker condition. Six out of 10 subjects utilize combined static and motion information to make their final decision in the combined condition. The performance of averaged old subject is shown on Fig.8. For averaged old subject the null hypotheses that the static and flicker cases do not differ is valid. The averaged old observer relies more on motion information.

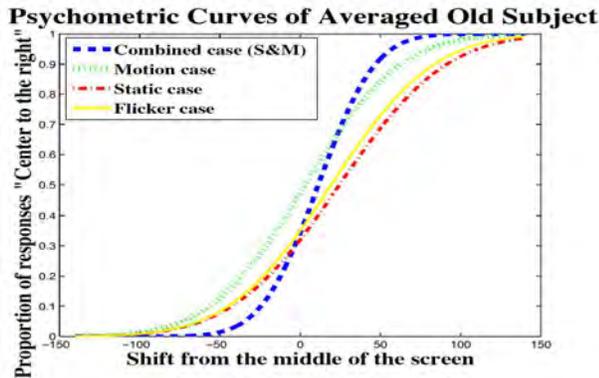

Figure 8. Psychometric Curves of Averaged Old Subject.

V. pPCR5 AND NCC RULES PERFORMANCE FOR PREDICTING HUMAN'S WAY OF FORM AND MOTION COMBINATION

The main question here is which fusion rule - pPCR5 or NCC used to combine available static and motion information predicts more adequately human cue integration? In order to answer this question we need to make a comparison between experimentally obtained and predicted (via pPCR5 and NCC rules) psychometric functions for combined condition (static and motion), for the three age contingent groups. This comparison is provided on the base of *goodness-of-fit test* [19], one important application of chi-squared criteria:  $\chi^2 = \sum_{j=1}^J \frac{(O_j - E_j)^2}{E_j}$  where  $\chi^2$  is an index of the agreement between an observed(*O*)/experimental and expected(*E*)/predicted via particular fusion rule sample values of psychometric function. For our case  $J = 14$  represents the number of pattern's shifts from the middle of the screen. The critical value of the test for  $\nu = J - 1 = 13$  degrees of freedom at assumed  $p = 0.1$  is  $\chi^2 = 19.81$  [19]. The respective results are given in Table I - for young group, in Table II - for middle aged group, and in Table III - for old persons' group.

In general, the results show that the pPCR5 fusion rule predicts more adequately than NCC rule human performance for the three age groups.

For young and for middle aged persons (Tables I and II) both fusion rules predict psychometric functions that do not differ significantly from the experimental ones, but the differences in the fits are smaller in case of pPCR5 rule than in case of NCC rule application. The same findings are valid for old people (Table III), but in this group NCC rule show

Table I  
CHI-SQUARED VALUES FOR YOUNG SUBJECTS.

Subject	(Form and Motion) pPCR5	(Form and Motion) NCC
1	0.8587	1.8482
2	0.4801	0.8456
3	0.3045	1.2690
4	0.1509	0.9716
5	0.1655	0.1458

3	0.4192	0.9341
4	0.9872	1.4716
5	0.2380	1.0143
6	0.2425	0.8456

worse performance for subject no.4 (put in bold in Table III) showing the exceeded critical value of  $\chi^2 = 19.81$ . The reason for this result reflects the situations, when the experimentally obtained psychometric functions, associated with single static and single motion conditions are characterized with distant underlying Gaussian distributions. In this case pPCR5 makes prediction, which models more correctly and adequately human combination behavior. Using NCC rule however, part of available information has been neglected, because the cue with bigger mean was weighted more heavily than the cue with a smaller one (as it was described in Section II).

VI. COMMON TRENDS OF AGE RELATED OBSERVER GROUPS

The goal here is to find the common trend, concerning the performance of the three groups. In order to achieve it, we consider each group as a set of different sources of evidence, associated with each person in the group. That way young group consists of 10 (middle aged of 6, old aged of 10) sources (subjects) of evidence, which should be combined all together via pPCR5 and NCC fusion rules.

The combined individual behaviors in particular group are estimated, revealing its intrinsic behavior as a whole, reducing uncertainties associated with individual performances. All the tested subjects in age groups are considered as independent and equally reliable sources of information, because each subject provides his/her own psychometric function, associated with the static and motion condition and should be taken into account with equal weights to derive these trends.

Our goal is to find out which combinational rule (pPCR5 or NCC) is able to model correctly and adequately such human age-contingent group trends in the process of decision making. The results obtained for experimental and estimated (via the

Table III

fusion rules) trends, concerning the cues combination groups' performance are presented in Figures 9, 10, and 11.

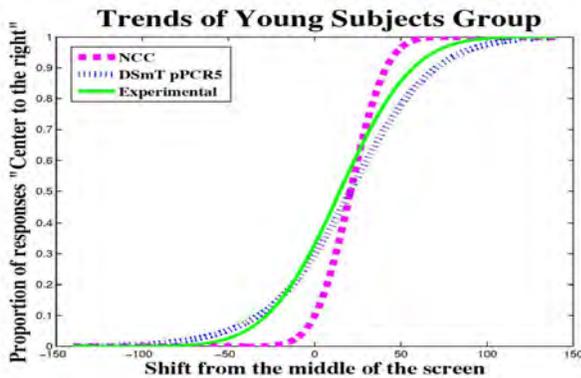

Figure 9. Trends of Young Subjects Group.

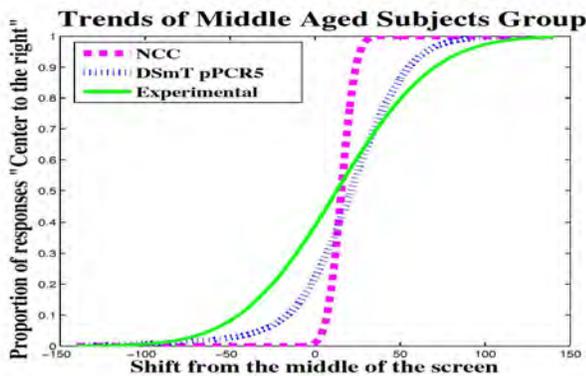

Figure 10. Trends of Middle aged Subjects Group.

In order to compare the performance of both fusion rules in estimating common trends' prediction the city-block errors between the corresponding triples (*young/middle/old* group experimental form and motion combination) - *young/middle/old* group estimated (via pPCR5 and NCC) form and motion combination are given in Table IV. Results show ultimately that experimentally obtained and those, based on pPCR5 fusion rule are closer and for the three age-contingent groups are more than two times less than those, obtained via NCC

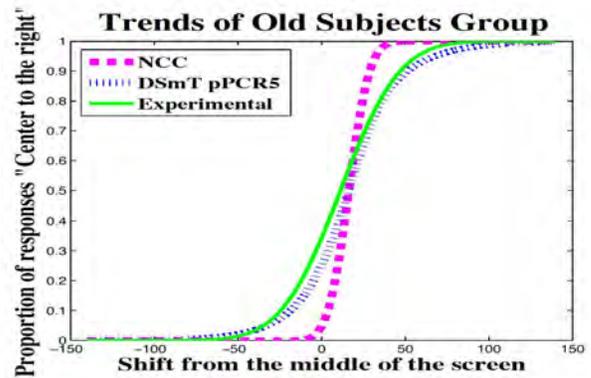

Figure 11. Trends of Old Subjects Group.

fusion rule. pPCR5 fusion rule predicts more correctly the human model of decision making, than NCC rule, utilizing all the available information (**Form and Motion**), even in case of conflict. NCC based trends are very sensitive to the sources (different subjects' psychometric functions) with the bigger means, neglecting that way part of the available information and acting as an amplifier of the information by reducing the variances.

## VII. CONCLUSIONS

This paper presented a study on human heading perception obtained on the base of motion and form visual cues integration. The influence of human age on this process was evaluated. The results obtained show age-related difference in the performance of the subjects in estimating the heading direction based on the combined static (form) and motion information.

Our experimentally obtained data for young observers suggest smaller effect of the static information case and provides indirect evidence that their performance is based more on the temporal integration of information in the motion and flicker conditions. The experimental results for Middle-aged group suggest less effect of the static information and an effect of the order of temporal and spatial integration. The old subjects used to rely more on the motion information. All age-related groups rely on combined (motion and form) information to take their final decisions for heading perception.

A comparison between experimentally obtained and predicted (via pPCR5 and NCC rules) psychometric functions for combined condition (static and motion), for the three age contingent groups was made and estimated on the base of *goodness-of-fit test*, one important application of chi-squared criteria. Results proved that pPCR5 makes prediction, which

models more correctly and adequately human combination behavior than NCC, especially in cases of conflicts between the different visual cues.

The combined individual behaviors (the trends) in particular age groups were estimated, revealing its intrinsic behavior as a whole, reducing uncertainties associated with individual observers' performance. Results show ultimately that pPCR5 fusion rule, utilizing all the available information - static (form) and motion, even in case of conflict, predicts more correctly the human model of decision making, than NCC rule. That way pPCR5 fusion rule assures preserving the richness of cues data in the process of visual stimuli combination and assures improvement of decision accuracy. pPCR5 describes better the characteristics of the different age groups in decision making based on the motion and form information in heading perception.

### VIII. ACKNOWLEDGEMENT

The reported work is partially supported by the project DN02/3/2016 'Modelling of voluntary saccadic eye movements during decision making' funded by the Bulgarian Science Fund.

**Abstract**—The extraction of building changes from very high resolution satellite images is an important but challenging task in remote sensing. Digital surface models (DSMs) generated from stereo imagery have proved to be valuable additional data sources for this task. In order to efficiently use the change information from the DSMs and spectral images, belief functions have been introduced. In this article, two-step building change detection fusion models based on both Dempster-shafer theory (DST) and Dezert-Smarandache Theory (DSMT) frameworks are proposed. In the first step, basic belief assignments (BBAs) of the change indicators from images and DSMs are calculated by using a refined sigmoidal BBA model. Then these BBAs are employed for the new proposed building change detection decision fusion approach. In order to cover the miss-detections introduced by the wrong height values of the DSMs and incomplete information from images, disparity maps from the DSM generation procedure and shadow maps from the multispectral channels are adopted to generate reliability maps, which are further integrated to the fusion models. In the last step, building change masks are generated based on four decision-making criteria. In the experimental part of this work, we evaluate the performance of this new building change detection method on real satellite images thanks to a building change reference mask representing the ground truth. Substantial accuracy improvements are achieved when comparing the new results with those obtained from classical 3D change detection approaches.

**Keywords:** change detection, belief functions, DSMT, DST, DSM.

## I. INTRODUCTION

Efficient and accurate detection of building changes using remote sensing data is of great importance for urban monitoring and disaster monitoring. It is one of the fundamental tasks in remote sensing and is attracting more interests due to the high and accelerated rate of urban growing and more frequent natural disasters with climate changes.

In the last decades, 2D change detection methods on large scale land cover monitoring have been extensively studied and applied on satellite images [1], [2], [3]. There are many excellent approaches available which can extract landcover changes from multi-temporal images [4], [5]. However, highlighting only building changes in urban area remains difficult due to the mixture of other background changes, for instance the changes introduced by different illumination conditions or

human activities. The influence of these changes is growing as higher resolution images show more details of the landcover objects. In addition, even with very high resolution data it is sometimes impossible to distinguish buildings and roads using simple spectral change.

Therefore, height information derived from Digital Surface Model (DSM) is posing new possibilities for building change detection. Benefiting from improved data quality and advanced computer vision techniques, the accuracy of the DSMs from satellite stereo imagery has been largely improved and enables building change detection in a larger region and with high frequency. However, the DSMs may exhibit some inaccurate height values resulting from failed matching and occlusions within the stereo and multiple views. Thus the fusing of changes from multispectral image and DSMs would be an effective solution for building change detection. The comparison of DSMs can locate the changes of high-level objects efficiently and robustly and the spectral images have rich spectral and texture features which can highlight more changes among the multi-temporal datasets. On the other hand, as the DSMs have been generated from the multispectral data, there is no time difference between them. The 2D and 3D information can be combined through post-refinement, region-based approaches or decision fusion [6]. In more recent researches, DSMs from multi-sensors and time-series data were involved [7], [8].

Regarding to feature fusion due to the diverse building characteristics and background information, the urban building monitoring approaches may perform variedly for different test regions. Thus recently some researches are trying to combine different change features and change classification methods, and fuse the results with a decision model. For instance, [9] have proposed a probabilistic framework to fuse the results from four local feature vectors for building detection. Based on an adaptive network-based fuzzy inference system, [10] have fused the change detection results from different feature combinations. Besides fusing the detection result, decision fusion can be also directly used for classification and change detection [11]–[15].

Thus until now there is no decision fusion model that

directly takes the change indices from images and height maps for building change detection. In our previous research works [16], belief functions have performed very well for 3D building change detection. As aforementioned, the accuracy of 2D change detection of specific objects is limited due to the misdetections caused by irrelevant changes. These irrelevant changes have a larger effect on very high resolution (VHR) images than on low and moderately high resolution images, since in VHR images their higher details are more sensitive to viewing and solar angle differences. DSMTs generated from satellite stereo imagery can largely help to solve this problem. Unfortunately, the fusion model proposed in [16] is rather basic, and it is not robust in dealing with high conflict situations. Therefore, the belief functions have been further investigated and improved in this article. Besides Dempster-Shafer Theory (DST) [17], [18], an extended Dezert-Smarandache Theory (DSMT) [19] will be adopted in this article to generate the building change detection models. One of the difficulties of using Dempster-Shafer theory is the definition of uncertainty and the calculation of the basic belief assignments (BBAs). [16] used one sigmoid function to distribute the values of one change feature to the BBAs ranging from 0 to 1. The symmetry point which indicates a certainty of 50% was automatically calculated with a thresholding method. However, the accuracy and robustness of the thresholding approach will directly influence the correctness of the obtained BBAs. Thus, as well as the fusion models, the BBAs construction approach should be updated to further improve the change detection result. These problems have been well addressed in our modified approach [20]. In addition, the uncertainty of change indicators was measured in order to improve the accuracy of BBAs. Due to space limitation constraint of conference paper format, the methodology part has been only shortly described in [20] and only small patches have been tested in the experimental part. A better description of this methodology with more experiments of our approach is presented in this article with the improvement of the reliability discounting approach.

Focusing on building change detection by fusing spectral and height information extracted from satellite stereo imagery, this article is organised as follows. First, the belief functions of DST and DSMT are briefly reviewed. Then, the building change models are proposed for these theoretical frameworks. The belief functions are used in both BBAs preparation and change detection procedure. Two sigmoid functions are simulated for each change feature to obtain the BBAs. In order to further improve the BBAs values reliability discounting techniques are presented. We use the unfilled disparity map and shadow maps to generate the reliability map of the changes from the height and 2D images, respectively. The reliability maps are then used in the fusion process to refine the initial BBAs. We generate four sets of global BBAs. With four decision criteria the final change detection masks can be generated. In the end, these refined fusion models are tested on four sets of real satellite images, and a comprehensive comparison is included to validate the new approaches.

## II. BELIEF FUNCTIONS, DST AND DSMT

### A. Basics of belief functions

The details of DST and DSMT have been presented by [18], [19] and [21]. Let  $\Theta$  be a frame of discernment of a problem under consideration.  $\Theta = \{\theta_1, \theta_2, \dots, \theta_N\}$  consists of a list of  $N$  exhaustive and mutually exclusive elements  $\theta_i$ ,  $i = 1, 2, \dots, N$ . Each  $\theta_i$  represents a possible state related to the problem we want to solve. The assumption of exhaustivity and mutual exclusivity of elements of  $\Theta$  is classically referred as *Shafer's model* of the frame  $\Theta$ . A BBA also called a belief mass function (or just a mass for short), is a mapping  $m(\cdot) : 2^\Theta \rightarrow [0, 1]$  from the power set<sup>1</sup> of  $\Theta$  (denoted  $2^\Theta$ ) to  $[0, 1]$ , that verifies [18]:

$$m(\emptyset) = 0, \quad \text{and} \quad \sum_{X \in 2^\Theta} m(X) = 1. \quad (1)$$

$m(X)$  represents the mass of belief exactly committed to  $X$ . An element  $X \in 2^\Theta$  is called a focal element if and only if  $m(X) > 0$ . The belief and plausibility functions based on DST theory are defined respectively as:

$$Bel(A) = \sum_{B \in 2^\Theta, B \subseteq A} m(B), \quad (2)$$

$$Pl(A) = \sum_{B \in 2^\Theta, B \cap A \neq \emptyset} m(B). \quad (3)$$

In DST, the combination (fusion) of several independent sources of evidences is done with Dempster-Shafer<sup>2</sup> (DS) rule, assuming that the sources are not in total conflict<sup>3</sup>. DS combination of two independent BBAs  $m_1(\cdot)$  and  $m_2(\cdot)$ , denoted symbolically by  $DS(m_1, m_2)$ , is defined by  $m^{DS}(\emptyset) = 0$ , and for all  $X \in 2^\Theta \setminus \{\emptyset\}$  by:

$$m^{DS}(X) = \frac{1}{1 - K^{DS}} \sum_{\substack{X_1, X_2 \in 2^\Theta \\ X_1 \cap X_2 = X}} m_1(X_1)m_2(X_2), \quad (4)$$

where the total degree of conflict  $K^{DS}$  is given by

$$K^{DS} \triangleq \sum_{\substack{X_1, X_2 \in 2^\Theta \\ X_1 \cap X_2 = \emptyset}} m_1(X_1)m_2(X_2). \quad (5)$$

A discussion on the validity of DS rule and its incompatibility with Bayes fusion rule for combining Bayesian BBAs can be found in the literature [21], [22], [23]. To circumvent the problems of DS rule, Smarandache and Dezert ([19], Vol. 2, Chap. 1), then Martin and Osswald ([19], Vol. 2, Chap. 2) have developed in DSMT [19] two fusion rules called PCR5 and PCR6 based on the proportional conflict redistribution (PCR) principle which consists

<sup>1</sup>The power set is the set of all subsets of  $\Theta$ , empty set included.

<sup>2</sup>Although the rule has been proposed originally by Dempster, we call it Dempster-Shafer rule as it has been widely promoted by Shafer in DST [18].

<sup>3</sup>otherwise DS rule is mathematically not defined because of 0/0 indeterminacy.

- 1) apply the conjunctive rule
- 2) calculate the total or partial conflicting masses
- 3) then redistribute the (total or partial) conflicting mass proportionally on non-empty sets involved in the conflict according to the integrity constraints one has for the frame  $\Theta$ .

This PCR principle transfers the conflicting mass only to the elements involved in the conflict and proportionally to their individual masses, so that the specificity of the information is not degraded. Because the proportional transfer can be done in different ways, this has yielded to several different fusion rules. It has been proved by [24] that only PCR6 rule is compatible with frequentist probability estimation, and that is why we recommend its use in the applications. PCR5 and PCR6 rules simplify greatly and their formulas coincide for the combination of two sources. In this case, the PCR6 combination is obtained by taking  $m^{PCR6}(\emptyset) = 0$ , and for all  $X \neq \emptyset$  in  $2^\Theta$  by

$$m^{PCR6}(X) = \sum_{\substack{x_1, x_2 \in 2^\Theta \\ x_1 \cap x_2 = X}} m_1(x_1)m_2(x_2) + \sum_{\substack{Y \in 2^\Theta \setminus \{X\} \\ X \cap Y = \emptyset}} \left[ \frac{m_1(X)^2 m_2(Y)}{m_1(X) + m_2(Y)} + \frac{m_2(X)^2 m_1(Y)}{m_2(X) + m_1(Y)} \right], \quad (6)$$

where all denominators in Eq. (6) are different from zero. If a denominator is zero, that fraction is discarded.

If a denominator, e.g.,  $m_1(X) + m_2(Y)$  tends towards 0, then also the conflicting mass  $m_1(X)m_2(Y)$  that is transferable tends to zero because  $m_1(X)$  and  $m_2(Y)$  tend to zero (since they are positive); therefore, the redistribution of masses also tends to zero. That reflects the continuity of PCR6.

### B. Reliability discounting

The reliability discounting has been described and discussed in the references [25], [26]. Briefly, if an additional knowledge about the reliability ( $\alpha$ ) of certain source of evidence is available, it can be adopted to refine the initial BBAs. For instance the height change and image change indicators may not perform well under some situations. This situation can be measured, and used as reliability factors. Each factor  $\alpha$  would be a value ranging from 0 to 1. And  $\alpha = 1$  means fully reliable, while  $\alpha = 0$  means the indicator is totally unreliable. And all the remaining discounted mass are transferred to the full ignorance  $\Theta$ . Based on Shafer's discounting model [18], the reliability discounting factor  $\alpha$  is introduced to discount any BBA  $m(\cdot)$  defined on the power set  $2^\Theta$  as follows  $\forall X \in 2^\Theta$ :

$$\begin{cases} m_\alpha(X) = \alpha \cdot m(X), \text{ for } X \neq \Theta, \\ m_\alpha(\Theta) = \alpha \cdot m(\Theta) + (1 - \alpha). \end{cases} \quad (7)$$

## III. BUILDING CHANGE DETECTION FUSION MODEL

### A. Choice of the frame of discernment

Focusing on change detection, as a data preparation step, DSMs are calculated from satellite stereo imagery based on

semi-global matching approach [27], [28]. It follows two main steps. First, the epipolar image pair is generated through a pyramidal local least squares matching. Then the matching is cast into dynamic programming to minimise the cost function. We use census feature to measure the similarity between two pixels [27]. The challenges and opportunities of the DSMs assisted building change detection have been well described in [16]. The geo-information is employed to co-register these data, which enables a sub-pixel accuracy. Focusing on building change detection, two change indicators, one from images and one from DSMs are extracted. Changes from spectral images are highlighted by using the Iteratively Reweighted Multivariate Alteration Detection (IRMAD) [5]. Consequently, height changes from DSMs are shown after robust height difference [29], [16]. We suppose that new, demolished or rebuilt buildings may exhibit both height and spectral changes. But the spectral changes can also be introduced by seasonal changes and other irrelevant changes. After excluding building changes, changed pixels exclude building regions are named here as *OtherChange*. Therefore, three classes are considered to define the frame of discernment satisfying Shafer's model (i.e. the elements of the frame of discernment are disjoint):

$$\begin{aligned} \Theta = \{ & \theta_1 \triangleq \text{Pixel} \in \text{BuildingChange}, \\ & \theta_2 \triangleq \text{Pixel} \in \text{OtherChange}, \\ & \theta_3 \triangleq \text{Pixel} \in \text{NoChange} \}, \end{aligned} \quad (8)$$

and

$$\theta_1 \cap \theta_2 \cap \theta_3 = \emptyset. \quad (9)$$

In image domain, each pixel represents a single sample, thus in Eq. (8), we have directly used the word 'Pixel'. Based on the three exclusive classes, the set of potential focal elements *FE* that enter in our application is:

$$FE = \{\theta_1, \theta_2, \theta_3, \theta_1 \cup \theta_2, \theta_1 \cup \theta_3, \theta_2 \cup \theta_3, \theta_1 \cup \theta_2 \cup \theta_3\}. \quad (10)$$

It is worth noting that even if we work with Shafer's model of the frame of discernment for this application (which is the basis of DST), we can also use PCR6 rule developed in DSMT because PCR6 works also with Shafer's model as shown in [19].

The whole procedure of the proposed building change detection model is shown in Fig. 1. After the changes from DSMs and images are extracted, they will be reprojected using the sigmoid function to calculate the concordance index  $a$  and discordance index  $b$ . Then the decision fusion rules will be performed to generate the BBAs for height change and image change, respectively. After that, global BBAs can be calculated by using both DST and DSMT fusion rules. Finally, change mask can be obtained with various decision-making criteria.

### B. BBAs construction for building change detection

In [30] a sigmoidal model for both concordance and discordance indexes has been briefly presented. The details and advantages of this approach are described in [31]. The concordance index measures the concordance of change indicator and BBA in the assertion, while the discordance measures the

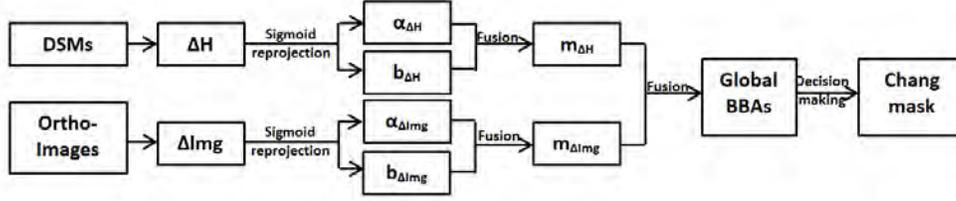

Fig. 1. Workflow of the proposed method.

opposition of change indicator to the BBAs in the assertion. In our previous works [16], the BBAs were built based on sigmoid curves related with the concordance index only. As explained in [16], the original sigmoid curve is defined as

$$f_{(\tau, T)}(x) = 0.99 / (1 + e^{-\frac{x-T}{\tau}}), \quad (11)$$

where  $x$  is the original value of each indicator ( $\Delta H, \Delta Img$ ), where  $\Delta H$  means the change in the height and  $\Delta Img$  means the change between two spectral images at a given pixel location. Two parameters  $T$  and  $\tau$  are used to control the symmetry point and the slope of the sigmoid function. The symmetry point indicates a certainty of 50%. In this article, we improve our model to construct the BBAs thanks to sigmoidal models for both concordance and discordance indexes following the idea proposed by [31]. The concordance index is similar as the indicator of our previous research. The green line in Fig. 2 shows an example of the concordance index from height changes. A higher height change indicator leads to a higher probability to be building change. The discordance index is defined as an indication for the opposite argument. The discordance index in Fig. 2 is shown in red color, which means that a higher height change reflects a lower probability to be *not building change*. The blue curve shows the conflict between the concordance and the discordance index. Both concordance index and discordance index are projected to the sigmoid curve distribution characterised by parameters  $T$  and  $\tau$ .

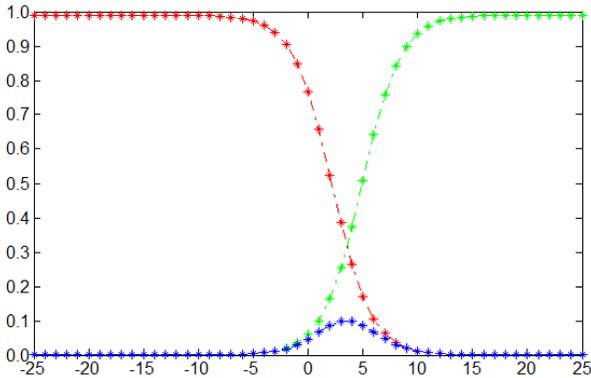

Fig. 2. Concordance and discordance index.

In [31] these two parameters  $T$  and  $\tau$  were manually selected. Here, as an improvement the multi-level Otsu's thresh-

olding method [32], [33] is used for automatically getting the symmetry points for both concordance index and discordance index. Otsu's algorithm assumes that an image is composed of objects and background. A discriminant analysis is performed by minimising the intra-class variance. When three classes are of interest, two thresholds  $T_1$  and  $T_2$  are expected, and Otsu's method can be extended to

$$\sigma_{\omega}^2(T_1, T_2) = \omega_1 \sigma_1^2(T_1, T_2) + \omega_2 \sigma_2^2(T_1, T_2) + \omega_3 \sigma_3^2(T_1, T_2). \quad (12)$$

The weights  $\omega_i$  are the probabilities obtained from the image histogram that are separated by the thresholds  $T_1$  and  $T_2$ .  $\sigma_i$  is the standard deviation of the  $i$ -th class, for  $i = 1, 2, 3$ .  $T_1$  and  $T_2$  can be used as the symmetry points of discordance and concordance index, respectively. Thus, using the height change index as in the example, the BBAs for concordance and discordance height change index are functions of values  $a_{\Delta H}$  and  $b_{\Delta H}$  defined by

$$a_{\Delta H} = f_{\tau, T_1}(\Delta H), \quad \text{and} \quad b_{\Delta H} = f_{-\tau, T_2}(\Delta H). \quad (13)$$

The discordance index can be considered as a reflection of the concordance index along the mirror line. Therefore, they are sharing the same  $\tau$ . Here, the factor  $\tau$  is calculated with a sample value ( $\Delta H = 1, a_{\Delta H} = 0.1$ ), which means 1 m height change indicates 10% probability to be building changes. The BBAs for discordance and concordance image change index are built similarly. Differences appearing in 2D images give a concordance indication for all changes, which include the building changes or other changes ( $\theta_1 \cup \theta_2$ ). In this article, the changes from images are named  $\Delta Img$ .

In the Tables I and II, we present the two ways of construction of the BBAs from the sources of evidence based either on DS or on PCR6 rules of combination for the height change indicator (i.e. the first source of evidence) and the image change indicator (i.e. the second source of evidence). It has to be noted that  $\theta_1 \cup \theta_3$  is not mentioned in the fusion model, as they do not share similar characters within the used feature space. In Table I,  $m_1(\cdot)$  and  $m'_1(\cdot)$  represent the concordance and discordance BBAs from  $\Delta H$ , whereas in Table II  $m_2(\cdot)$  and  $m'_2(\cdot)$  represent the concordance and discordance BBAs from images.  $K_{\Delta H}$  is the total conflicting mass value between  $m_1(\cdot)$  and  $m'_1(\cdot)$ , and  $K_{\Delta Img}$  in Table II is the total conflicting mass value between  $m_2(\cdot)$  and  $m'_2(\cdot)$ ,

### C. Reliability discounting

In the DSM assisted building change detection, false alarms arise if wrong heights are presenting in the DSM for large regions [16]. And these wrong heights are mostly introduced not in the stereoscopic images matching procedure, but in the gaps filling step. In the last step of the DSM generation procedure, the height of un-matched pixels is interpolated using the height values of neighbourhood pixels. Normally a reliable height value can be achieved for small gaps. But when large gaps appear in the disparity map, for example, for a whole building roof, the height of that building can not be correctly interpolated. Thus, the percentage of available successfully matched pixels inside a predefined neighbourhood region can be used to generate the height reliability. Fig. 3 shows an example of the generated reliability map. Fig. 3a is the gap mask. The gaps region of the disparity map is represented with black colour. Pixels with proper elevation values are displayed with white colour. It can be observed, based on our approach that pixels in the centre of a gap get lower reliability factor values than pixels next to the gap boundary (see Fig. 3b).

In the building change detection procedure, the reliability map of two DSMs ( $\alpha_{DSM1}$  and  $\alpha_{DSM2}$ ) are calculated, respectively. They are then fused together to generate a final reliability map  $\alpha_{\Delta H}$  for the height change mass.

$$\alpha_{\Delta H} = \alpha_{DSM1} \cdot \alpha_{DSM2}. \quad (14)$$

Shadow has played an important role when analysing very

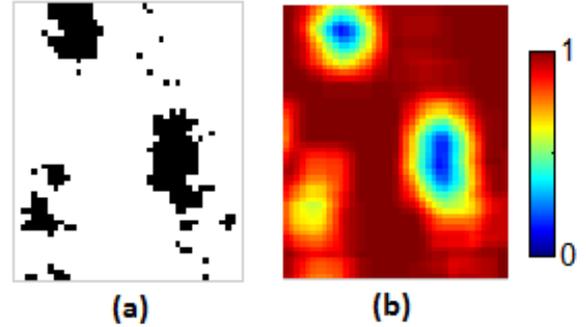

Fig. 3. Reliability map (b) generated from the gaps mask (a).

high resolution images in urban region. Both of the changes of shadow and coverage of shadow will bring false alarms for change detection. Therefore, the 2D changes that are detected in shadow regions are less reliable than in non-shadow regions. Benefit to this character, we can adopt the shadow map as the reliability map of BBA from the image change indicator. For this purpose, first a shadow map is generated by calculating the average brightness of the multi-spectral image, as normally a dark colour indicates the existence of shadows. We take an easy and fast shadow detection approach as shown in Eq. (15) to highlight the shadow class. It is a pixel-based approach, therefore,  $B_k$  in Eq. (15) represents the intensity values at one pixel location in different multi-spectral band images.

And  $n$  is the number of the multispectral bands. The detected shadow map from brightness is enough for our purpose. In this shadow map, a smaller value indicates higher probability to be shadows; thus, the 2D changes detected in these regions are less reliable.

$$\text{Brightness} = \frac{1}{n} \sum_{k=1}^n B_k. \quad (15)$$

A further process is proposed to obtain a valid reliability map from the shadow map. First, it has been projected to a sigmoid curve. The lower threshold value from the two-level Ostu threshold is used as the symmetry point of the sigmoid curve. The obtained probability map is denoted as *ShadowMap*. In order to control the influence of the *ShadowMap*, we have only kept the values less than 0.5.

$$\alpha_{img} = \begin{cases} 0.5 + I_{ShadowMap}, & \text{if } I_{ShadowMap} < 0.5, \\ 1, & \text{otherwise.} \end{cases} \quad (16)$$

where  $I_{ShadowMap}$  is the pixel intensity of the shadow map in  $[0, 1]$ . The reliability map generated from the shadow map is then recorded as  $\alpha_{\Delta Img}$ , and it is the combination of the shadow maps of two dates.

$$\alpha_{\Delta Img} = \alpha_{img1} \cdot \alpha_{img2}. \quad (17)$$

#### D. Global BBAs

The BBAs related with the concordance and discordance indexes are combined to get the global BBA regarding each source of evidence. These global BBAs will then be used as input for solving the change detection problem thanks to their combination. From the previous step of BBAs modelling, each pixel will get two sets of BBAs to combine results from Table I and II. More precisely, we will have to combine either  $\{m_1^{DS}(\cdot), m_2^{DS}(\cdot)\}$  if DS rule is preferred for the BBA modeling, or  $\{m_1^{PCR6}(\cdot), m_2^{PCR6}(\cdot)\}$  if the PCR6 rule is adopted. These BBAs from Table I and II are represented by  $a_1, a_2, a_3$  and  $b_1, b_2, b_3$ . In this article, the mass values  $a_1, a_2$  and  $a_3$  are further discounted by the generated reliability map  $\alpha_{\Delta H}$  and denoted respectively as  $A_1, A_2$  and  $A_3$ . The mass values from the image change indicator  $b_1, b_2$  and  $b_3$  are discounted by the vegetation and shadow indicators  $\alpha_{\Delta Img}$  obtained in formula Eq. (17) to  $B_1, B_2$  and  $B_3$ .

More precisely, one computes

$$\begin{cases} A_1 = \alpha_{\Delta H} \cdot a_1, \\ A_2 = \alpha_{\Delta H} \cdot a_2, \\ A_3 = \alpha_{\Delta H} \cdot a_3 + (1 - \alpha_{\Delta H}). \end{cases} \quad (18)$$

$$\begin{cases} B_1 = \alpha_{\Delta Img} \cdot b_1, \\ B_2 = \alpha_{\Delta Img} \cdot b_2, \\ B_3 = \alpha_{\Delta Img} \cdot b_3 + (1 - \alpha_{\Delta Img}). \end{cases} \quad (19)$$

Table III and Table IV describe the final building change detection models based either on DS or on PCR6 rules. Here, the discounted height change indicator is denoted as  $m_{1\alpha_{\Delta H}}(\cdot)$ ,

and the discounted image change indicator is denoted as  $m_{2\alpha_{\Delta Img}}(\cdot)$ .

TABLE III  
DS FUSION MODEL FOR BUILDING CHANGE DETECTION.

Focal Elem.	$m_{1\alpha_{\Delta H}}(\cdot)$	$m_{2\alpha_{\Delta Img}}(\cdot)$	$m_{12}^{DS}(\cdot)$
$\theta_1$	$A_1$	0	$\frac{A_1(B_1+B_3)}{1-A_1B_2}$
$\theta_2$	0	0	$\frac{A_2B_1}{1-A_1B_2}$
$\theta_3$	0	$B_2$	$\frac{(A_2+A_3)B_2}{1-A_1B_2}$
$\theta_1 \cup \theta_2$	0	$B_1$	$\frac{A_3B_1}{1-A_1B_2}$
$\theta_2 \cup \theta_3$	$A_2$	0	$\frac{A_2B_3}{1-A_1B_2}$
$\Theta$	$A_3$	$B_3$	$\frac{A_3B_3}{1-A_1B_2}$

TABLE IV  
PCR6 FUSION MODEL FOR BUILDING CHANGE DETECTION.

Foc. Elem.	$m_{1\alpha_{\Delta H}}(\cdot)$	$m_{2\alpha_{\Delta Img}}(\cdot)$	$m_{12}^{PCR6}(\cdot)$
$\theta_1$	$A_1$	0	$A_1(B_1 + B_3) + \frac{A_1A_1B_2}{A_1+B_2}$
$\theta_2$	0	0	$A_2B_1$
$\theta_3$	0	$B_2$	$(A_2 + A_3)B_2 + \frac{B_2A_1B_2}{A_1+B_2}$
$\theta_1 \cup \theta_2$	0	$B_1$	$A_3B_1$
$\theta_2 \cup \theta_3$	$A_2$	0	$A_2B_3$
$\Theta$	$A_3$	$B_3$	$A_3B_3$

$m_{1\alpha_{\Delta H}}(\cdot)$  can be obtained from the discounting of the fusion results presented in Table I. Thus they have been denoted respectively as  $m_{1\alpha_{\Delta H}}^{DS}(\cdot)$  and  $m_{1\alpha_{\Delta H}}^{PCR6}(\cdot)$ . These discounted height change indicators are fused in the second step with the image change indicator  $m_{2\alpha_{\Delta Img}}(\cdot)$  to generate the final global BBAs. From the Tables III and IV, four sets of global BBAs can be computed based on different BBAs and fusion models. The flow diagram in Fig. 4 summarises the different fusion schemes tested in our application.

As one sees, if both the BBA modelling procedure and global BBAs are constructed based on DS fusion rule, the generated global BBA is recorded as  $G_1$ . If the global BBAs are constructed based on PCR6 fusion rule, they are recorded as  $G_2$ . The basic BBAs can also be calculated with PCR6 fusion rule, as shown in Table II. Based on these BBAs, the global BBAs can be also constructed using DS theory  $G_3$  and PCR6 rule  $G_4$ . It has to be mentioned that these four fusion schemes have different computational cost and  $G_1$  is the simplest one and  $G_4$  is the most expensive one in terms of computational burden.

#### E. Change mask generation

The final building change mask is our decision-making procedure. After the second step of fusion, each pixel in the images will get a certain degree of belief for all focal elements. The value of global BBAs in  $\theta_1$  gives a direct building change probability map. A decision criterion is required in generating

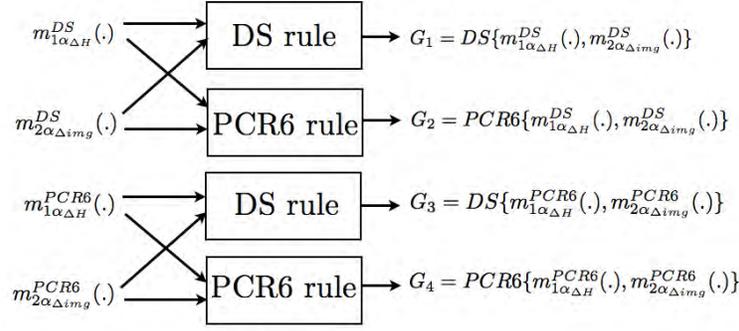

Fig. 4. Four fusion schemes based DS and PCR6 rules.

the final building change detection masks. A change mask can be generated after giving a threshold value [16]. However, BBAs on the partial ignorance and full ignorance set should also be considered in the decision-making procedure. The building change probability map is only a part of the global BBAs. DST and DSmt propose different approaches to make the final decision. Several decision criteria are available. In this article, four decision criteria are tested. They are: 1) maximum of belief (Max\_Bel), 2) maximum of plausibility (Max\_Pl), 3) maximum of betting probabilities (Max\_BetP) and 4) the maximum of DSmtP (Max\_DSmtP) [18], [19](Vol. 3, Chap. 3).

1) *Maximum of Belief (Max\_Bel)*: Valid for different strategies of BBA modelings and fusions according to Fig. 4. More precisely, for a strategy  $G$  generating a combined mass  $\in G_1, G_2, G_3, G_4$ , the label (decision) is obtained by comparing the final global mass values obtained from Table. III and IV.

$$Label = \operatorname{argmax}\{G(\theta_1), G(\theta_2), G(\theta_3)\}. \quad (20)$$

2) *Maximum of plausibility (Max\_Pl)*: Plausibility is defined in Eq. (3). Max\_Pl compares the plausibility of each class.

$$Label = \operatorname{argmax}\{Pl(\theta_1), Pl(\theta_2), Pl(\theta_3)\}. \quad (21)$$

3) *Maximum of betting probabilities (Max\_BetP)*: The pignistic probabilities, denoted as  $BetP$ , is making decisions on the pignistic level. In the betting probabilities, global masses of joint focal elements are averagely redistributed to each class.

$$BetP(A) = \sum_{B \in \Theta} \frac{|A \cap B|}{|B|} m(B), A \in \Theta. \quad (22)$$

$$Label = \operatorname{argmax}\{BetP(\theta_1), BetP(\theta_2), BetP(\theta_3)\}. \quad (23)$$

4) *Maximum of DSmtP (Max\_DSmtP)*: DSmtP probabilistic transformation is an important alternative to the pignistic transformation [34]. The basic idea of DSmtP is to redistribute the mass of (partial and total) ignorances proportionally to the masses of singletons involved in the ignorances.

$$DSmtP_\varepsilon(A) = \sum_{B \in \Theta} \frac{\sum_{\substack{Z \subset A \cap B \\ |Z|=1}} m(Z) + \varepsilon |A \cap B|}{\sum_{\substack{Z \subset B \\ |Z|=1}} m(Z) + \varepsilon |B|} m(B). \quad (24)$$

where  $\varepsilon \geq 0$  is a small positive number (typically 0.001) that avoids numerical indeterminacies in very degenerated cases occurring if the mass in the denominator of Eq. (24) is zero. More detailed information about DSmtP is given in [34]–[35].

$$Label = \operatorname{argmax}\{DSmtP(\theta_1), DSmtP(\theta_2), DSmtP(\theta_3)\}. \quad (25)$$

Among the four decision-making rules, max of belief or max of plausibility have the advantage to be very simple to calculate but they represent respectively two extreme pessimistic or optimistic decisional attitudes. The choice of one of these extreme attitudes depends on the consequence of decision error we are ready to take which is conditioned by the type of application under concern. Moreover, it has been shown by [34] that the more sophisticated transformation DSmtP outperform BetP transformation at a price of much higher computational complexity, which can be a bottleneck in some real-time image processing applications.

## IV. EXPERIMENTS

### A. Datasets

The belief function-based building change detection models have been tested on four pairs of satellite images. Each of the first three experimental datasets consist of two pairs of IKONOS stereo imagery captured in February 2006 and May 2011 over an industrial region in Dong-an, North Korea. These three sub-test regions are shown in Fig. 5 and 6 and 7, respectively. The original IKONOS stereo imagery has 1 m pixel size in the panchromatic band and 4 m pixel size in the multispectral bands. The fourth experimental dataset (shown in Fig. 8) was captured over the centre of Munich, Germany, which is a typical European urban region. The two pairs of stereo data of this dataset were captured by IKONOS on July 15, 2005 and WorldView-2 on July 12, 2010, respectively. In Fig. 5 to Fig. 8, the first two images are the panchromatic images of before- and after-change. (c) and (d) are the generated DSMs. They have been generated based on the method explained by [27]. The elevation values from low to high are represented with the colours from dark blue to dark red as described in the colour bar. These images are co-registered through camera model parameter corrections before the DSM

generation procedure with block adjustment among all datasets [27], [36]. A sub-pixel accuracy in planimetry and 1 to 2 m in height can be achieved. The Gram-Schmidt pan-sharpening method which has been widely used and implemented in ENVI software is applied to the multispectral channels of all three test regions [37]. In the first three subsets the generated DSMs have been re-sampled to 1 m resolution. As the IKONOS and WorldView-2 data for the Munich test region have different resolutions, the IKONOS images are up sampled to 0.5 m resolution, to be equal to WorldView-2 data. Instead of down-scale [38], an up-scale re-sampling is selected here to keep the sharp boundaries in the WorldView-2 data. The resulting DSMs also have a resolution of 0.5 m.

Fig. 5 and Fig. 6 show normal building change examples with DSMs in high accuracy. The size of these two test regions are  $450 \times 700 \text{ m}^2$ , and  $1000 \times 400 \text{ m}^2$ , respectively. In Fig. 5 some seasonal changes are visible. The generated DSMs are displayed in Fig. 5c and 5d. The second test region (Fig. 6) shows much larger sized buildings, and these buildings are well separated from each other.

The third test region consists of two images with the size of  $160 \times 340$  pixels. This region is characterised by small sized buildings (Fig. 7). It has to be mentioned, the largest building with a dark colour roof does not have the correct height in the first DSM, as is shown in Fig. 7c. This test region is especially selected to prove the robustness of our fusion models. The image size of the fourth test region is  $1600 \times 1600$  pixels, which is  $640,000 \text{ m}^2$ . It has mainly large size buildings with complex roof shapes. From 2005 to 2010, besides newly constructed buildings, there are also rebuilt/demolished buildings. Especially, many roofs have been renovated with another material. Without height information, it is very difficult to separate the newly constructed buildings from other kinds of changes.

## B. Results

The proposed DS fusion model and PCR6 fusion model have been applied to all datasets. In the first step, the four sets of global BBAs for all three focal elements and joint elements are generated based on various fusion rules and fusion rule combinations. In the second step, building change masks are generated by using four decision criteria. All three classes including *BuildingChange*, *OtherChange* and *NoChange* are generated. But this article focuses on the newly constructed buildings, thus only the *BuildingChange* results are analysed and evaluated. The proposed models have two novel properties. The first one is the improved fusion model, and the second one is the reliability discounting. In the experimental part, the minimal value of the reliability map generated from DSM gaps is manually modified to 0.1 to remove too small values. In the height change reliability map generation procedure, a window size of  $9 \times 9$  is selected.

To prove the advantages of the proposed method, firstly the best building change detection results are displayed together with the original height change map. The results of all four test regions are displayed in Fig. 9, Fig. 10, Fig. 11 and Fig.

12, respectively. In each figure, different colours represent different height changes in Figs. 9-12(a). Figs. 9-12(b) are the generated building change masks. To show the quality of these building change masks, these masks have been overlaid with the change reference data, which have been manually extracted for all four test regions. In Figs. 9-12(b) the green colour represents the correctly detected building changes. The false alarms which indicate pixels that are wrongly detected as building changes are presented with red colours. The blue colour objects are the misdetracted changed buildings, which are named as *false negatives* in this article.

Generally speaking, the proposed models are able to extract the newly constructed buildings in high accuracy. Noise effects from the height change map have been largely reduced in the final change results. The four selected test regions present four different situations. In the first test region most of the buildings are relatively low in the height and well separated from each other. The second test region has much higher and larger buildings, which produce large regions of shadow. The third test region is a special case. As we observe, in the first DSM of test region 3 the height of one big building is not correctly extracted. Actually the same building has been detected as false alarm and been discussed in the reference [16]. It has been explained in [16], due to the large region size and height change values, the false alarm can not be avoided. The fourth test region is much more complicated than the others, exhibiting very high building density, complex roof shapes and various building change types.

Benefiting from the improved fusion models and the reliability discounting procedure, some false alarms can be successfully avoided. Especially for the building in the left-bottom corner in the test region 1 and that big building in test region 3. In both situations, the first DSM is not able to get the correct height values. Based on the traditional feature fusion approach or our initial fusion model [16], this kind of buildings will very possibly be detected as *BuildingChange*. However, as we observe in the presented change detection results, these buildings are correctly detected as *NoChange*. It has to be noted that vegetation change is not considered in this model. Thus, in the centre of the first region, these two large regions of false alarms, which are newly planted trees from visual interpretation, are not able to be avoided. Another difficult to detect region is one building in construction. Half of the building has been finished in the after-change data; thus, this region has both height and spectral changes. As it can not be called a finished building yet, we did not include it as *BuildingChange* in our reference data.

Many false negatives (blue regions/pixels) in Fig. 10(b) are visible. Most of these false negatives can be explained by the quality of the DSMs. A subset of the gaps mask of test region 2 in date2 is displayed in Fig. 13. As it shows all of the four missed buildings (shown in blue colour) are actually gaps in the unfilled DSM. After gaps filling, they are not interpreted with correct height values, as shown in Fig. 6 (d). Thus, these four buildings only feature spectral changes, therefore are falsely identified as *OtherChange*.

### C. Results evaluation

To further understand the quality of these results and the advantages of the method, more evaluation and analysis are proposed. First, the building change masks extracted from these four global BBA sets are compared and evaluated. Each global BBA set results four building change masks based on the four decision criteria. The building change masks are compared with the masks from [30]. The accuracy of these results have been evaluated by comparing them with ground truth images, which have been manually prepared by visually comparing the pre- and post-event images and referring additional Google Earth history data [39]. The similarity between the obtained result and the ground truth is measured in terms of Kappa Accuracy (KA) [40]. The evaluation results of test region 1, 2, 3 and 4 are shown in Table. V, VI, VII and VIII, respectively. Limited to the available reference data, only the *BuildingChange* class is evaluated.

1) *Comparison of the fusion and decision rules:* Table V to VIII mainly aim to describe and compare the performance of the DS fusion and DSMT fusion rules and the four decision criteria. Unfortunately, the differences among these four global BBA sets of all four test regions are indistinguishable. Our quantitative evaluations results allow comparing the different fusion and decision-making strategies for building change mask construction in different types of region under analysis. As we have observed, there is no unique best fusion and decision strategy working for all types of regions which is an interesting result to be aware of and the different fusion methods (with a chosen decision strategy) perform always better with our refined approach than the previous (original) works which is the main contribution of this work for all type of regions tested.

2) *Validation of the reliability discounting:* The global BBAs obtained with and without reliability discounting are listed under the name of *Refined* and *Original* in Table V to VIII. *Original* refers to the approach presented by [30], in which the reliability discounting is not involved.

In the first test region, the advantage of the reliability discounting is not obvious. By using the Max\_Pl and Max\_BetP decision rules, the refined models perform better than the original models. However, the original models get higher KA values when using the Max\_Pl and Max\_BetP decision rules. This can be partly explained by the shadow detection results, as one dark colour building roof (middle left in the test region) get higher probability to be shadow; thus, a lower probability to be *BuildingChange*.

The second test region is characterised mainly by large and high buildings; thus, the influences of shadows are stronger than in the first test region. The refined models with reliability discounting get generally better accuracy than the original fusion models. Here, we will compare the Max\_DSMT of  $G_4$  of this test region, as it shows the highest difference among these four decision criteria in Table VI. Fig. 14 shows building change masks of the top left part of the test region 2. Fig.

14 (a) and (b) display the change masks obtained from the original model and the refined model overlaid with the change reference mask respectively. The same as Fig. 10 (b), the green colour represents the true detected, the red colour shows the false alarms, while the blue colour pixels are the false negatives. As it shows, based on the refined model, building boundary regions of the change mask obtain less false alarms than the results from the original fusion model.

The advantage of the improved decision fusion models has been well proved by Table VII. The first DSM of this test region contains a large region of pixels with incorrect height introduced by stereo image matching failures. The improved models can solve this problem by adopting the reliability map of height change. Therefore, the increase of KA value of this region is much higher than for the other two test regions. More precisely, under all fusion rules the KAs have improved from around 0.30 to 0.50. For better understanding of this improvement, the global BBAs of *BuildingChange* without and with reliability discounting are displayed in Fig. 15 (a) and (b), respectively. We display here only the  $Prob(\theta_1)$  of  $G_1$ . Both probability maps are less noisy than the original height change map, which are displayed in Fig. 11. By observing the original panchromatic images in Fig. 7, it is not difficult to find out that this building exists in the panchromatic images of both dates. This is the same building that has been mentioned in [16], for which only the DSM of pre-change contains the correct height values. In Fig. 7 (c), this building can not be recognised as a high-level object. A higher value in  $m_1(.)$  leads to a larger global BBA in the class of *BuildingChange*. Thus, this building would be incorrectly detected as *BuildingChange* if no reliability discounting is applied (Fig. 15(a)). Fig. 16 shows the generated height change reliability map. As can be seen, that building region get very low reliability values, that means the height changes of this region cannot be trusted. Therefore, the proposed model is able to remove this kind of errors and correctly recognise this region as *NoChange* (Fig. 11).

The Munich test region has a much larger size and includes several kinds of building changes. The proposed method is able to fuse the spectral and height information efficiently; thus, to identify the newly constructed buildings. The main false negatives are produced in the rebuilt buildings and construction sites. As shown in Fig. 17, the labelled four buildings represent four types of changes. Building A is labelled as a newly constructed building in our reference data. However, half of that building has similar shape and height as the original one, which brings false negatives to our result. Building B, C and D are buildings in different construction phases. By referring [39], in the reference data only D is identified as *OtherChange* as it is almost completed in Fig. 17(a). In the result we are able to correctly identify B as a newly constructed building and D as *OtherChange*. But building C is falsely labeled as *OtherChange* due to low height change values.

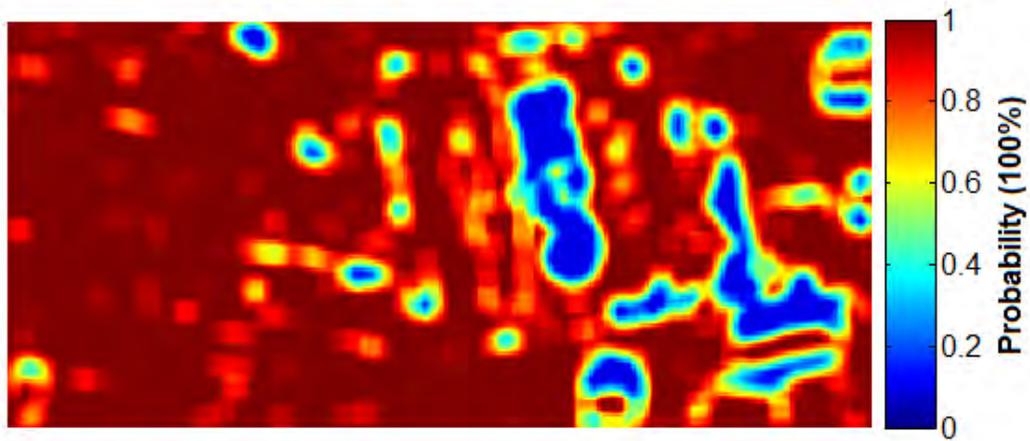

Fig. 16. Reliability discounting map of the height changes of test region 3.

Fig. 17. Example of the various building change types in test region 4.

A window size of  $9 \times 9$  has been used to generate the  $\alpha_{\Delta H}$ . In order to test the sensitivity of our fusion model to the window width used, we have changed the width parameter from 3 to 13 by steps of 2. For each size, we generate the global BBA  $G_1$ . Thus four final building change masks based on the four decision criteria can be regenerated. We provide the KA for each mask as show in Fig. 18. As a comparison, we have also provided the KAs without using  $\alpha_{\Delta H}$ . This test shows that the final results benefit largely from the reliability discounting procedure, but the KA rate did not change significantly with various window sizes for all four test regions.

#### D. Comparison with existing methods

In this section, the improved belief fusion models are compared with the directly feature fusion method [41] and the initial fusion model that described in [16].

As a typical feature fusion approach, [41] adopted the kernel Minimum Noise Fraction (kMNF) approach to fuse change features from the DSMs and panchromatic images. Based on the resulting kMNF components, a change mask was extracted with iterated canonical discriminant analysis (ICDA). [30] randomly selected the training data from the ground truth, as the experiments were devoted to algorithm comparison. However, it was not a practical procedure, because in real situations the ground truth is unknown. Therefore, in this article as well as using the set of random pixels from the ground truth, another set of training data for each test region is prepared by manually selecting changed regions. All pixels in these regions are then used as training samples.

The results generated based on these two sets of training data are described as  $kMNF_{random}$  and  $kMNF_{manual}$ , respectively, in Table IX in the term of KA and Overall Accuracy (OA). All training data in the first three test regions contain around 200 pixels/samples. In the fourth test region, 500 pixels are used to fit with the large image size. If the training data are selected from the ground truth, the newly proposed approach can deliver a slightly better result than the approach in [41]. When using the manually selected training data, the advantages of the newly developed approach are obvious. As in real applications the ground truth is normally unknown, we conclude that the proposed fusion method is more robust for larger test regions with diverse characterised objects.

In addition, the approach proposed by [16] is tested on the same test data, and the results are shown in the third and fourth columns. In that approach, after the fusion approach a shape-based refinement was proposed to reach the final building change mask. Thus, the resulting masks before and after the refinement procedure are both calculated and evaluated. In the North Korea test region, we have used  $T_{height} = 3m$ ,  $T_{area} = 50m^2$  and  $T_{convexity} = 0.55$  as thresholds. And in the Munich test region, as the buildings have a larger size and complicated roof shapes than North Korea, we manually modified these threshold values to  $T_{area} = 100m^2$  and  $T_{convexity} = 0.50$  to improve the results. The accuracies are recorded in the columns  $[16]_{before}$  and  $[16]_{after}$  in Table IX. The refinement

is not included in this article to avoid unnecessary threshold parameters; thus, to achieve an automatic and robust workflow. By comparing the KAs with Tables V, VI and VII, one can see that the shape-based refinement can further improve the result accuracy. But the fusion model in [16] performs rather weakly. All obtained KAs are lower than values from the proposed refined decision fusion approaches, especially for test regions 2 and 3.

TABLE IX  
COMPARISON WITH EXISTING METHODS.

	$kMNF_{random}$		$kMNF_{manual}$		[16] <sub>before</sub>		[16] <sub>after</sub>	
	KA	OA	KA	OA	KA	OA	KA	OA
Region1	<b>0.7178</b>	0.9799	0.5477	<b>0.9803</b>	0.5929	0.9628	0.6312	0.9683
Region2	<b>0.6791</b>	<b>0.9822</b>	0.2458	0.9688	0.6433	0.9681	0.6718	0.9718
Region3	0.2195	0.9794	0.2272	<b>0.9799</b>	0.3060	0.9375	<b>0.3287</b>	0.9447
Region4	0.2057	0.9878	0.1937	0.9876	0.4909	0.9912	<b>0.5641</b>	<b>0.9941</b>

It has to be mentioned that vegetation change is not noted as false alarm in the improved decision fusion model. As the vegetation change and building change can be easily separated by using a vegetation index. [16] has adopted vegetation index as *no-building change* indicators to highlight building changes. This step is not considered in this article as not many forest changes are available in the test regions. Moreover, if forest changes are of interest, we can easily modify this model using vegetation index to separate forest changes from building changes.

#### V. CONCLUSIONS AND PERSPECTIVES

Building change detection is a difficult topic, to solve uncertain change information from images and DSMs, decision fusion methods have been introduced as a new concept and proved to be efficient and appropriate. The innovative contribution of this article is the improvement of the decision fusion models. DS as well as DSMT decision fusion models are further developed to solve the building change detection problem in this article. Another contribution lies in the BBA calculation procedure, and the sigmoid distribution is further improved by taking both concordance and discordance situations. As a third contribution, the reliability of each indicator is introduced according to the change objects of interest.

The proposed building change detection models enable an improved result by comparing to the original fusion model and other change detection methods. A comparative analysis of the results shows that there is not a so big difference of performances between DS and DSMT fusion methods based on the best decisional strategy and so we can in practise use the simplest fusion method to reduce to computational burden without degrading too much the performance. Of course the most critical question is to select beforehand the decisional strategy based on type of region under analysis, for this we need to define efficient indicators for characterising each type of region which then will help us to automatically select the best criterion to use. Our future research works will address, and hopefully help, to solve this important question.

**Abstract**—This paper investigates the use of the URREF ontology to characterize and track uncertainties arising within the modeling and formalization phases. Estimation of trust in reported information, a real-world problem of interest to practitioners in the field of security, was adopted for illustration purposes. A functional model of trust was developed to describe the analysis of reported information, and it was implemented with belief functions. When assessing trust in reported information, the uncertainty arises not only from the quality of sources or information content, but also due to the inability of models to capture the complex chain of interactions leading to the final outcome and to constraints imposed by the representation formalism. A primary goal of this work is to separate known approximations, imperfections and inaccuracies from potential errors, while explicitly tracking the uncertainty from the modeling to the formalization phases. A secondary goal is to illustrate how criteria of the URREF ontology can offer a basis for analyzing performances of fusion systems at early stages, ahead of implementation. Ideally, since uncertainty analysis runs dynamically, it can use the existence or absence of observed states and processes inducing uncertainty to adjust the tradeoff between precision and performance of systems on-the-fly.

**Keywords:** uncertainty, reported information, trust, belief functions, information fusion, DSMT, URREF ontology.

## I. INTRODUCTION

A key element when designing information fusion systems is the way the system designer isolates and analyzes real world phenomena. A model is abstracted into a simpler representation, in which components, modules, interactions, relationships and data flows are easier to express. Uncertainty tracking highlights approximations induced by model construction and its formalization, as well as providing a checklist to ensure that all uncertainty factors have been identified and considered ahead of system implementation.

This paper illustrates the use of the uncertainty representation and reasoning framework (URREF) ontology [1] to identify and assess uncertainties arising during the modeling and formalization phases of an information fusion system intended to estimate trust in reported information.

Trust assessment is a real-world problem grounded in many applications relying on reported items, with different persons observing and then reporting on objects, individuals, actions or events. For such contexts, using inaccurate, incomplete or distorted items can result in unfortunate consequences and

analysts need to ensure the consistency of reported information by collecting multiple items from several sources.

From the perspective of an information analyst, trust can be analyzed along two dimensions: the subjective evaluation of items reported by the source itself, called self-confidence, and the evaluation of source by the analyst, called reliability. While self-confidence encompasses features of subjectivity, the reliability of a source is related to the quality of previously reported items, the competence of the source for specific topics, and the source's capacity for misleading intentions. Trust estimation aims at capturing, in an aggregated value, the combined effects of self-confidence and reliability on the perceived quality of information. The model is represented with belief functions, a formalism which offers a sound mathematical basis to implement fusion operators which estimate trust by combining self-confidence and reliability.

The model developed for trust assessment focuses on the global characterization of information and provides a better understanding of how trust is to be estimated from various dimensions. The overall process has humans as a central element in both the production and the analysis of information.

Trust in reported information offers a good illustration for tracking uncertainty: the phenomenon is complex, so any model adopted is generally a simplification of the real world interactions. Uncertainties can be made explicit not only for static elements of the model, such as sources or items, but also for the dynamic processes of combining items with one another. Moreover, adopting belief functions as representation formalism will have an impact on the way an information system could be implemented and on the accuracy of its results.

The contribution of this paper is twofold: first, it presents a trust estimation model which combines the reliability of sources and self-confidence of reported items, and, second, the paper analyzes types of uncertainty occurring during modeling and formalization by relating elements of the model to uncertainty criteria defined by the URREF ontology.

The remainder of this paper is divided into 8 sections: section II discusses related approaches for trust modeling and uncertainty assessment. The problem tackled in this paper is presented in section III. Section IV describes the model developed for trust estimation, while its implementation with

belief functions is presented in section V. The analysis of uncertainty is discussed in VI, while examples and scenarios for trust assessment are presented in section VII. Strengths and limitations of belief-based formalization are discussed in section VIII and section IX concludes this paper.

## II. RELATED APPROACHES

The work presented in this paper is related to approaches for trust modeling and assessment as well as solutions for uncertainty analysis for information fusion systems. Trust modeling is not a new research topic; it spans diverse areas such as agent systems [2] and logical modeling and argumentation [3]. The Internet and social media offer new application contexts for trust assessment; this topic is addressed in relation to service provision on the Internet [4], social networks analysis [5], and crowdsourcing applications [6]. Trust analysis is also of interest in the military field where techniques have been developed in order to identify clues of veracity in interview statements [7].

The concept of trust in these communities varies in how it is represented, computed and used. Although having an obvious social dimension, trust is not only understood with regard to other humans, but also towards information pieces [6], information sources [8], Internet sites [9], algorithms for data and knowledge fusion [10], intelligent agents [2], and services for the Internet of things [11].

While definitions of trust vary from one domain to another, there are some common elements. The first commonality for all research areas cited above is to consider trust as a user-centric notion that needs to be addressed in integrated human-machine environments which rely heavily on information collected by humans, even if further processing can be executed automatically. Moreover, all definitions associate some degree of uncertainty with trust, which is then captured by concepts such as subjective certainty [12] and subjective probability [13].

Trust goes hand in hand with the concepts veracity [14] and deception. [15] addresses veracity along the dimensions of truthfulness / deception, objectivity / subjectivity and credibility / implausibility. The authors developed a veracity index ranging from true/objective/credible to untrustworthy/subjective/implausible to characterize texts in the context of big data analysis. Deception is defined as a message knowingly transmitted with the intent to foster false beliefs or conclusions. The topic is addressed in studies from areas such as interpersonal psychology and communication [16], [17] and it is also considered in the field of natural language processing, as part of a larger research direction tackling subjectivity analysis and the identification of private states (emotions, speculations, sentiments, beliefs). These solutions stem from the idea that humans express various degrees of subjectivity [18] that are marked linguistically and can be identified with automatic procedures [19].

Contributions on trust estimation keep the distinction between analyzing the source of information, the item reported and reasoning about trust. Approaches developed for trust

in information sources consider that trust is not a general attribute of the source but rather related to certain properties: competence [20], sincerity and willingness to cooperate [3]. On this basis, it becomes possible to consider the competence of a source not in general but with respect to specific topics [21]. Trust can be also analyzed in relation to roles, categories or classes [22].

Research efforts on reasoning about trust analyze information sources from past behaviors rather than directly from their properties [23], or they infer trust from estimations already computed for a set of properties [24]. These approaches generally focus on building trust by using argumentation [25] or beliefs functions [26], or investigating the joint integration of those techniques [27]. Taking this work a step further, [28] identified several patterns for reasoning about trust and its provenance while the notion of conflict in handling trust is discussed in [29].

As shown by approaches above, trust is a multifaceted concept and, in practice, this complex notion can be decomposed into two components: communication or interaction trust, and data trust [30]. The model developed deals with data trust and keeps the distinction between sources and items provided by those sources, although several approaches consider these elements as a whole [26], estimating the trust of information sources [24], [29] rather than information items. The model does not require statistical data to infer the behavior of the source [23] and introduces reliability to characterize the source. More specifically, reliability encompasses not only competence [22], [20] and reputation [21] - two attributes already considered by previous approaches - but also intentions which constitute an original aspect of the model. Intention is of important significance in the context of human-centered systems, including open-sources, and supports the analysis of emerging phenomena such as on-line propaganda or disinformation. Another original aspect of the model is consideration of the characterization of items by the source itself, thus overcoming a main limitation of the solution presented in [31]. Our approach can be considered as partially overlapping solutions investigating trust propagation in direct and indirect reporting [28], [25], and the model enables a particular kind of trust estimation, based both on more or less complete characterizations of the source by the analyst, and more or less accurate characterizations of the items by the source. The model also addresses disagreement and the fusion of diverging opinions, not in a panel of experts as described in [27], but rather between items showing high levels of confidence according to the source and sources having low reliability according to the analyst. By ascribing characterizations to both information sources and reported items, the model allows analysts to make use of both prior experience and their own beliefs in order to assess various degrees of trust.

From a different perspective, the evaluation of uncertainty regarding the inputs, reasoning and outputs of the information fusion is the goal of Evaluation Techniques for Un-

certainty Representation Working Group<sup>1</sup> (ETURWG). The group developed an ontology for this purpose [1]. The URREF ontology defines the main subjects under evaluation [32], such as uncertainty representation and reasoning components of fusion systems. Furthermore, the frame also introduces criteria for secondary evaluation subjects: sources and pieces of information, fusion methods and mathematical formalisms. URREF criteria have generic definitions and therefore can be instantiated for applications with coarser or finer granularity levels. This means evaluation metrics can be defined for data analysis [33], increased particularity for data specific types [34] or attributes, reliability and credibility [35], self-confidence [36] or veracity [37].

In addition to allowing a continuous analysis of uncertainty representation, quantification and evaluation, as described in [38], URREF criteria are detailed enough to capture model-embedded uncertainties [39], imperfection of knowledge representations [40], and their propagation in the context of the decision loop [41]. The frame also offers a basis to compare different fusion approaches [42]. URREF criteria were used for uncertainty tracking and investigation in several applications: vessel identification for maritime surveillance [43], activity detection for rhino poaching [44] and imagery analysis for large area protection [45].

Beyond developing a model for trust estimation, this paper also fills a gap within the ETURWG community by illustrating how uncertainty analysis tracks imperfections occurring from problem definition to model abstraction and formalization.

### III. HUMAN SOURCES AND REPORTED INFORMATION

Many applications rely on human sources which are used to continuously supply observations, hypotheses, subjective beliefs and opinions about what they sense or learn. In such applications reports are often wrong, due to environment dynamics, simple error, malicious act or intentions, [46]. From the analyst standpoint, decisions have to be made based on indirect reporting and trust relies upon the in-depth investigation of items and sources, thus the analysis of reported items is a critical step. This analysis is a multilevel process, relying on the ability of analysts to understand the content of messages and assess their quality from additional clues. The use cases described below highlight levels of indirection occurring when collecting information and their with impact on trust estimation.

#### A. Assertions, opinions and reported information

For illustration, let's consider  $X$ , the analyst receiving information provided by a human source  $Y$ .

**Case 1: direct reporting**  $X$  is an analyst collecting evidence in order to decide whether or not an individual is involved in terrorist activities. In particular, he takes into account reports submitted by  $Y$ , a human source. Those reports usually consist on a mixed set of assertions (e.g., descriptions of events or states observed by  $Y$ ) and opinions

(i.e., judgments, assessments, or beliefs) expressed by  $Y$  about assertion which give the analyst an insight into how strongly the source commits to the assertion, see fig. 1.

It is very likely that John is a terrorist.

Opinion                      Primary information

Fig. 1. Assertions and opinions in human messages.

In the statement contained in fig. 1, the source  $Y$  lets us know that she does not commit her full belief to the assertion that *John is a terrorist*, otherwise the reporter would have used phrasing such as *I am completely convinced* or *it is without doubt* or simply reported *John is a terrorist* as an unadorned statement.

The information item is the sentence, which contains the assertion *John is a terrorist* and the uncertainty degree to be assigned because the analyst knows that  $Y$  is not completely certain about her own statements. The analyst must make a judgment about the veracity of John being a terrorist based upon factors such as previous experience with  $Y$ 's assessments in the past, or, perhaps, on the fact that other sources are relating the same information.

**Case 2: indirect reporting** Again, let  $X$  be an analyst collecting evidence in order to decide whether or not an individual is involved in terrorist activities. In this case, he takes into account reports submitted by  $Y$ , a human source who is herself relating information obtained from a secondary source named Mary, see fig. 2.

Mary told me it is very likely that John is a terrorist.

Secondary source      Reporting                      Opinion                      Primary information

Fig. 2. Hearsay, assertions and opinions in human messages.

The source  $Y$  does not report on her direct observations or her deductions or beliefs, but conveys information received from a second source, in this case Mary, in the statement in fig. 2.

In this report the information item is again the sentence containing the assertive part *John is a terrorist* but this use case introduces more levels of complexity in uncertainty to deal with. The information that the assertion comes from Mary, who has added her own opinion, is a distancing mechanism on the part of the source  $Y$  as (unlike in fig. 1), she is neither claiming the opinion nor the assertion.

This case introduces yet more layers of uncertainty. How sure can we be that the reporter  $Y$  has accurately repeated what Mary said? For example, did Mary really say *it is likely*

<sup>1</sup><http://eturwg.c4i.gmu.edu/>

or did the reporter insert this (intentionally or unintentionally) based upon the reporter's assessment of the reliability of Mary as a source of information? Or perhaps, subtly, *Y* is expressing her own uncertainty by putting words in Mary's mouth. Furthermore, it is possible Mary made this statement under circumstances which would strengthen or weaken this statement, but those conditions have not been passed on by the reporter.

The goal of the analyst is to take this assertion into account, but also to encode his own belief about the quality of the source further in the analysis. All these different attitudes have to be evaluated by the analyst, who may have additional background information or prior evaluation of the source that have to be considered.

In both cases discussed above, the outcome of the analyst is the assertive part of the information item, augmented with a coefficient that helps to measure and track the different levels of trust for their future exploitation. For the purpose of this work, this quality is called *trust in reported information*.

### B. Concepts and notions for trust assessment

This section introduces several notions that are relevant for trust analysis.

*Trustworthiness of information sources* is considered, for the purpose of this work, as confidence in the ability and intention of an information source to deliver correct information, see [47]. Trustworthiness is an attribute of information sources who have the competences to report information, and who can be relied upon to share sincerely and clearly their beliefs on the uncertainty level of reported information. An item provided by such a source is then trusted by analysts.

*Self-confidence* [36] captures the explicit uncertainty assigned to reported assertions by the source. Statements may include the source's judgments when lacking complete certainty; these judgments are generally identified through the use of various lexical clues such as *possibly*, *probably*, *might be*, *it is unlikely*, *undoubtedly*, etc., all of which signal the source's confidence (or lack thereof) in the veracity of the information being conveyed. It should be noted that self-confidence, in our usage understood as the linguistic dimension of the certainty degree that the source assigns to reported items, is an aspect exhibited by the source, but it will be considered from the analyst's standpoint during trust analysis.

*Reliability of sources* indicates how strongly the analyst is willing to accept items from a given source at their face-value. As an overall characterization, reliability is used in this work to rate how much a source can be trusted with respect to their reputation, competence and supposed intentions.

*Reputation of sources* [48] captures a commonly accepted opinion about how the source performs when reporting information, and is generally understood as the degree to which prior historical reports have been consistent with fact. For human sources, reputation is considered by the analyst for each source based on previous interactions with the source and on the source's history of success and failure in delivering accurate information. Reputation relies, to a large extent, upon

negative and positive experiences provided to the analyst by the source in the past.

*Competence of sources* [20] is related to a source's possession of the skills and knowledge in reporting on various topics: This aspect defines to what extent a human source can understand the events they report on, whether the source has the ability to accurately describe those events, and how capable the source is of following the logic of processes producing the information.

*Intentions* correspond to specific attitudes toward the effect of one's actions or conduct. Reporting information can become *more a means to manipulate others than a means to inform them* [49] and thus can be carried out with the express purpose of inducing changes in another person's beliefs and understanding. Intentions are specific to human sources as only humans have the capacity to deliberately provide false or misleading information. Sensors may provide erroneous data due to a number of factors such as device failure or environmental conditions, but never due to intention.

In addition to the above facets, *credibility of information* and *reliability of sources* are two notions introduced by the STANAG 2511 [50], which standardizes the terminology used in analysis of intelligence reports used by NATO Forces with distinct focus on sources and information provided. STANAG reliability is understood with respect to the quality of information that has been delivered by sources in the past. STANAG credibility relies on the intuition that a joint analysis of items in combination with each other will likely reveal inconsistencies, contradictions or redundancies. Reliability and credibility are independent criteria for evaluation. Definitions for both reliability and credibility are in natural language.

Attributes of sources and information items adopted for the model of trust are related to the notions introduced by the STANAG 2511 but are addressed differently: reliability of sources is understood here in terms of source competence, reputation and intentions, while credibility is restricted to features of self-confidence as described above.

## IV. A FUNCTIONAL MODEL OF TRUST

This section introduces the model developed to estimate trust in reported information by taking into account the reliability of the source and the source's own characterization of reported items. The advantage of this distinction is to better dissociate the impact of both beliefs of sources and opinions of analysts on the source on the information provided.

Even if the primary function of a source is to provide information, we keep the distinction between the source and the information by considering separate dimensions for each element. The rationale behind this is the observation that even reliable sources can sometimes provide inaccurate or imprecise information from one report to another, which is even more plausible in the case of human sources.

The model, illustrated in fig. 3., is composed of a source which provides an information item augmented with a degree of uncertainty captured by self-confidence to an analyst. Based upon his direct assessment of the reliability of the source,

the analyst constructs his own estimation of trust in the item reported.

Fig. 3. Model for trust analysis.

In the following section, the model is discussed using a granularity that is detailed enough to describe its elements, but still rough enough to avoid the adoption of a representation formalism.

#### A. Elements of the trust model

The model is composed of two elements: an information source and reported items from that source. The analyst is considered to be outside the model, although she has multiple interactions with its elements.

**Definition of information source:** An information source is an agent who provides an information item along with a characterization of its level of uncertainty. "Source" is a relative notion, depending on the perspective of analysis. In general, information is propagated within a chain relating real world information to some decision maker, and agents along the path can be both trained observers, whose job is to provide such reports, as well as witnesses or lay observers who may add items, in spite of not being primarily considered as information sources, but rather as opportunistic ones.

The notion of source is central in many information fusion applications and numerous research efforts aimed at modeling the properties of those applications. A general analysis of sources is undertaken by [51], who identify three main classes: S-Space, composed of physical sensors, H-Space for human observers and I-Space for open and archived data on the Internet. In [52], a unified characterization of hard and soft sources is described, along with a detailed description of their qualities and processing capabilities.

Processing hard sensor information is widely covered [53] in the research community, and can be considered quite mature, while the integration of human sources brings many new challenges. Our model addresses human sources, and reported items can refer to actions, events, persons or locations of interest.

Information reported by humans is unstructured, vague, ambiguous and subjective, and thus is often contrasted with

information coming from physical sensors, described as structured, quantitative and objective. While humans can deliberately change the information or even lie, sensors are also prone to errors and therefore hard information items are not always accurate.

For human agents, the source is part of the real world, (a community, a scene, an event) and can be either directly involved in the events reported, or just serving as a witness.

**Definition of reported information:** Reported information is a couple  $(I, \chi(I))$ , where  $I$  is an item of information and  $\chi(I)$  the confidence level as assigned by the source. Items are information pieces that can be extracted from natural language sentences, although the extraction and separation from subjective content are out of the scope for the model developed. Each item  $I$  has assertive  $i_a$  and subjective  $i_s$  components conveying factual and subjective contents respectively.

The analysis of reported information continues to be an open topic as the fusion of information from soft sources receives increasing attention in recent years. Although some authors have developed logic-based approaches for modelling distortions of items exchanged between agents who have both the intention and the ability to deceive [31], there are still more challenges arising when the information is analyzed in its textual form.

Features of uncertainty, as expressed in natural language statements, are analyzed in [54] while [55] provides a broader discussion of pitfalls and challenges related to soft data integration for information fusion.

#### B. Functions of the trust model

The model introduces several functions estimating features of reliability, self-confidence and trust, as described hereafter.

**Definition of a reliability function:** A reliability function is a mapping which assigns a real value to an information source.

This real value is a quantitative characterization of the source, inferred with respect to the source's previous failures, its reputation and the relevance of its skills for specific domains. For this model, the reliability of human sources combines three features: competence, reputation and intention. Competence captures the intuition that the quality of information reported by a source depends on the level of training and expertise, which may be designated as satisfactory or not, depending upon the task. Reputation is the overall quality of a source, estimated by examination of the history of its previous failures. Intentions refer to attitudes or purposes, often defined with respect to a hidden purpose or plan to achieve.

Reliability is a complex concept and, from a practical standpoint, it is difficult to have complete information about the global reliability of a source. Thus, this model describes reliability along the three attributes (competence of a source, its reputation and its intentions) described above. In practical applications, this solution allows for compensation for insufficient information on one or several aspects of reliability and

to conduct, if necessary, the analysis of reliability based on just one attribute.

**Evaluation of reliability:** Assessing reliability is of real interest when opportunistic sources are considered because the analyst has neither an indication of how the source might behave nor the ability to monitor or control either the human providing the information or the environment in which the source operates. Various methods can be developed to estimate competence, reputation and intentions of the source. For example, competence is closely related to the level of training of an observer or can be defined by domain knowledge. Values can be expressed either in a linguistic form (*bad, good, fair, unknown*) or by a number. Reputation is an attribute which can be constructed not just by examining previous failures of the source but also by considering its level of conflict with other sources; this too can be expressed by numeric or symbolic values.

While reputation and competence can be, at least in some cases, estimated from prior knowledge, characterizing the intentions of a source is subject to human perception and analysis. Judgment of human experts is needed not just because there usually is no *a priori* characterization of the source with respect to its intentions but also because it is important to assess those aspects from the subjective point of view of an expert in the form of binary values only.

From a practical standpoint, it is suitable to provide an expert with a description of source competence, reputation and intentions as assessed independently. This way, experts can have the opportunity to develop different strategies of using reliability: they can decide to assign different importance to those attributes under different contexts or can use their own hierarchy of attributes. For instance, an expert may consider as irrelevant the information provided by a source whose competences is lower than a specific threshold or if he suspects the source of having malicious intentions.

**Definition of a self-confidence function:** A self-confidence function is a mapping linking a real value and an information item. The real value is a measure of the information credibility as evaluated by the sensor itself and is of particular interest for human sources, as often such sources provide their own assessments of the information conveyed. Identifying features of self-confidence requires methods related to a research task of natural language processing: the identification of assertions and opinions in texts. In this field, the commonly adopted separation of those notions considers assertions as statements that can be proven true or false, while opinions are hypotheses, assumptions and theories based on someone's thoughts and feelings and cannot be proven.

**Evaluation of self-confidence:** The estimation of self-confidence aims at assigning a numerical value which captures how strongly the author stands behind assertions in the statement, on the basis of lexical clues he has included in the utterance. More generally, markers of an author's commitment are in the form of hedges, modal verbs and forms of passive/

active language. A hedge is a mitigating word that modifies the commitment to the truth of propositions, i.e., certainly, possibly. Its impact can be magnified by a booster (highly likely) or weakened by a downtoner (rather certain).

Modal verbs indicate if something is plausible, possible, or certain (*John could be a terrorist, you might be wrong*). Moreover, in some domains sentences making use of the passive voice are considered as an indicator of uncertainty, in the sense that author seeks to distance himself from the assertions in the items reported through use of passive voice. Quantifying self-confidence is a topic of particular interest for intelligence analysis, and it was early addressed by Kent in 1962, [56] who created a standardized list of words of estimative probability which were widely used by intelligence analysts. This list has continued to be a common basis to be used by analysts to produce uncertainty assessments. Kesselman describes in [57] a study conducted to analyze the way the list was used by analysts over the past, and identifies new trends to convey estimations and proposes a new list having the verb as a central element. Given the variety of linguistic markers for uncertainty, the estimation of a numerical value based on every possible combination seems unrealistic, as the same sentence often contains not just one but multiple expressions of uncertainty. Additionally, assigning numerical values to lexical expressions is not an intuitive task, and Rein shows that there are no universal values to be associated in a unique manner to hedges or other uncertainty markers, see [58]. As the author argues further, it is, however, possible to order those expressions and use this relative ordering as a more robust way to compare combinations of uncertainty expressions, and thus highlight different levels of uncertainty in natural language statements.

**Using the model for trust analysis:** The model proposed in this work proposed in this work combines various attributes of the source (discussed previously under "reliability") with "self-confidence" in order to capture trust of information as conveyed by the human. The model is source-centric predominantly focused on the source's ability to correct, alter or qualify the information report. Although the rules for ranking, prioritizing and combining the attributes introduced by the model can be drafted empirically, the estimation of a trust value requires a formal representation of the model.

A possible solution for estimating a unified value for trust is to consider reliability and self-confidence within the framework of an uncertainty theory and to rely on the set of combination rules the theory defines - for example, those developed in probability theory, in possibility theory, or in belief functions theory. All these theories provide various operators to combine reliability and self-confidence in order to estimate trust.

In the following the model is represented by using belief functions and several scenarios are used to illustrate trust estimation.

## V. TRUST FORMALIZATION WITH BELIEF FUNCTIONS

The aim of trust formalization is to provide a formal representation of the model, combining the capability to exploit the structure and relationship of elements of the model with the ability to express degrees of uncertainty about those elements. Of particular interest to this paper is the observation that the developed model introduces a cognitive view of trust as a complex structure of beliefs that are influenced by the individual's opinions about certain features and elements, including their own stances. Such a structure of beliefs determines various degrees of trust, which are based on personal choices made by analyst, on the one hand, and the source, on the other hand. Therefore, the formalization requires a formalism that is more general than probability measures or fuzzy category representation, which are more suitable for applications considering trust in the context of interactions between agents. Moreover, the limitations of using subjective probabilities to formalize trust from this cognitive standpoint are clearly stated in [13]. As a result, the model was represented with belief functions, a formalism that is consistent with the cognitive perspective of trust adopted by the model. This belief-based representation provides the most direct correspondence with elements of the model and their underlying uncertainty, while being able to quantify subjective judgments.

After introducing main concepts of belief functions, this section shows how the formalism is used to represent the trust model.

## A. Basic Belief Assignment

Belief Functions (BF) have been introduced by Shafer in his his mathematical theory of evidence [59], also referred to Dempster-Shafer Theory (DST), to model epistemic uncertainty. The frame of discernment (FoD) of the decision problem under consideration, denoted  $\Theta$ , is a finite set of exhaustive and mutually exclusive elements. The powerset of  $\Theta$  denoted  $2^\Theta$  is the set of all subsets of  $\Theta$ , empty set included. A body of evidence is a source of information characterized by a Basic Belief Assignment (BBA), or a mass function, which is the mapping  $m(\cdot) : 2^\Theta \rightarrow [0, 1]$  that satisfies  $m(\emptyset) = 0$ , and the normalization condition  $\sum_{A \in 2^\Theta} m(A) = 1$ . The belief (a.k.a credibility)  $Bel(\cdot)$  and plausibility  $Pl(\cdot)$  function, usually interpreted as lower and upper bounds of unknown (subjective) probability measure  $P(\cdot)$ , are defined from  $m(\cdot)$  respectively by

$$Bel(A) = \sum_{B \subseteq A | B \in 2^\Theta} m(B), \quad (1)$$

$$Pl(A) = \sum_{B \cap A \neq \emptyset | B \in 2^\Theta} m(B). \quad (2)$$

An element  $A \in 2^\Theta$  is called a focal element of the BBA  $m(\cdot)$ , if and only if  $m(A) > 0$ . The set of all focal elements of  $m(\cdot)$  is called the core of  $m(\cdot)$  and is denoted  $\mathcal{K}(m)$ . This formalism allows for modeling a completely ignorant source

by taking  $m(\Theta) = 1$ . The Belief Interval (BI) of any element  $A$  of  $2^\Theta$  is defined by

$$BI(A) \triangleq [Bel(A), Pl(A)]. \quad (3)$$

The width of belief interval of  $A$ , denoted  $U(A) = Pl(A) - Bel(A)$  characterizes the degree of imprecision of the unknown probability  $P(A)$ , often called the uncertainty of  $A$ . We define the uncertainty (or imprecision) index by

$$U(m) \triangleq \sum_{A \in \Theta} U(A), \quad (4)$$

to characterize the overall imprecision of the subjective (unknown) probabilities committed to elements of the FoD bounded by the belief intervals computed with the BBA  $m(\cdot)$ .

Shafer proposed using Dempster's rule of combination for combining multiple independent sources of evidence [59] which is the normalized conjunctive fusion rule. This rule has been strongly disputed in the BF community after Zadeh's first criticism in 1979, and since the 1990s many rules have been proposed to combine (more or less efficiently) BBAs; the reader is advised to see discussions in [60], in particular the proportional conflict redistribution rule number 6 (PCR6). To combine the BBAs we use the proportional conflict redistribution (PCR) rule number 6 (denoted PCR6) proposed by Martin and Osswald in [60] because it provides better fusion results than Dempster's rule in situations characterized by both high and low conflict as explained in detail in [61], [62].

The PCR6 rule is based on the PCR principle which transfers the conflicting mass only to the elements involved in the conflict and proportionally to their individual masses, so that the specificity of the information is entirely preserved. The steps in applying the PCR6 rule are:

- 1) apply the conjunctive rule;
- 2) calculate the total or partial conflicting masses; and
- 3) redistribute the (total or partial) conflicting mass proportionally on non-empty sets.

The general PCR6 formula for the combination of  $n > 2$  BBAs is very complicated (see [60] Vol. 2, Chap. 2). For convenience's sake, we give here just the PCR6 formula for the combination of only two BBAs. When we consider two BBAs  $m_1(\cdot)$  and  $m_2(\cdot)$  defined on the same FoD  $\Theta$ , the PCR6 fusion of these two BBAs is expressed as  $m_{PCR6}(\emptyset) = 0$  and for all  $X \neq \emptyset$  in  $2^\Theta$

$$m_{PCR6}(X) = \sum_{\substack{x_1, x_2 \in 2^\Theta \\ x_1 \cap x_2 = X}} m_1(x_1)m_2(x_2) + \sum_{\substack{Y \in 2^\Theta \setminus \{X\} \\ X \cap Y = \emptyset}} \left[ \frac{m_1(X)^2 m_2(Y)}{m_1(X) + m_2(Y)} + \frac{m_2(X)^2 m_1(Y)}{m_2(X) + m_1(Y)} \right], \quad (5)$$

where all denominators in (5) are different from zero. If a denominator is zero, that fraction is discarded. A very basic (not optimized) Matlab code implementing the PCR6 rule can

be found in [60] and [63], and also in the toolboxes repository on the web<sup>2</sup>.

Instead of working with quantitative (numerical) BBA, it is also possible to work with qualitative BBA expressed by labels using the linear algebra of refined labels proposed in Dezert-Smarandache Theory (DSMT), [60] (Vol. 2 & 3).

### B. Trust formalization model

Because beliefs are well defined mathematical concepts in the theory of belief functions, we prefer to use self-confidence terminology to represent the confidence declared by a source  $Y$  on its own assertion  $A$ . Let's denote by  $A$  the assertion given by the source, for instance  $A = \text{John is a terrorist}$ . With respect to elements of the model,  $A$  (the assertion) corresponds to  $i_a$ , the assertive part of the item  $I$  and  $v(A)$  is a numeric estimation of the subjective  $i_s$  component of  $I$ .

The valuation  $v(A)$  made by the source  $Y$  about the assertion  $A$  can be done either quantitatively (by a probability or a BBA) or qualitatively (by a label associated to a linguistic form). This paper considers quantitative representation of  $v(A)$  for simplicity<sup>3</sup>.

The basic information items provided by a source  $Y$  consists of  $A$  (the assertion), and  $v(A)$  (its valuation). To be as general as possible, we suppose that  $v(A)$  is a basic belief mass assignment defined with respect to the very basic frame of discernment  $\Theta_A \triangleq \{A, \bar{A}\}$  where  $\bar{A}$  denotes the complement of  $A$  in  $\Theta_A$ , that is  $v(A) = (m(A), m(\bar{A}), m(A \cup \bar{A}))$ . Note that only two values of the triplet are really necessary to define  $v(A)$  because the third one is automatically derived from the normalization condition  $m(A) + m(\bar{A}) + m(A \cup \bar{A}) = 1$ . So one could also have chosen equivalently  $v(A) = [Bel(A), Pl(A)]$  instead of the BBA. In a probabilistic context, one will take  $m(A \cup \bar{A}) = 0$  and so  $v(A) = P(A)$  because  $Bel(A) = Pl(A) = P(A)$  in such a case.

The self-confidence of the source  $Y$  is an extra factor  $\alpha_Y \in [0, 1]$  which characterizes the self-estimation of the quality of the piece of information  $(A, v(A))$  provided by the source itself.  $\alpha_Y = 1$  means that the source  $Y$  is 100% confident in his valuation  $v(A)$  about assertion  $A$ , and  $\alpha_Y = 0$  means that the source  $Y$  is not at all confident in his valuation  $v(A)$ . In the theory of belief functions, this factor is often referred as the discounting factor of the source because this factor is usually used to discount the original piece of information  $(A, v(A))$  into a discounted one  $(A, v'(A))$  as follows [59]:

$$m'(A) = \alpha_Y \cdot m(A), \quad (6)$$

$$m'(\bar{A}) = \alpha_Y \cdot m(\bar{A}), \quad (7)$$

$$m'(A \cup \bar{A}) = \alpha_Y \cdot m(A \cup \bar{A}) + (1 - \alpha_Y). \quad (8)$$

The idea of Shafer's discounting technique is to diminish the belief mass of all focal elements with the factor  $\alpha_Y$  and redistribute the missing discounted mass  $(1 - \alpha_Y)$  to the whole

ignorance  $A \cup \bar{A}$ . Note that the valuation of the discounted piece of information is always degraded because its uncertainty index is always greater than the original one, that is,  $U(m') > U(m)$ , which is normal.

The reliability factor  $r$  estimated by the analyst  $X$  on the piece of information  $(A, v(A))$  provided by the source  $Y$  must take into account both the competence  $C_Y$ , the reputation  $R_Y$  and the intention  $I_Y$  of the source  $Y$ . A simple model to establish the reliability factor  $r$  is to consider that  $C_Y$ ,  $R_Y$  and  $I_Y$  factors are represented by numbers  $[0, 1]$  associated to select subjective probabilities, that is  $C_Y = P(Y \text{ is competent})$ ,  $R_Y = P(Y \text{ has a good reputation})$  and  $I_Y = P(Y \text{ has a good intention (i.e. is fair)})$ . If each of these factors has equal weight, then one could use  $r = C_Y \times R_Y \times I_Y$  as a simple product of probabilities. However, in practice, such simple modeling does not fit well with what the analyst really needs to take into account epistemic uncertainties in Competence, Reputation and Intention. In fact, each of these factors can be viewed as a specific criterion influencing the level of the global reliability factor  $r$ . This is a multi-criteria valuation problem. Here we propose a method to solve the problem.

We consider the three criteria  $C_Y$ ,  $R_Y$  and  $I_Y$  with their associated importance weights  $w_C$ ,  $w_R$ ,  $w_I$  in  $[0, 1]$  with  $w_C + w_R + w_I = 1$ . We consider the frame of discernment  $\Theta_r = \{r, \bar{r}\}$  about the reliability of the source  $Y$ , where  $r$  means that the source  $Y$  is reliable, and  $\bar{r}$  means that the source  $Y$  is definitely not reliable. Each criteria provides a valuation on  $r$  expressed by a corresponding BBA. Hence, for the competence criteria  $C_Y$ , one has  $(m_C(r), m_C(\bar{r}), m_C(r \cup \bar{r}))$ , while for the reputation criteria  $R_Y$ , one has  $(m_R(r), m_R(\bar{r}), m_R(r \cup \bar{r}))$  and for the intention criteria  $I_Y$ , one has  $(m_I(r), m_I(\bar{r}), m_I(r \cup \bar{r}))$ .

To get the final valuation of the reliability  $r$  of the source  $Y$ , one needs to efficiently fuse the three BBAs  $m_C(\cdot)$ ,  $m_R(\cdot)$  and  $m_I(\cdot)$ , taking into account their importance weights  $w_C$ ,  $w_R$ , and  $w_I$ . This fusion problem can be solved by applying the importance discounting approach combined with PCR6 fusion rule of DSMT [63] to get the resultant valuation  $v(r) = (m_{PCR6}(r), m_{PCR6}(\bar{r}), m_{PCR6}(r \cup \bar{r}))$  from which the decision ( $r$ , or  $\bar{r}$ ) can be drawn (using BI distance, for instance). If a firm decision is not required, an approximate probability  $P(r)$  can also be inferred with some lossy transformations of BBA to probability measure [60]. Note that Dempster's rule of combination cannot be used here because it does not respond to the importance discounting, as explained in [63].

The trust model consists of the piece of information  $(A, v(A))$  and the self-confidence factor  $\alpha_Y$  provided by the source  $Y$ , as well as the reliability valuation  $v(r)$  expressed by the BBA  $(m(r), m(\bar{r}), m(r \cup \bar{r}))$  to infer the trust valuation about the assertion  $A$ . For this, we propose using the mass  $m(r)$  of reliability hypothesis  $r$  of the source  $Y$  as a new discounting factor for the BBA  $m'(\cdot)$  reported by the source  $Y$ , taking into account its self-confidence  $\alpha_Y$ . Hence, the trust valuation  $v_t(A) = (m_t(A), m_t(\bar{A}), m_t(A \cup \bar{A}))$  of assertion

<sup>2</sup>[http://bfaswiki.iut-lannion.fr/wiki/index.php/Main\\_Page](http://bfaswiki.iut-lannion.fr/wiki/index.php/Main_Page)

<sup>3</sup>Without loss of generality one can always map a qualitative representation to a quantitative one by a proper choice of scaling and normalization (if necessary).

$A$  for the analyst  $X$  is defined by

$$m_t(A) = m(r) \cdot m'(A), \quad (9)$$

$$m_t(\bar{A}) = m(r) \cdot m'(\bar{A}), \quad (10)$$

$$m_t(A \cup \bar{A}) = m(r) \cdot m'(A \cup \bar{A}) + (1 - m(r)), \quad (11)$$

or equivalently by

$$m_t(A) = m(r)\alpha_Y \cdot m(A), \quad (12)$$

$$m_t(\bar{A}) = m(r)\alpha_Y \cdot m(\bar{A}), \quad (13)$$

$$m_t(A \cup \bar{A}) = m(r)\alpha_Y \cdot m(A \cup \bar{A}) + (1 - m(r)\alpha_Y). \quad (14)$$

The DSMT framework using the PCR6 fusion rule and the importance discounting technique provides an interesting solution for the fusion of attributes having different degrees of importance while making a clear distinction between those attributes.

The discounting method proposed in this work is directly inspired by Shafer's classical discounting approach [59]. In our application, the classical discounting factor that we propose integrates both the mass of reliability hypothesis  $m(r)$  and the self-confidence factor  $\alpha_Y$ . It is worth noting that more sophisticated (contextual) belief discounting techniques [64] exist and they could also have been used, in theory, to refine the discounting but these techniques are much more complicated and they require additional computations. The evaluation of contextual belief discounting techniques for such types of application is left for further investigations and research works.

## VI. UNCERTAINTY ANALYSIS UNDER URREF CRITERIA

Tracking uncertainties from problem description to model construction and formalization is done under criteria of the uncertainty representation and reasoning evaluation framework.

The goal of URREF is to place the focus on the evaluation of uncertainty representation and reasoning procedures. The URREF ontology defines four main classes of evaluation criteria: Data Handling, Representation, Reasoning and Data Quality. These criteria make distinctions between the evaluation of the fusion system, the evaluation of its inputs and outputs, and the evaluation of the uncertainty representation and reasoning aspects.

Listing all criteria is an extensive task and in this paper the authors will provide one piece of the puzzle by considering criteria that relate to the evaluation of uncertainty induced by the proposed model. In the model developed in this paper, uncertainty is due to imperfections of information gathering and reporting as well as constraints of the representation formalism.

Uncertainty analysis is carried out by assigning uncertainty criteria to elements and functions of the trust model in order to make explicit the uncertainty arising when the problem is abstracted by the model and the model is then simplified in order to fulfill constraints of specific formalism, fig. 6.

The URREF criteria selected are subclasses of two main concepts: *Credibility*, a subclass under *DataCriteria*, and *EvidenceHandling*, a subclass of *RepresentationCriteria*.

Fig. 4. Trust estimation from source to analyst.

To summarize, uncertainties of the model will be captured by the following URREF criteria :

- **Objectivity**, subconcept of **Credibility**: indicates a source providing unbiased information;
- **ObservationalSensitivity**, subconcept of **Credibility**: characterizes the skills and competences of sources;
- **SelfConfidence**, subconcept of **Credibility**: measures the certainty degree about the piece of information reported, according to the source;
- **Ambiguity**, subconcept of **EvidenceHandling**: captures if the sources provide data supporting different conclusions;
- **Dissonance**, subconcept of **EvidenceHandling**: captures the ability of formalism to represent inconsistent evidence;
- **Completeness**, subconcept of **EvidenceHandling**: is a measure of how much is known given the amount of evidence; and
- **Conclusiveness**, subconcept of **EvidenceHandling**: indicates how strong the evidence supports a conclusion;

Besides selecting uncertainty criteria relevant for trust estimation, the analysis also discusses the mapping of URREF criteria to attributes of the model and sheds a light on imperfect matchings. This mapping offers a basis for identifying the limitations of the URREF ontology, by emphasizing those elements whose characterizations in terms of uncertainty are out of the ontology's reach or beyond the ontology's intended scope.

### A. Uncertainties from problem definition to model abstraction

Let  $M$  be the model for trust estimation, with elements introduced in paragraph IV: the source  $Y$ , the reported item  $I$  with its assertive  $i_a$  and subjective  $i_s$  parts, and  $\chi(I)$  the confidence level assigned by the source  $Y$  to  $I$ .

From an information fusion standpoint, inputs of the model are the source and the information items, along with their uncertainty, captured with the following URREF criteria: *Objectivity*, *ObservationalSensitivity* and *SelfConfidence*. These criteria are subclasses of the concept *InputCriteria*.

*Objectivity* is an attribute of the source, related to its ability to provide factual, unbiased items, without adding their own points of view or opinions. For a source  $Y$  providing

information item  $i$ , having  $i_s$  and  $i_a$  as the subjective and factual parts respectively, objectivity can be expressed as:

$$\text{Objectivity}(Y, I) = \psi_o(i_s, i_a), \quad (15)$$

where  $\psi_o(i_s, i_a)$  represents the mathematically quantified expression of the subjective over the factual content of  $i$ .

*ObservationalSensitivity* is an attribute of the source which represents the source's ability to provide accurate reports. In the proposed model, this criterion is an aggregation of competence  $C$  and reputation  $R$ , two attributes of the model.

$$\text{ObservationalSensitivity}(Y, i) = \psi_{os}(C, R), \quad (16)$$

where  $\psi_{os}(C, R)$  is a function aggregating values of competence and reputation.

Information items entering the system are described by *SelfConfidence*. Again, considering  $i_s$  and  $i_a$  as the subjective and factual items conveyed by  $I$ , *SelfConfidence* can be expressed as:

$$\text{SelfConfidence}(I) = \psi_{sc}(i_s), \quad (17)$$

with  $\psi_{sc}(i_s)$  a function quantifying the subjective content of item  $I$ .

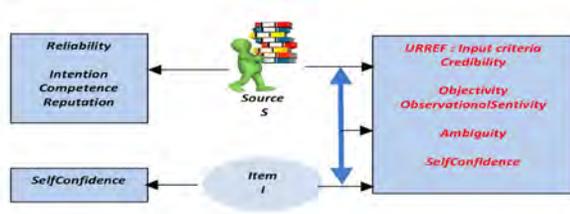

Fig. 5. Mapping of model attributes to URREF criteria.

Fig. 5 shows the mapping between the elements of the model and the set of relevant URREF uncertainty criteria. The mapping shows a perfect match between *SelfConfidence* as introduced by the model and the eponymous URREF criterion as well as several imperfect matches described later in this paper.

At source level, URREF criteria are not able to capture in a distinct manner the features of competence, reputation and intentions, the main attributes of the sources added by the model under Reliability. To some extent, competence and reputation can be related to *ObservationalSensitivity*, but intentions clearly remains out of reach for URREF criteria.

### B. Uncertainties from model to formal representation

Let  $F$  be the DST formalization of the trust estimation model, with parameters introduced in paragraph V. The formalism induces two types of uncertainty related to its capacity to handle incomplete, ambiguous or contradictory evidence. The uncertainty of evidence handling is captured by *Ambiguity*, *Dissonance*, *Conclusiveness* and *Completeness*. Those criteria are subclasses of the concept *EvidenceHandling*.

*Ambiguity* measures the extent to which the formalism can handle data sets which support different conclusions.

$$\text{Ambiguity}(F) = \phi_a(\alpha_Y, R_Y), \quad (18)$$

where the function  $\phi_a(\alpha_Y, R_Y)$  considers the self-confidence factor  $\alpha_Y$  provided by the source  $Y$  and the reliability of  $Y$  provided by the analyst  $R_Y$  to estimate the degree of ambiguity. The measure is of particular interest in the case where items having high values of self-confidence are provided by unreliable sources.

*Dissonance* captures the ability of the formalism to represent inconsistent evidence. For BBA representations, dissonance can be related to the capacity of the formalism to assign belief mass to an element and its negation, and can therefore be assessed for every BBA representation build for the model. For example, the dissonance for a source's competence can be in the form:

$$\text{Dissonance}(F) = \phi_d(m_C(r), m_C(\bar{r})), \quad (19)$$

where  $\phi_d(m_C(r), m_C(\bar{r}))$  is a function combining the belief mass assigned to whether the source is considered to be competent or incompetent, respectively.

Dissonance is useful for highlighting situations in which there are significant differences in belief masses assigned at the attribute level, such as when a source is considered to be incompetent (low  $m_C(r)$ , high  $m_C(\bar{r})$ ) but has a good reputation (high  $m_R(r)$ , low  $m_R(\bar{r})$ ).

*Conclusiveness* is a measure expressing how strongly the evidence supports a specific conclusion or unique hypothesis:

$$\text{Conc.}(F) = \phi_{cc}(m_t(A), m_t(\bar{A}), m_t(A \cup \bar{A})), \quad (20)$$

where  $\phi_{cc}(m_t(A), m_t(\bar{A}), m_t(A \cup \bar{A}))$  is a function combining the belief masses estimated for truthful, untruthful and unknown qualifications of assertion  $A$  respectively. This measure indicates to which extent the result of inferences can support a conclusion, in this case whether the hypothesis that the assertion under analysis is trustworthy or not. It can be used during the inference process to show how taking into account additional elements such as the competence of the source, its reputation or intentions impact the partial estimations of trust.

*Completeness* is a measures of the range of the available evidence, and captures the ability of formalism to take into account how much is unknown. The measures is somewhat similar to *Dissonance*, as is can be assessed for every BBA representation build for the model. Thus, completeness of source's reliability is described as:

$$\text{Completeness}(F) = \phi_{cp}(m(r \cup \bar{r})), \quad (21)$$

where  $\phi_{cp}(m(r \cup \bar{r}))$  is a function depending on the belief mass assigned to unknown.

The measure is used for estimation and analysis before entering the fusion process, in order to have a picture of how complete the evidence describing the various elements of the model is, and to avoid performing fusion on highly incomplete data sets. Both *EvidenceHandling* and *KnowledgeHandling* are subclasses of *RepresentationCriteria*.

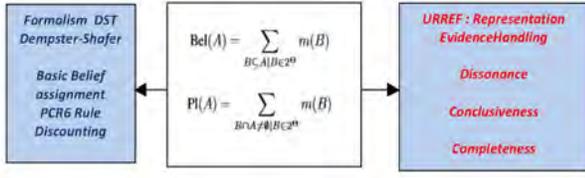

Fig. 6. Mapping of formalism uncertainties to URREF criteria.

This section has analyzed the nature of uncertainties arising when going from problem to model definition and then on to formalization with belief functions. The next section shows how uncertainties can be highlighted for particular scenarios of trust estimation.

## VII. UNCERTAINTY ANALYSIS FOR TRUST ESTIMATION

### A. Running example and method for uncertainty tracking

As a running example, let's consider an assertion  $A$  and its valuation  $v(A)$  provided by the source  $Y$  as follows:  $m(A) = 0.7$ ,  $m(\bar{A}) = 0.1$  and  $m(A \cup \bar{A}) = 0.2$ . Its self-confidence factor is  $\alpha_Y = 0.75$ . Hence, the discounted BBA  $m'(\cdot)$  is given by

$$\begin{aligned} m'(A) &= 0.75 \cdot 0.7 = 0.525 \\ m'(\bar{A}) &= 0.75 \cdot 0.1 = 0.075 \\ m'(A \cup \bar{A}) &= 1 - m'(A) - m'(\bar{A}) = 0.4 \end{aligned}$$

Let's assume that the BBAs about the reliability of the source based on Competence, Reputation and Intention criteria are given as follows:

$$\begin{aligned} m_C(r) &= 0.8, m_C(\bar{r}) = 0.1, m_C(r \cup \bar{r}) = 0.1, \\ m_R(r) &= 0.7, m_R(\bar{r}) = 0.1, m_R(r \cup \bar{r}) = 0.2, \\ m_I(r) &= 0.6, m_I(\bar{r}) = 0.3, m_I(r \cup \bar{r}) = 0.1, \end{aligned}$$

with importance weights  $w_I = 0.6$ ,  $w_R = 0.2$  and  $w_C = 0.2$ .

After applying the importance discounting technique presented in [63] which consists of discounting the BBAs with the importance factor and redistributing the missing mass onto the empty set, then combining the discounted BBAs with PCR6 fusion rule, we finally get, after normalization, the following BBA

$$\begin{aligned} m(r) &= 0.9335, \\ m(\bar{r}) &= 0.0415, \\ m(r \cup \bar{r}) &= 1 - m(r) - m(\bar{r}) = 0.025. \end{aligned}$$

The final trust valuation of assertion  $A$  reported by the source  $Y$  taking into account its self-confidence  $\alpha_Y = 0.75$  and the reliability factor  $m(r)$  is therefore given by Eqs. (12)–(14) and obtaining

$$\begin{aligned} m_t(A) &= 0.4901, \\ m_t(\bar{A}) &= 0.0700, \\ m_t(A \cup \bar{A}) &= 1 - m_t(A) - m_t(\bar{A}) = 0.4399. \end{aligned}$$

Note that if  $m_C(r) = m_R(r) = m_I(r) = 1$ , then we will always get  $m(r) = 1$  regardless of the choice of weightings factors, which is normal. If there is a total conflict between valuations of reliability based on Competence, Reputation and Intention criteria, then Dempster's rule cannot be applied to get the global reliability factor  $m(r)$  because of  $0/0$  indeterminacy in the formula of Dempster's rule. For instance, if one has  $m_C(r) = m_R(r) = 1$  and  $m_I(\bar{r}) = 1$ , then  $m(r)$  is indeterminate with Dempster's rule of combination, whereas it corresponds to the average value  $m(r) = 2/3$  using PCR6 fusion rule (assuming equal importance weights  $w_C = w_R = w_I = 1/3$ ), which makes more sense.

The following subsections explore several scenarios for trust assessment, corresponding to different situations of BBAs distributions, and track the uncertainty according to URREF criteria. Each scenario illustrates specific instances of the model developed for trust estimation.

The method adopted to track uncertainty defines the following measures to estimate URREF criteria:

$$\begin{aligned} SelfConfidence &= \alpha_Y, \\ Ambiguity &= |\alpha_Y - m(r)|, \\ Objectivity &= m_I(r), \\ ObservationalSensitivity &= \min(m_C(r), m_R(r)). \end{aligned}$$

As shown in previous formulas, URREF criteria are estimated based on features of the BBA formalization and are assigned to the static elements of the model, i.e., the source and the information item. While *Objectivity* and *ObservationalSensitivity* captures imperfections of observations, *SelfConfidence* and *Ambiguity* reflect inaccuracies in reporting information to analysts. These criteria are assessed before entering the fusion phase, and describe the initial uncertainty present in the system before inferences.

In addition, *Dissonance*, *Conclusiveness* and *Completeness* will be estimated at the scenario level by adopting the following formulas:

$$\begin{aligned} Dissonance &= 1 - |m_t(A) - m_t(\bar{A})|, \\ Conclusiveness &= |m_t(A) - m_t(\bar{A})|, \\ Completeness &= 1 - m(A \cup \bar{A}). \end{aligned}$$

Criteria above will be assessed for elements impacted by the fusion process: the reliability of the source, the updated BBAs of the initial assertion and estimated trust. In the following subsection we illustrate several scenarios for trust estimation and the uncertainty analysis underlying each scenario.

### B. Scenarios for trust assessment and uncertainty analysis

Scenarios introduced below provide examples of trust construction using various operators and highlight the uncertainty assigned to elements of the model and its propagation during the fusion process.

**Scenario 1 - Consensus:** Suppose that  $Y$  provides the assertion  $A$ , while stating that  $A$  certainly holds and that  $X$  considers  $Y$  to be a reliable source.

In this case, the trust will be constructed on the basis of two consensual opinions: the analyst  $X$  that considers  $Y$  as a

reliable source, and the source’s conviction that the information provided is certain. In this case,  $m(A) = 1$ ,  $\alpha_Y = 1$  and  $m(r) = 1$ , so that  $m'(A) = 1$  and  $m_t(A) = m(r) \cdot m'(A) = 1$ . The result will be in the form  $(A, v(A))$  initially provided by the source.

Uncertainty of inputs		
2*Observation	Objectivity	1
	ObservationalSensitivity	1
2*Reporting	SelfConfidence	1
	Ambiguity	0

TABLE I  
CONSENSUS: INPUT UNCERTAINTY.

Fusion uncertainty	Dissonance	Conclusiv.	Comple.
Updated BBAs	0	1	1
Reliability	0	1	1
Trust	0	1	1

TABLE II  
CONSENSUS: FUSION UNCERTAINTY.

This scenario illustrates an ideal situation for trust assessment, where the source is trustworthy and well known to the analyst, and observations are reported in perfect conditions. As shown in table I, there is no uncertainty induced by the source, and once fusion is performed the items impacted show high values for conclusiveness and completeness, while dissonance is 0 for the updates BBAs for values, source’s reliability and estimated trust, as shown in table II.

**Scenario 2 - Uncertain utterances:**  $Y$  is considered by  $X$  to be a reliable source and reports the assertion  $A$ , while showing a low level of certainty  $v(A)$  about the veracity of  $A$ . This example is relevant for situations where a reliable source provides (possibly) inaccurate descriptions of events due to, say, bad conditions for observation. This scenario corresponds by example to the following case for inputs:  $\alpha_Y = 0.6$

$$m(A) = 0.8, m(\bar{A}) = 0.1, m(A \cup \bar{A}) = 0.1,$$

$$m_C(r) = 0.9, m_C(\bar{r}) = 0, m_C(r \cup \bar{r}) = 0.1,$$

$$m_R(r) = 0.9, m_R(\bar{r}) = 0, m_R(r \cup \bar{r}) = 0.1,$$

$$m_I(r) = 0.3, m_I(\bar{r}) = 0.3, m_I(r \cup \bar{r}) = 0.6,$$

and  $w_C = 0.5$ ,  $w_R = 0.5$  and  $w_I = 0$ .  
This results in

$$m'(A) = 0.48, m'(\bar{A}) = 0.06, m'(A \cup \bar{A}) = 0.46,$$

and

$$m(r) = 0.9846, m(\bar{r}) = 0, m(r \cup \bar{r}) = 0.0154.$$

Therefore, one finally obtains the trust valuation

$$m_t(A) = 0.47, m_t(\bar{A}) = 0.05, m_t(A \cup \bar{A}) = 0.46.$$

This case shows that self-confidence has an important impact on the values of discounted BBA, as  $m'(A)$  is decreased

from 0.8 to 0.48, and thus the remaining mass is redistributed on  $m'(A \cup \bar{A})$ .

The combination of competence, reliability and intention are in line with the assumption of the scenario, which states that  $Y$  is a reliable source. After normalization, values for trust assessment clearly highlight the impact of uncertain utterances, as the BBA shows a mass transfer from  $m_t(A)$  to  $m_t(A \cup \bar{A})$ . Still, values of trust are close to BBA integrating the self-confidence, which confirms the intuition that when the analyst  $X$  considers  $Y$  to be a reliable source, the assertion  $A$  is accepted with an overall trust level almost equal to the certainty level stated by the source.

Uncertainty of inputs		
2*Observation	Objectivity	0.3
	ObservationalSensitivity	0.9
2*Reporting	SelfConfidence	0.6
	Ambiguity	0.38

TABLE III  
UNCERTAIN UTTERING: INPUT UNCERTAINTY.

Fusion uncertainty	Dissonance	Conclusiv.	Comple.
Updates BBAs	0.3	0.7	0.9
Reliability	0.02	0.98	0.98
Trust	0.59	0.41	0.54

TABLE IV  
UNCERTAIN UTTERANCE: FUSION UNCERTAINTY.

This scenario illustrates uncertainty induced by observations failures, as *Objectivity*, and *SelfConfidence* are low, see table III.

While the quality of the source is highlighted by high values of *Conclusiveness* and *Completeness*, showing the analyst’s confidence in the reports analyzed, the impact of imperfect observation is shown in the overall estimation of trust, through a combination of *Dissonance*, *Conclusiveness* and *Completeness* which have values close to 0.5, see table IV.

**Scenario 3 - Reputation:** Suppose that  $Y$  provides  $A$  and  $v(A)$  and  $X$  has no global description of  $Y$  in terms of reliability. As the reliability of  $Y$  is not available,  $Y$ ’s reputation will be used instead, as derived from historical data and previous failures. This scenario corresponds by example to the following case for inputs:  $\alpha_Y = 1$

$$m(A) = 0.8, m(\bar{A}) = 0.1, m(A \cup \bar{A}) = 0.1,$$

$$m_C(r) = 0.1, m_C(\bar{r}) = 0.1, m_C(r \cup \bar{r}) = 0.8,$$

$$m_R(r) = 0.9, m_R(\bar{r}) = 0.1, m_R(r \cup \bar{r}) = 0,$$

$$m_I(r) = 0.1, m_I(\bar{r}) = 0.1, m_I(r \cup \bar{r}) = 0.8,$$

and  $w_C = 0.1$ ,  $w_R = 0.8$  and  $w_I = 0.1$ .

Hence, one gets

$$m'(A) = 0.8, m'(\bar{A}) = 0.1, m'(A \cup \bar{A}) = 0.1,$$

and

$$m(r) = 0.94, m(\bar{r}) = 0.01, m(r \cup \bar{r}) = 0.03.$$

Therefore, one finally obtains the trust valuation

$$m_t(A) = 0.75, m_t(\bar{A}) = 0.09, m_t(A \cup \bar{A}) = 0.14.$$

For this scenario, the source is confident about their own assertions, and therefore

$$m(A) = 0.8, m(\bar{A}) = 0.1, m(A \cup \bar{A}) = 0.1$$

and

$$m'(A) = 0.8, m'(\bar{A}) = 0.1, m'(A \cup \bar{A}) = 0.1$$

have identical BBA distributions. The reliability of the source is built namely on its reputation, as there are clues about the competence and intentions of the source. Hence, the overall BBA

$$m(r) = 0.9449, m(\bar{r}) = 0.0196, m(r \cup \bar{r}) = 0.0355$$

is close to the initial reputation distribution

$$m_R(r) = 0.9, m_R(\bar{r}) = 0.1, m_R(r \cup \bar{r}) = 0$$

Values of trust show the impact of using not completely reliable sources, which decreased the certainty level of the initial BBA

$$m'(A) = 0.8, m'(\bar{A}) = 0.1, m'(A \cup \bar{A}) = 0.1$$

to

$$m_t(A) = 0.75, m_t(\bar{A}) = 0.09, m_t(A \cup \bar{A}) = 0.14$$

They also support the intuition that the trust assigned by the analyst to  $A$  will have an upper limit equal to the reputation of the source.

Uncertainty of inputs		
2*Observation	Objectivity	0.10
	ObservationalSensitivity	0.10
2*Reporting	SelfConfidence	1
	Ambiguity	0.60

TABLE V  
REPUTATION: INPUT UNCERTAINTY.

Fusion uncertainty	Dissonance	Conclusiv.	Compleat.
Updated BBAs	0.30	0.70	0.90
Reliability	0.07	0.93	0.95
Trust	0.34	0.66	0.84

TABLE VI  
REPUTATION: FUSION UNCERTAINTY.

This scenario is similar the previous one as, in both cases, there are incomplete descriptions of the source. For this particular case, a historical recording of source's failures offers a basis to overcome the missing pieces and, in spite of low values for *Objectivity* and *ObservationalSensitivity* (see table V), the final trust evaluation is improved with respect to the previous scenario and shows a better combination of *Dissonance*, *Conclusiveness* and *Completeness*, as shown in table VI.

**Scenario 4 - Misleading report:** In this case,  $Y$  provides the assertion  $A$ , while stating that it certainly holds and  $X$  considers  $Y$  to be a completely unreliable source. For this case, the analyst knows that the report is somehow inaccurate, for example, it cannot be corroborated or it contradicts, at least in part. information from other (more reliable) sources. The analyst suspects the source of having misleading intentions, and can therefore assign a maximal uncertainty level to the information reported. This scenario corresponds by example to the following case for inputs:  $\alpha_Y = 1$

$$\begin{aligned} m(A) &= 1, m(\bar{A}) = 0, m(A \cup \bar{A}) = 0, \\ m_C(r) &= 0.1, m_C(\bar{r}) = 0.1, m_C(r \cup \bar{r}) = 0.8, \\ m_R(r) &= 0.1, m_R(\bar{r}) = 0.1, m_R(r \cup \bar{r}) = 0.8, \\ m_I(r) &= 0.1, m_I(\bar{r}) = 0.8, m_I(r \cup \bar{r}) = 0.1, \end{aligned}$$

and  $w_C = 0.1, w_R = 0.1$  and  $w_I = 0.8$ . Hence, one gets

$$m'(A) = 1, m'(\bar{A}) = 0, m'(A \cup \bar{A}) = 0,$$

and

$$m(r) = 0.02, m(\bar{r}) = 0.91, m(r \cup \bar{r}) = 0.06.$$

Therefore, one finally obtains as trust valuation

$$m_t(A) = 0.023, m_t(\bar{A}) = 0, m_t(A \cup \bar{A}) = 0.976.$$

The values for this scenario reflect the high self-confidence of the source and high accuracy of the assertion provided; therefore, the initial BBA is unchanged after fusion with self-confidence. Nevertheless, the impact of having misleading intention is visible first on the mass distribution assigned to reliability and then on the overall values of trust. With respect to the initial values

$$m(A) = 1, m(\bar{A}) = 0, m(A \cup \bar{A}) = 0,$$

and the partially fused ones

$$m'(A) = 1, m'(\bar{A}) = 0, m'(A \cup \bar{A}) = 0,$$

the integration of a misleading source transfers the mass assignment almost exclusively to  $m_t(A \cup \bar{A})$ . Intuitively, the assertion  $A$  will be ignored, as the reliability of the source is dramatically decreased by a high mass assignment on misleading intentions.

Uncertainty of inputs		
2*Observation	Objectivity	0.10
	ObservationalSensitivity	0.10
2*Reporting	SelfConfidence	1.00
	Ambiguity	0.97

TABLE VII  
MISLEADING REPORT: INPUT UNCERTAINTY.

This scenario illustrates the impact of misleading sources on trust estimation. Hence, the use case has very good values for reporting induced uncertainty, with high *SelfConfidence* and low *Ambiguity* (see table VII), but the overall trust

Fusion uncertainty	Dissonance	Conclusiv.	Compleat.
Assertion	0	1	1
Source	0.11	0.89	0.93
Trust	0.76	0.23	0.03

TABLE VIII  
MISLEADING: FUSION UNCERTAINTY.

characterization shows strong *Dissonance*, corroborated with low *Conclusiveness* and near zero *Completeness*, as shown in table VIII.

**Scenario 5 - Ambiguous report:** The source  $Y$  provides  $A$  and  $v(A)$ , the uncertainty level. Suppose that  $v(A)$  has a low value, as the source is not very sure about the events reported, and that  $X$  considers  $Y$  to be unreliable. This scenario corresponds by example to the following case for inputs:  $\alpha_Y = 0.3$

$$\begin{aligned} m(A) &= 0.6, m(\bar{A}) = 0.2, m(A \cup \bar{A}) = 0.2, \\ m_C(r) &= 0.1, m_C(\bar{r}) = 0.8, m_C(r \cup \bar{r}) = 0.1, \\ m_R(r) &= 0.1, m_R(\bar{r}) = 0.8, m_R(r \cup \bar{r}) = 0.1, \\ m_I(r) &= 0.1, m_I(\bar{r}) = 0.1, m_I(r \cup \bar{r}) = 0.8, \end{aligned}$$

and  $w_C = 0.2$ ,  $w_R = 0.4$  and  $w_I = 0.4$ .  
Hence, one gets

$$m'(A) = 0.18, m'(\bar{A}) = 0.06, m'(A \cup \bar{A}) = 0.76,$$

and

$$m(r) = 0.02, m(\bar{r}) = 0.43, m(r \cup \bar{r}) = 0.53.$$

Therefore, one finally obtains the trust valuation

$$m_t(A) = 0.0040, m_t(\bar{A}) = 0.0013,$$

and

$$m_t(A \cup \bar{A}) = 0.9946.$$

This scenario is an illustration for the worst practical case and is relevant when the analyst receives a report provided by a source that lacks the skills or competence to provide accurate descriptions of events. In this case, the reports are incomplete, ambiguous, or even irrelevant. In addition to low competence and reliability, the source himself is also unsure about the statement.

The first modification of BBA shows the strong impact of self-confidence, which changes drastically the BBA of the initial assertions, from

$$m(A) = 0.6, m(\bar{A}) = 0.2, m(A \cup \bar{A}) = 0.2,$$

to

$$m'(A) = 0.18, m'(\bar{A}) = 0.06, m'(A \cup \bar{A}) = 0.76.$$

Unsurprisingly, the overall reliability is low:

$$m(r) = 0.0223, m(\bar{r}) = 0.4398, m(r \cup \bar{r}) = 0.5379,$$

Uncertainty of inputs		
2*Observation	Objectivity	0.10
	ObservationalSensitivity	0.10
2*Reporting	SelfConfidence	0.30
	Ambiguity	0.27

TABLE IX  
AMBIGUOUS REPORT: INPUT UNCERTAINTY.

Fusion uncertainty	Dissonance	Conclusiv.	Compleat.
Assertion	0.6	0.4	0.8
Source	0.583	0.417	0.47
Trust	0.973	0.027	0.006

TABLE X  
AMBIGUOUS REPORT: FUSION UNCERTAINTY.

and the results of the final combination show an important mass assigned to  $m_t(A \cup \bar{A}) = 0.9946$ . Intuitively, the information provided is useless, and considered as highly uncertain.

This scenario shows the combined effects of uncertain reporting and incomplete source description for trust estimation. First, the outcome is affected by high values of uncertainty induced during observation and reporting passes, table IX. Then, fusion leads to a trust estimation having high values of *Dissonance*, and very low values of *Conclusiveness* and *Completeness*.

The same criteria estimated for reliability show the main difference with respect to the previous case, which was also based on unreliable sources. While in scenario 4 the source still has important *Completeness*, this measure is drastically decreased for this scenario, as shown in table X.

#### VIII. STRENGTHS AND LIMITATIONS OF BELIEF-BASED FORMALIZATION FOR TRUST ASSESSMENT

This section discusses the strengths and limitations of the belief-based perspective in trust modeling in the light of results shown by previous scenarios. The main advantage of using belief functions is that the formalism is consistent with the cognitive perspective of trust adopted by the model, thanks to the notion of belief. It also captures uncertainties both of the analyst with respect to the source and of the source with respect to their own statements with different mechanisms. First, self-confidence is implemented thanks to a discounting coefficient, as, in practice, the values of self-confidence may rely upon linguistic clues of certainty/uncertainty that can be translated into numerical values. Second, the formalization introduces weighting factors in order to offer a flexible solution, which allow for situations in which the analyst has more or less complete knowledge about distinct attributes of the source, or wishes to emphasize one particular attribute. Moreover, the formalization is able to handle ignorance on various aspects, including missing data. The overall fusion mechanism performs trust estimation in several steps, which allows for a better traceability of the outcome and the mapping at different processing stages using URREF criteria. The results of these scenarios are in line with their specific hypotheses, reflecting the intuition that the fusion technique is appropriate for estimating trust.

As with any user-centric approach, the main limitation of the solution discussed in this paper is the lack of guidance for choosing the set of numerical values with which to instantiate the model. For example, two different analysts may choose differing mass distribution and weight coefficients with respect to the same source, and they may also use slightly different approaches to infer a numerical value from linguistic clues when handling self-confidence. Thus, the outcome depends crucially on the interventions of users and their ability to build a model able to capture the situation under analysis. Also, the solution requires preexisting knowledge about the source's reputation, competence, and intention, indeed, in practice, it is difficult to have access to information on those aspects. Provided that there is no other meta-data or domain knowledge available for use, the model is likely to fail to produce an accurate trust evaluation in some contexts due to the shortage of knowledge on critical aspects.

As such, the belief-based formalization has limited capabilities to explain the outcome. To overcome this limitation, a mapping to URREF uncertainty criteria is used. The mapping highlights when uncertainties are added into the system and which partial results are affected. It facilitates the interpretation of results by adding additional information as to why the item is to be trusted or no; for example, whereas the fusion process outputs low values of trust for a given item, the mapping to URREF criteria allows to underline problems related to evidence collection or reporting, dissonance or incompleteness during the fusion stages.

As shown in previous scenarios, using a belief-oriented formalism and URREF criteria mapping offers a pragmatic approach to develop a more comprehensive and easy to interpret solution for trust estimation.

## IX. CONCLUSION

This paper presents a computational model by which an analyst is able to assess trust in reported information based on several possible unknown attributes of the source as well as additional characterization of the informational content by the source itself. The paper also illustrates the use of URREF criteria to track uncertainty affecting the results, from model construction to its formalization with belief functions. First, a model for trust estimation has been developed that combines several attributes of sources and their own assessment of the items reported. The model is implemented using belief functions, and takes advantage of its mathematical background to define fusion operators for trust assessment. Several scenarios are presented to illustrate uncertainty analysis, illustrating when uncertainty occurs and how it affects partial results for different applications.

Tracking uncertainty is suitable for fusion systems in which various human sources send observations of questionable quality and there is a need to continuously update the trust associated with reports to be analyzed. The set of URREF criteria offers a unified basis to analyze inaccuracies affecting trust estimation during different phases: observation, reporting, and fusion. Select use cases clearly illustrated the benefits

of managing uncertainties arising during the modeling and formalization phases, with the twofold analysis offering additional details on results and improving their interpretation.

The general approach taken in this paper could be adapted to investigate the general mechanisms by which fusion processes integrate information from multiple sources. The solution is especially useful for comparing different fusion approaches with respect to their implications for uncertainty management.

**Abstract**—In this paper, we present a deciding technique for robotic dexterous hand configurations. This algorithm can be used to decide on how to configure a robotic hand so it can grasp objects in different scenarios. Receiving as input, several sensor signals that provide information on the object's shape, the DSMT decision-making algorithm passes the information through several steps before deciding what hand configuration should be used for a certain object and task. The proposed decision-making method for real time control will decrease the feedback time between the command and grasped object, and can be successfully applied on the robot dexterous hands. For this we have used the Dezert-Smarandache theory which can provide information even on contradictory or uncertain systems.

**Keywords:** neutrosophy, DSMT, decision-making algorithms, robotic dexterous hands, grasping configurations, grasp type.

## I. INTRODUCTION

The purpose of autonomous robotics is to build systems that can fulfill all kind of tasks without human intervention, in different environments which were not specially build for robot interaction. A major challenge for this autonomous robotics field comes from high uncertainty within real environments. This is because the robot designer can't know all the details regarding the environment. Most of the environment parameters are unknown, the position of humans and objects can't be previously anticipated and the motion path might be blocked. Beside these, the accumulated sensor information can be uncertain and error prone. The quality of this information is influenced by noise, visual field limitations, observation conditions and the complexity of interpretation technique.

The artificial intelligence and the heuristic techniques were used by many scientists in the field of robot control [1] and motion planning. Regarding the grasping and object manipulations, the main research activities were to design a mechanism for hand [2-4] and dexterous finger motion [5], which are a high complexity research tasks in controlling robotic hands.

Currently in the research area of robotics, it's desired to develop robotic systems with applications in dynamic and unknown environments, in which human lives would be at risk, like natural or nuclear disaster areas, and also in different fields of work, ranging from house chores or agriculture to military applications. In any of these research areas, the robotic system must fulfill a series of tasks which implies object manipulation and transportation, or using equipment and tools. From here arises the necessity of development grasping systems [6] to reproduce as well as possible human hand motion [7-9].

To achieve an accurate grasping system, grasp taxonomy of human hand was analyzed by Feix (et. al) [10] who found 33 different grasp types, sorted by opposition type, virtual finger assignments, type in terms of power, precision or intermediate grasp, and the position of the thumb. While Alvarez [11] (et. al) researched human grasp strategies within grasp types, Fermuller (et. al) [12] focused on manipulation action for human hand on different object types including hand pre-configuration. Tsai (et. al) [13] found that classifying objects into primitive shapes can provide a way to select the best grasping posture, but a general approach can also be used for hand-object geometry fitting [14]. This classification works well for grasping problems in constrained work space using visual data combined with force sensors [15] and also for under-actuated grasping which uses rotational stiffness [16]. But for unknown objects, scientists found different approaches to solve the hand grasping problem. Choi (et. al) [17] used two different neural networks and data fusion to classify objects, Seredynski (et. al) [18] achieved fast grasp learning with probabilistic models, while Song (et. al) [19] used a tactile-based blind grasping along with a discrete-time controller. The same approach is used by Gu (et. al) [20] which proposed a blind haptic exploration of unknown objects for grasp planning of dexterous robotic hand. Using grasping methods, Yamakawa (et. al) [21] developed a robotic hand for knot manipulation, while Nancy (et. al) [22] used artificial neural network algorithms for slip prevention and Zaidi (et. al) [23] used a multi-fingered robot hand to grasp 3D deformable objects, applying the method on spheres and cubes.

While other scientists developed grasping strategies for different robotic hands [21-23], an anthropomorphic robotic hand has the potential to grasp regular objects of different shapes and sizes [24, 25], but selecting the grasping method for a certain object is a difficult problem. A series of papers have approached this problem by developing algorithms for classifying the grasping by the contact points [26, 27]. These algorithms are focused on finding a fix number of contact areas without taking into consideration the hand geometry. Other methods developed grasping systems for a certain robotic hand architecture, scaling down the problem to finding a grasping method with the tip of the fingers [27]. These methods are useful in certain object manipulation, but can't be applied for a wide range of objects because it doesn't provide a stable grasping due to the face that it's not used, the finger's interior surface or the palm of the hand. A method for filtering the high

number of hand configurations is to use predefined grasping hand configurations. Before grasping an object, humans, unconsciously simplify the grasping action, choosing one of the few hand positions which match the object's shape and the task to accomplish. In the scientific literature there are papers which have tried to log in the positioning for grasping and taxonomy, and one of the most known papers is [28]. Cutkosky and Weight [29] have extended Napier's [28] classification by adding the required taxonomy in the production environment, by studying the way in which the weight and geometry of the object affects choosing the grasping positioning. Iberall [30] has analyzed different grasping taxonomies and generalized them by using the virtual finger concept. Stransfield [31] has chosen a simpler classification and built a system based on rules which provided a grasping positioning set, starting from a simplified description of the object gained from a video system.

The developed algorithm presented in this paper, has the purpose to determine the grasping position according to the object's shape. To prove the algorithm's efficiency we have chosen 3 types of grasping: cylindrical, spherical and prismatic. For this, we start from the hypothesis that the environment data are captured through a stereovision system [32] and a Kinect sensor [33]. On this data, which the two system observers provide, we apply a template matching algorithm [34]. This algorithm will provide a matching percentage of the object that needs to be grasped with a template object. Thus, each of the two sources will provide 3 matching values, for each of the three grasping types. These values represent the input for our detection algorithm, based of Dezert-Smarandache Theory (DSMT) [35] for data fusion. This algorithm has as input data from two or multiple observers and in the first phase they are processed through a process of neutrosification which is similar with the fuzzification process. Then, the neutrosophic observers' data are passed through an algorithm which applies the classic DSMT theory [35] in order to obtain a single data set on the system's states, by combining the observers' neutrosophic values. On this obtained data set, we apply the developed DSMT decision-making algorithm that decides on the category from which the target object is part of. This decision facilitates the detection-recognition-grasping process which a robotic hand must follow, obtaining in the end a real-time decision that doesn't stop or delay the robot's task.

In recent years, using more sensors for a certain applications and then using data fusion is becoming more common, in the military and nonmilitary research fields. The data fusion techniques combine the information received from different sensors with the purpose of eliminating disturbances and to improve precision compared to the situations when a single sensor is used [36, 37]. This technique works on the same principle used by humans to feel the environment. For example, a human being can't see over the corner or through vegetation, but with his hearing he can detect certain surrounding dangers. Beside the statistical advantage build from combining the details for a certain object (through redundant observations),

using more types of sensors increases the precision with which an object can be observed and characterized. For example, an ultrasonic sensor can detect the distance to an object, but a video sensor can estimate its shape, and combining these two information sources will provide two distinct data on the same object.

The evolution on the new sensors, the hardware's processing techniques and capacity improvements facilitate more and more the real time data fusion. The latest progress were made in the area of computational and detection systems, and provide the ability to reproduce, in hardware and software, the data fusion capacity of humans and animals. The data fusion systems are used for targets tracking [38], automatic targets identification [39] and automated reasoning applications [40]. The data fusion applications are widespread, ranging from the military [41] applications (target recognition, autonomous moving vehicles, distance detection, battlefield surveillance, automatic danger detection) to civilian application (monitoring the production processes, complex tools maintenance based on certain conditions, robotics [42], and medical applications [43]). The data fusion techniques undertake classic elements like digital signal processing, statistical estimation, control theory, artificial intelligence and numeric methods [44].

Combined data interpretation requires automated reasoning techniques taken from the area of artificial intelligence. The purpose of developing the recognition based systems, was to analyze issues like the data gathering context, the relationship between observed entities, hierarchical grouping of targets or objects and to predict future actions of these targets or entities. This kind of reasoning is encountered in humans, but the automated reasoning techniques can only closely reproduce it. Regardless of the used technique, for a knowledge based system, 3 elements are required: one or more reasoning diagrams, an automated evaluation process and a control diagram. The reasoning diagrams are techniques of facts representation, logical relations, procedural knowledge and uncertainty. For these techniques, uncertainty from the observed data and from the logical relations can be represented using probabilities, fuzzy theory [45, 46], Demspter-Shafer [47] evidence intervals or other methods. Dezert-Smarandache theory [35] comes to extend these methods, providing advanced techniques of uncertainty manipulation. The automated reasoning system's developing purpose is to reproduce the human capability of reasoning and decision making, by specifying rules and frames that define the studied situation. Having at hand an information database, it's required an evaluation process so this information can be used. For this there are formal diagrams developed on the formal logic, fuzzy logic, probabilistic reasoning, template based methods, case based reasoning and many others. Each of these reasoning diagrams has a consistent internal formalism which describes how to use the knowledge database for obtaining the final conclusion. An automated reasoning system needs a control diagram to fulfill the thinking process. The used techniques include searching methods, systems for maintaining the truth based on assumptions and justifications, hierarchical decomposition, control theory, etc. Each of these

methods has the purpose of controlling the reasoning evolution process.

The results presented in this paper, were obtained using the classic Dezert Smarandache Teory (DSMT) to combine inputs from two different observers that want to classify objects into three categories: Sphere, Parallelepiped and Cylinder. These categories were chosen to include most of the objects that a manipulator can grasp. The algorithm's inputs were transformed into belief values of certainty, falsity, uncertainty and contradiction values. Using these four values and their combinations according to DSMT we applied Petri net diagram logic for taking decisions on the shape type of the analysed objects. This type of algorithm has never been used before for real time decision on hand grasping taxonomy. Comparing to other algorithms [13-15] and methods [16-18],

ours has the advantage to detect high uncertainties and contradictions which in practice has a very low encounter rate but can have drastic effects on the decision type or robot, because if the object's shape is not detected properly, then the robot might not be able to grasp it, which can lead to serious consequences. In deciding how to grasp objects, researchers have used different methods to choose the grasping taxonomy using a blind haptic exploration [20] or in different applications for tying knots [21] or grasp deformable objects [23]. Because the proposed algorithm can detect anomalies of contradicting and uncertain input values, we can say that the proposed method transforms the deciding process into a less difficult problem of grasping method [24, 25].

## II. OBJECTS GRASPING AND ITS CLASSIFICATION

Mechanical hands have been developed to provide the robots with the ability of grasping objects with different geometrical and physical properties [48]. To make an anthropomorphic hand seem natural, its movement and the grasping type must match the human hand.

On this regard, grasping position taxonomy for human hands has been long studied and applied for robotic hands. Seventeen different categories of human hands grasping positions were studied. But first we must consider two important things. The first one is that these categories are derived from human hand studies, which proved that they are more flexible and able to perform a multitude of movements than any other robotic hand, so that the grasping taxonomy for robot hands can be only a simple subset of the human hand. Secondly, the human behavior studies of real object grasping, have shown some differences between the real observations and the classified properties [49].

In conclusion, any proposed taxonomy is only a reference point which the robot hand must attain. Below are described the most used grasping positions (extracted from [50]), which should be considered when developing an able robotic hand:

- 1) Power grasping. The contact with the objects is made on large surfaces of the hand, including hand phalanges and the palm of the hand. For this kind of grasping high forces can be exerted on the object.
  - Spherical grasping: used to grasp spherical objects;

- Cylindrical grasping: used to grasp long objects which can't be completely surrounded by the hand;
- Lateral grasping: the thumb exert a force towards the lateral side of the index finger.

- 2) Precision grasping: the contact is made only with the tip of the fingers.
  - Prismatic grasping (pinch): used to grasp long objects (with small diameter) or very small. Can be achieved with two to five fingers.
  - Circular grasping (tripod): used in grasping circular or round objects. Can be achieved with three, four or five fingers.

- 3) No grasping:
  - Hook: the hand forms a hook on the object and the hand force is exerted against an external force, usually gravity.
  - Button pressing or pointing
  - Pushing with open hand.

In the table I, are shown manipulation activities that the robotic hand can achieve, correlated with the required activity grasping positions [51].

## III. OBJECT DETECTION USING STEREO-VISION AND KINECT SENSOR

Object recognition in artificial sight represents the task of searching a certain object in a picture or a video sequence. This problem can be approached as a learning problem. At first, the system is trained with sample images which belong to the target group, the system being taught to spot these among other pictures. Thus, when the system receives new images, it can 'feel' the presence of the searched object/sample/template.

Template matching is a techniques used to sort objects in an image. A model is an image region, and the goal is to find instances of this model in a larger picture. The template matching techniques represent a classic approach for localization problems and object recognition in a picture. These methods are used in applications like object tracking, image compression, stereograms, image segmentation [52], and other specific problems of artificial vision [53]. Object recognition is very important for a robot that must fulfill a certain task. To complete its task, the robot must avoid obstacles, to obtain the size of the object, to manipulate it, etc. For the case of detected object manipulation, the robot must detect the object's shape, size and position in the environment. The main methods for achieving the depth information use stereoscopic cameras, laser scanners and depth cameras. To achieve the proposed decision-making algorithm, we assumed that the environment information is captured with a stereoscopic system and a Kinect sensor.

Stereovision systems [32] represents a passive technique of achieving a virtual 3D image of the environment in which the robot moves, by matching the common features of an image set of the same scene. Because this method works with images, it needs a high computational power. The depth information can be noisy in certain cases, because the method depends

TABLE I: Grasping position for certain tasks.

Object	Activity	Grasping position
Bottles, cups and mugs	Transport Pouring/ filling	Force: Cylindrical grasping (from the side or the top)
Cups (using handles)	Pouring/filling	Force: Lateral grasping Precision: Prismatic grasping
Plates/trays	Transport Receiving from humans	Power: Lateral grasping Precision: Prismatic grasping No grasp: pushing (open hand)
Pens, cutlery	Transport	Precision: Prismatic grasping
Door handle	Open/Close	Force: Cylindrical grasping No grasp: Hook
Small objects	Transport	Power: Spherical grasping Precision: Circular grasping (tripod)
Switches, buttons	Pushing	No grasp: Button pressing
Round switches, bottle caps	Rotation	Force: Lateral grasping Precision: Circular grasping (tripod)

on the texture of the environment objects and on the ambient light.

Kinect [33] is a fairly easy to obtain platform, which makes it widespread. It uses a depth sensor based on structured light. By using an ASIC board, the Kinect sensor generates a depth map on 11 bits with a resolution of  $640 \times 480$  pixels, at 30Hz. Given the price of the device, the information quality is pretty good, but it has both advantages and disadvantages, meaning that the depth images contain areas where the depth reading couldn't be achieved. This problem appears from the fact that some materials don't reflex infrared light. When the device is moved really fast, like any other camera, it records blurry pictures, which also lead to missing information from the acquired picture.

#### IV. NEUTROSOPHIC LOGIC AND DSM THEORY

##### A. Neutrosophic Logic

The neutrosophic triplet (truth, falsity and uncertainty) idea appeared in 1764 when J.H. Lambert investigates a witness credibility which was affected by the testimony of another person. He generalized Hooper's rule of sample combination (1680), which was a Non-Bayesian approach for finding a probabilistic model. Koopman in 1940 introduces the low and high probability, followed by Good and Dempster (1967) who gave a combination rule of two arguments. Shafer (1976) extended this rule to Dempster-Shafer Theory for Trust Functions by defining the Trust and Plausibility functions and using the inference rules of Dempster for combining two samples from two different sources. The trust function is a connection between the fuzzy reasoning and probability. Dempster-Shafer theory for Trust functions is a generalization of Bayesian Probability (Bayes 1760, Laplace 1780). It uses the mathematical probability in a more general way and it is based on the probabilistic combination of artificial intelligence samples. Lambert one said that "there is a chance  $p$  that the witness can be trustworthy and fair, a chance  $q$  that he will be deceiving and a chance  $1 - p - q$  that he will be indifferent". This idea was taken by Shafer in 1986 and later, used by Smarandache to further develop the neutrosophic logic [54, 55].

1) *Neutrosophic Logic Definition:* A logic in which each proposition has its percentage of truth in a subset  $T$ , its percentage of uncertainty in a subset  $I$  and its percentage of falsity in a subset  $F$  is called neutrosophic logic [54,55]. This paper extends the general structure of the Neutrosophic Robot Control (RNC), known as the Vlădăreanu–Smarandache method [55]–[57] for the robot hybrid force-position control in a virtual platform [58,59], which applies neutrosophic science to robotics using the neutrosophic logic and set operators. Thus, using two observers, a stereovision system and a Kinect sensor, will provide 3 matching values for DSMT decision-making algorithms. A subset of truth, uncertainty and falsity is used instead of a single number because in many cases one cannot know with precision the percentage of truth or falsity. But these can be approximated. For example, a supposition can be 30% to 40% true and 60% to 70% false [60].

2) *Neutrosophic components definition:* Let  $T, I, F$  be three standard or non-standard subsets of  $]^{-0}, 1^{+}[$  with

$$\begin{aligned} \sup T &= t_{sup} & \inf T &= t_{inf}, \\ \sup I &= i_{sup} & \inf I &= i_{inf}, \\ \sup F &= f_{sup} & \inf F &= f_{inf}, \end{aligned}$$

and

$$\begin{aligned} n_{sup} &= t_{sup} + i_{sup} + f_{sup} \\ n_{inf} &= t_{inf} + i_{inf} + f_{inf} \end{aligned}$$

The  $T, I, F$  sets are not always intervals, but can be subsets: discrete or continuum; with a single element; finite or infinite (the elements are countable or uncountable); subsets union or intersection. Also, these subsets can overlap, and the real subsets represent the relative errors in finding the  $t, i, f$  values (when the  $T, I, F$  subsets are reduced to single points).

$T, I, F$  are called the neutrosophic components and represents the truth, uncertainty and falsity values, when referring to neutrosophy, neutrosophic logic, neutrosophic sets, neutrosophic probability or neutrosophic statistics. This representation is closer to the human reasoning and defines knowledge imprecision or linguistic inaccuracy received from different

observers (this is why  $T, I, F$  are subsets and can be more than a set of points), the uncertainty given by incomplete knowledge or data acquisition errors (for this we have the set  $I$ ) and the vagueness caused by missing edges or limits.

After defining the sets, we need to specify their superior ( $x_{sup}$ ) and inferior ( $x_{inf}$ ) limits because in most of the cases they will be needed [61,62].

3) *Dezert-Smarandache Theory (DSMT)*: To develop artificial cognitive systems a good management of sensor information is required. When the input data are gathered by different sensors, according to the environment certain situations may appear when one of the sensors cannot give correct information or the information is contradictory between sensors. To resolve this issue a strong mathematical model is required, especially when the information is inaccurate or uncertain.

The Dezert-Smarandache Theory (DSMT) [53,54,60] can be considered an extension of Dempster-Shafer theory (DST) [46]. DSMT allows information combining, gathered from different and independent sources as trust functions. DSMT can be used for solving information fusion on static or dynamic complex problems, especially when the information differences between the observers are very high.

DSMT starts by defining the notion of *DSM free model*, denoted by  $\mathcal{M}^f(\Theta)$  and says that  $\Theta$  is a set of exhaustive elements  $\theta_i, i = 1, \dots, n$  which cannot overlap. This model is free because there are no other suppositions over the hypothesis. As long as the DSM free model is fulfilled, we can apply the associative and commutative DSM rule of combination.

DSM theory [62] is based on defining the Dedekind lattice, known as the *hyper power set* of frame  $\Theta$ . In DSMT,  $\Theta$  is considered a set  $\{\theta_1, \dots, \theta_n\}$  of  $n$  exhaustive elements, without adding other constraints. DSMT can tackle information samples, gathered from different information sources which don't allow the same interpretation of the set  $\Theta$  elements. Let  $\Theta = \{\theta_1, \theta_2\}$  be the simple case, made of two assumptions, then [54]:

- the probability theory works (assuming exclusivity and completeness assumptions) with basic probability assignments (bpa)  $m(\cdot) \in [0, 1]$  such that

$$m(\theta_1) + m(\theta_2) = 1$$

- the Dempster-Shafer theory works, (assuming exclusivity and completeness assumptions) with basic belief assignments (bba)  $m(\cdot) \in [0, 1]$  such that

$$m(\theta_1) + m(\theta_2) + m(\theta_1 \cup \theta_2) = 1$$

- the DSM theory works (assuming exclusivity and completeness assumptions) with basic belief assignment (bba)  $m(\cdot) \in [0, 1]$  such that

$$m(\theta_1) + m(\theta_2) + m(\theta_1 \cup \theta_2) + m(\theta_1 \cap \theta_2) = 1$$

**The  $D^\Theta$  hyperpower set notion**

One of the base elements of DSM theory is the notion of hyper power set. Let  $\Theta = \{\theta_1, \dots, \theta_n\}$  be a finite set (called

frame) with  $n$  exhaustive elements. The Dedekind lattice, called hyper power set  $D$  within DSMT frame, is defined as the set of all built statements from the elements of set  $\Theta$  with the  $\cup$  and  $\cap$  operators such that:

- 1)  $\emptyset, \theta_1, \dots, \theta_n \in D^\Theta$ ;
- 2) If  $A, B \in D^\Theta$ , then  $A \cap B \in D^\Theta$  and  $A \cup B \in D^\Theta$ ;
- 3) No other element is included in  $D^\Theta$  with the exception of those mentioned at 1 and 2.

$D^\Theta$  dual's (obtained by changing within expressions the operator  $\cap$  with the operator  $\cup$ ) is  $D^\Theta$ . In  $D^\Theta$  there are elements that are dual with themselves. The cardinality of  $D^\Theta$  increases with  $2^n$  when the cardinality of  $\Theta$  is  $n$ . Generating the  $D^\Theta$  hyper power set is close connected with the Dedekind [54,55] known problem of isotone Boolean function set. Because for any finite set  $\theta, |D^\Theta| \geq |2^\Theta|$ ,  $D^\Theta$  is called the hyper power set of  $\Theta$ .

The  $\theta_i, i = 1, \dots, n$  elements from  $\Theta$  form the finite set of suppositions/concepts that characterize the fusion problem.  $D^\Theta$  represents the free model of DSM  $\mathcal{M}^f(\Theta)$  and allows working with fuzzy concepts that describe the intrinsic and relative character. This kind of concepts cannot be accurately distinguished within an absolute interpretation because of the unapproachable universal truth.

With all of this, there are certain particular fusion problems that imply discrete concepts, where the  $\theta_i$  elements are exclusively true. In this case, all the exclusivity constraints of  $\theta_i, i = 1, \dots, n$  must be included in the previous model, to properly characterize the truthiness character of the fusion problem and to match reality. For this, the hyper power set  $D^\Theta$  is decreased to the classic power set  $2^\Theta$  forming the smallest hybrid DSM model, noted with  $\mathcal{M}^0(\Theta)$ , and coincide with Shafer's model.

Besides the problem types that correspond with the Shafer's model  $\mathcal{M}^0(\Theta)$  and those that correspond with the DSM free model  $\mathcal{M}^f(\Theta)$ , there is an extensive class of fusion problems that include in  $\Theta$  states, continuous fuzzy concepts and discrete hypothesis. In this case we must take into consideration certain exclusivity constraints and some non-existential constraints. Each fusion hybrid problem is described by a DSM hybrid model  $\mathcal{M}(\Theta)$  with  $\mathcal{M}(\Theta) \neq \mathcal{M}^f(\Theta)$  and  $\mathcal{M}(\Theta) \neq \mathcal{M}^0(\Theta)$ .

**The generalized belief functions**

Starting from a general frame  $\Theta$ , we define a  $D^\Theta \rightarrow [0, 1]$  transformation associated with an information source  $\mathcal{B}$  like [54]:

$$m(\emptyset) = 0, \text{ and } \sum_{A \in D^\Theta} m(A) = 1. \tag{1}$$

The  $m(A)$  value is called *generalized basic belief assignment* of  $A$ .

The generalized trust and plausibility are defined in the same way as in Dempster-Shafer theory [47]:

$$Bel(A) = \sum_{\substack{BA \\ B \in D^\Theta}} m(B), \tag{2}$$

$$Pl(A) = \sum_{\substack{B \cap A \neq \emptyset \\ B \in D^\Theta}} m(B). \quad (3)$$

These definitions are compatible with the classic trust function definition from the Dempster-Shafer theory when  $D^\Theta$  is reduced to  $2^\Theta$  for fusion problems where the Shafer model  $\mathcal{M}^0(\Theta)$  can be applied. We're still having for all  $A \in D^\Theta$ ,  $Bel(A) \leq Pl(A)$ . To notice that when we work with the free DSm  $\mathcal{M}^f(\Theta)$  model, we will always have  $Pl(A) = 1$ ,  $\forall A \neq \emptyset \in D^\Theta$ , which is normal [54].

### The DSm classic rule of combination

When the DSm free model  $\mathcal{M}^f(\Theta)$  can be applied, the combination rule  $m_{M^f(\Theta)} \equiv m(\cdot) \triangleq [m_1 \otimes m_2](\cdot)$  of two independent sources  $\mathcal{B}_1$  and  $\mathcal{B}_2$  that provide information on the same frame  $\Theta$  with the belief functions  $Bel_1(\cdot)$  and  $Bel_2(\cdot)$  associated to gbbas  $m_1(\cdot)$  and  $m_2(\cdot)$  correspond to the conjunctive consensus of sources. Data combinations are done by using the formula [54]:

$$\forall C \in D^\Theta, m_{M^f(\Theta)}(C) = m(C) = \sum_{\substack{A, B \in D^\Theta \\ A \cap B = C}} m_1(A)m_2(B). \quad (4)$$

Because  $D^\Theta$  is closed under  $\cap$  and  $\cup$  operators, this new combination rule guarantees that  $m(\cdot)$  is a generalized trust value, meaning that  $m(\cdot) : D^\Theta \rightarrow [0, 1]$ . This rule of combination is commutative and associative and can be used all the time for sources fusion which implies fuzzy concepts. This rule can be extended with ease for combining  $k > 2$  independent information sources [55,56].

Because of the high number of elements in  $D^\Theta$ , when the cardinality of  $\Theta$  increases, the need of computational resources also increases for processing the DSm combination rule. This observation is true only if the core (the set of generalized basic belief assignment for the needed elements)  $\mathcal{K}_1(m_1)$  and  $\mathcal{K}_2(m_2)$  coincide with  $D^\Theta$ , meaning that when  $m_1(A) > 0$  and  $m_2(A) > 0$  for any  $A \neq \emptyset \in D^\Theta$ . For the most practical applications, the  $\mathcal{K}_1(m_1)$  and  $\mathcal{K}_2(m_2)$  dimensions are much smaller than  $|D^\Theta|$  because the information sources provide most of the time the generalized basic belief assignment for only one subset of hyper power set. This facilitates the DSm classic rule implementation.

Figure 1 presents the DSm combination rule architecture. The first layer is formed by all the generalized basic belief assignment values of the needed elements  $A_i, i = 1, \dots, n$  of  $m_1(\cdot)$ . The second layer is made out of all the generalized basic belief assignment values  $B_j, j = 1, \dots, k$  of  $m_2(\cdot)$ . Each node from the first layer is connected with each node of the second layer. The output layer is created by combining the generalized basic belief assignment values of all the possible intersections  $A_i \cap B_j, i = 1, \dots, n$  and  $j = 1, \dots, k$ . If we would have a third source to provide generalized basic belief assignment values  $m_3(\cdot)$ , this would have been combined by placing it between the output layer and the second one that provides the generalized basic belief assignment values  $m_2(\cdot)$ . Due to the commutative and associative properties of DSm

classic rule of combination, in developing the DSm network, a particular order of layers is not required [54].

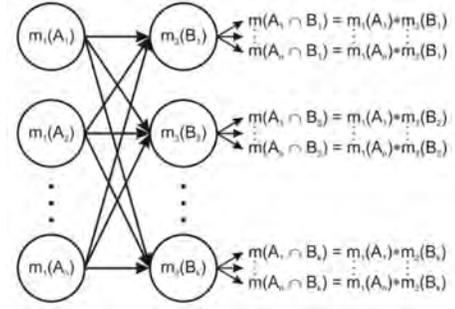

Fig. 1: Graphical representation of DSm classic rule of combination for  $M^f(\Theta)$  [35].

### V. DECISION-MAKING ALGORITHM

As observed in this paper, according to the object shape and assigned task, grasping is divided into 8 categories [63]: spherical grasping, cylindrical grasping, lateral grasp, prismatic grasp, circular grasping, hook grasping, button pressing and pushing. From these grasping types, the most used ones are cylindrical and prismatic grasping (see table I). These can be used in almost any situation and we can say that spherical grasping is a particular grasping of these two. The spherical grasp is used for power grasping, when the contact with the object is achieved with all the fingers' phalanges and the hand's palm. This is why a requirement for classification by the shape of the object is needed. Due to the fact that these types are more often encountered, they were taken into consideration for the studied fusion problems.

The fusion problem aims to achieve a classification, by shape of objects to grasp, so that these can match with the other three types of grasping studied. The target objects are classified into three categories: sphere, parallelepiped and cylinder. For each category, a grasping type is assigned [56].

Following the presented theory in section IV, the information is provided by two independent sources (observers): a stereovision system and a Kinect sensor. The observers are presented in section III, and are used to scan the robot's work environment. By using the information provided by the two observers, a 3D virtual image of the environment is achieved, from which the human operator chooses the object to be grasped, thus defining the grasping task that must be achieved by the robot. The 3D image of the object, isolated from the scene, is compared with three templates, formed by similar methods, which represents a sphere, a parallelepiped and a cylinder. Afterwards, a template matching algorithm is applied to place the object in one of the three categories, with a certain matching percentage. This percentage can vary according to the conditions in which the images are obtained (weak light, object from which the light is reflected, etc.). The data taken from each sensor are then individual processed

with a neutrosophication algorithm, with the purpose of obtaining the generalized basic belief assignment values for each hypothesis that can characterize the system. In the next step, having the basic belief assignment values, we combine the data provided by the two observers by using the classic DSMT rule of combination. The next step is to apply a de-neutrosophication algorithm on the obtained values, to achieve the decision on the shape of the object by placing it into the three categories mentioned above. The entire process is graphical represented in figure 2.

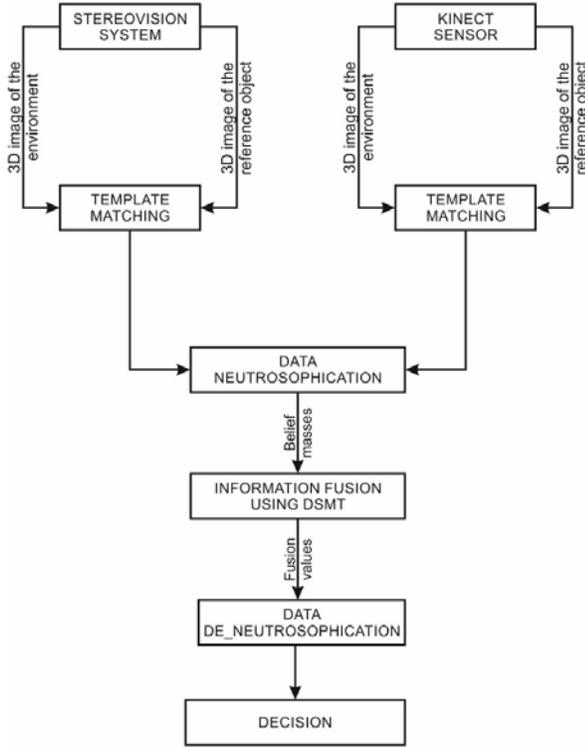

Fig. 2: Diagram of the proposed algorithm.

#### A. Data neutrosophication

Each observer provides a truth percentage for each system's state. The state set  $\Theta = \{\theta_1, \theta_2, \theta_3\}$  that characterizes the fusion problem is:

$$\Theta = \{Sp, Pa, Cy\}, \quad (5)$$

where  $Sp$  = Sphere,  $Pa$  = Parallelepiped and  $Cy$  = Cylinder.

To compute the belief values for the hyper power set  $D^\Theta$  elements we developed an algorithm based on the neutrosophic logic. The hyper power set  $D^\Theta$  is formed by using the method presented in the paragraph devoted to the  $D^\Theta$  hyperpower set notion, and has the form:

$$\begin{aligned} D^\Theta = \{ & \emptyset, Sp, Pa, Cy, Sp \cup Pa, Sp \cup Cy, Cy \cup Pa, \\ & Sp \cap Pa, Sp \cap Cy, Cy \cap Pa, Sp \cap (Cy \cup Pa), \\ & Cy \cap (Sp \cup Pa), Pa \cap (Cy \cup Sp), \\ & Sp \cup Cy \cup Pa, Sp \cap Cy \cap Pa \}. \end{aligned} \quad (6)$$

The statements of each observer are handled in ways of truth ( $T$ ), uncertainty ( $I$ ) and falsity ( $F$ ), specific to the neutrosophic logic. Due to the fact that  $F = 1 - T - I$ , the statements of falsity are not taken into consideration.

The neutrosophic algorithm has as input the certainty probabilities (truth) provided by the observers on the system's states. These probabilities are then processed using the described rules in figure 3. If the difference between the certainties probabilities used at a certain point by the processing algorithm is larger than a certain threshold found by trial and error, then we'll consider that the uncertainty percentage between the compared states is null, and the probability that one of the states is true increases. In the case where this difference is not a set threshold, we compute the uncertainty probability by using the formula

$$m(A \cup B) = 1 - \frac{m(A) - m(B)}{const}, \quad (7)$$

where  $A, B \in \Theta$ , and "const" depends of the chosen threshold. While the point determined by the two probabilities approaches the main diagonal, the uncertainty approaches the maximum probability value.

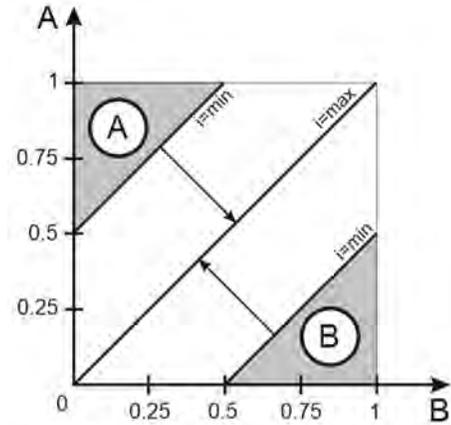

Fig. 3: Data neutrosophication rule for the observer's data.

From the hyper power set  $D^\Theta$ , we can determine the belief masses only for the values  $Obs_i(D^\Theta)$  (information obtained after observer's data interpretation) presented below, because the intersection operation  $\cap$  represents contradiction in DSM theory and we cannot compute the contradiction values for a single observer using:

$$\begin{aligned} Obs_i(D^\Theta) = \{ & Sp, Pa, Cy, Sp \cup Pa, Sp \cup Cy, \\ & Cy \cup Pa, Sp \cap Cy \cup Pa \}. \end{aligned} \quad (8)$$

The neutrosophic probabilities are detailed in Table II.

#### B. Information fusion

Having known the trust values of the hyper power set elements  $Obs_i(D^\Theta)$ , presented in table II, we apply the fusion algorithm, using the classic DSM combination rule described previously.

TABLE II: Grasping position for certain tasks.

Mathematical representation	Description
$Sp$	Certainty that the target object is a 'sphere'
$Pa$	Certainty that the target object is a 'parallelepiped'
$Cy$	Certainty that the target object is a 'cylinder'
$Sp \cup Pa$	Uncertainty that the target object is a 'sphere' or 'parallelepiped'
$Sp \cup Cy$	Uncertainty that the target object is a 'sphere' or 'cylinder'
$Cy \cup Pa$	Uncertainty that the target object is a 'cylinder' or 'parallelepiped'
$Sp \cup Cy \cup Pa$	Uncertainty that the target object is a 'sphere', 'cylinder' or 'parallelepiped'

TABLE III: Contradictions that may appear between the neutrosophic probabilities.

Mathematical representation	Description
$Sp \cap Pa$	Contradiction between the certainties that the target object is a 'sphere' and 'parallelepiped'
$Sp \cap Cy$	Contradiction between the certainties that the target object is a 'sphere' and 'cylinder'
$Cy \cap Pa$	Contradiction between the certainties that the target object is a 'cylinder' and 'parallelepiped'
$Sp \cap (Cy \cup Pa)$	Contradiction between the certainty that the target object is a 'sphere' and the uncertainty that the target object is a 'cylinder' or 'parallelepiped'
$Pa \cap (Sp \cup Cy)$	Contradiction between the certainty that the target object is a 'parallelepiped' and the uncertainty that the target object is a 'sphere' or 'cylinder'
$Cy \cap (Pa \cup Sp)$	Contradiction between the certainty that the target object is a 'cylinder' and the uncertainty that the target object is a 'parallelepiped' or 'sphere'
$Sp \cap Cy \cap Pa$	Contradiction between the certainties that the target object is a 'sphere' and 'cylinder', and 'parallelepiped'

Applying equation (4), we get the following formulas for the combination values:

$$\begin{aligned}
 m(Sp) = & m_1(Sp)m_2(Sp) + m_1(Sp)m_2(Sp \cup Pa) \\
 & + m_1(Sp \cup Pa)m_2(Sp) + m_1(Sp)m_2(Sp \cup Cy) \\
 & + m_1(Sp \cup Cy)m_2(Sp) \\
 & + m_1(Sp)m_2(Sp \cup Cy \cup Pa) \quad (9) \\
 & + m_1(Sp \cup Cy \cup Pa)m_2(Sp) \\
 & + m_1(Sp \cup Pa)m_2(Sp \cup Cy) \\
 & + m_1(Sp \cup Cy)m_2(Sp \cup Pa),
 \end{aligned}$$

$$\begin{aligned}
 m(Pa) = & m_1(Pa)m_2(Pa) + m_1(Pa)m_2(Sp \cup Pa) \\
 & + m_1(Sp \cup Pa)m_2(Pa) + m_1(Pa)m_2(Cy \cup Pa) \\
 & + m_1(Cy \cup Pa)m_2(Sp) \\
 & + m_1(Pa)m_2(Sp \cup Cy \cup Pa) \quad (10) \\
 & + m_1(Sp \cup Cy \cup Pa)m_2(Pa) \\
 & + m_1(Sp \cup Pa)m_2(Cy \cup Pa) \\
 & + m_1(Cy \cup Pa)m_2(Sp \cup Pa),
 \end{aligned}$$

$$\begin{aligned}
 m(Cy) = & m_1(Cy)m_2(Cy) + m_1(Cy)m_2(Cy \cup Pa) \\
 & + m_1(Cy \cup Pa)m_2(Cy) + m_1(Cy)m_2(Sp \cup Cy) \\
 & + m_1(Sp \cup Cy)m_2(Cy) \\
 & + m_1(Cy)m_2(Sp \cup Cy \cup Pa) \quad (11) \\
 & + m_1(Sp \cup Cy \cup Pa)m_2(Cy) \\
 & + m_1(Sp \cup Cy)m_2(Cy \cup Pa) \\
 & + m_1(Cy \cup Pa)m_2(Sp \cup Cy)
 \end{aligned}$$

$$\begin{aligned}
 m(Sp \cup Pa) = & m_1(Sp \cup Pa)m_2(Sp \cup Pa) \\
 & + m_1(Sp \cup Pa)m_2(Sp \cup Cy \cup Pa) \quad (12) \\
 & + m_1(Sp \cup Cy \cup Pa)m_2(Sp \cup Pa)
 \end{aligned}$$

$$\begin{aligned}
 m(Sp \cup Cy) = & m_1(Sp \cup Cy)m_2(Sp \cup Cy) \\
 & + m_1(Sp \cup Cy)m_2(Sp \cup Cy \cup Pa) \quad (13) \\
 & + m_1(Sp \cup Cy \cup Pa)m_2(Sp \cup Cy)
 \end{aligned}$$

$$\begin{aligned}
 m(Cy \cup Pa) = & m_1(Cy \cup Pa)m_2(Cy \cup Pa) \\
 & + m_1(Cy \cup Pa)m_2(Sp \cup Cy \cup Pa) \quad (14) \\
 & + m_1(Sp \cup Cy \cup Pa)m_2(Cy \cup Pa)
 \end{aligned}$$

$$m(Sp \cup Cy \cup Pa) = m_1(Sp \cup Cy \cup Pa)m_2(Sp \cup Cy \cup Pa) \quad (15)$$

During the fusion process, between the information provided by the two observers contradiction situations may appear. These are included in the hyper power set  $D^\ominus$  and are described in table III.

Fusion values for contradiction are determined as following:

$$m(Sp \cap Pa) = m_1(Sp)m_2(Pa) + m_1(Pa)m_2(Sp) \quad (16)$$

$$m(Sp \cap Cy) = m_1(Sp)m_2(Cy) + m_1(Cy)m_2(Sp) \quad (17)$$

$$m(Cy \cap Pa) = m_1(Cy)m_2(Pa) + m_1(Pa)m_2(Cy) \quad (18)$$

$$\begin{aligned}
 m(Sp \cap (Cy \cup Pa)) = & m_1(Sp)m_2(Cy \cup Pa) \\
 & + m_1(Cy \cup Pa)m_2(Sp) \quad (19)
 \end{aligned}$$

$$\begin{aligned}
 m(Pa \cap (Sp \cup Cy)) = & m_1(Pa)m_2(Sp \cup Cy) \\
 & + m_1(Sp \cup Cy)m_2(Pa) \quad (20)
 \end{aligned}$$

$$\begin{aligned}
 m(Cy \cap (Sp \cup Pa)) = & m_1(Cy)m_2(Sp \cup Pa) \\
 & + m_1(Sp \cup Pa)m_2(Cy) \quad (21)
 \end{aligned}$$

C. Data de-neutrosophication and decision-making

The combination values found in the previous section are de-neutrosophicated using the logic diagram presented in figure 4. For the decision-making algorithm we opted to use Petri nets [64], for it's easier to notice the system's states transitions.

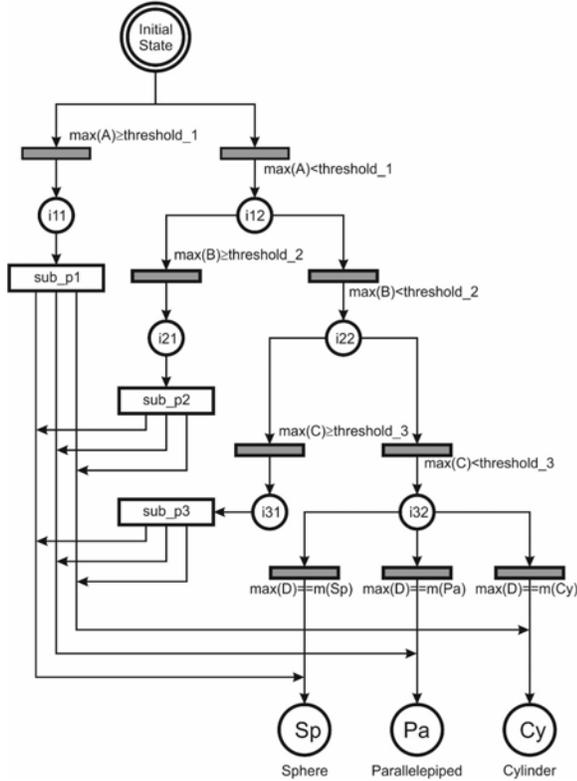

Fig. 4: Petri diagram for decision-making algorithm.

The decision-making diagram proved to have a certain difficulty level, which required adding three sub diagrams:

1) **sub\_p1** (figure 5) – this sub diagram deals with the contradiction between:

- the certainty probability that the target object is a 'sphere' and the uncertainty probability that the target object is either a 'parallelepiped' or a 'cylinder';
- the certainty probability that the target object is a 'cu parallelepiped be' and the uncertainty probability that the target object is either a 'sphere' or a 'cylinder';
- the certainty probability that the target object is a 'cylinder' and the uncertainty probability that the target object is either a 'parallelepiped' or a 'sphere'.

2) **sub\_p2** (figure 6) – this sub diagram deals with the contradiction between:

- The certainty probability that the target object is a 'sphere' and a 'parallelepiped';
- The certainty probability that the target object is a 'sphere' and a 'cylinder';

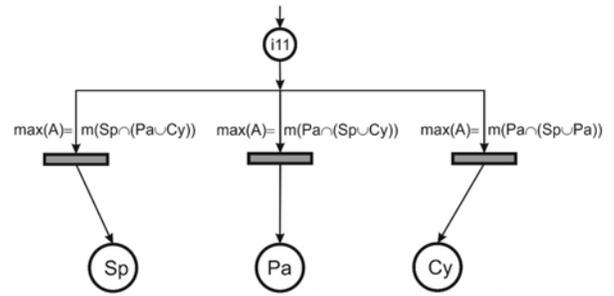

Fig. 5: Petri net for sub\_p1.

- The certainty probability that the target object is a 'cylinder' and a 'parallelepiped'.

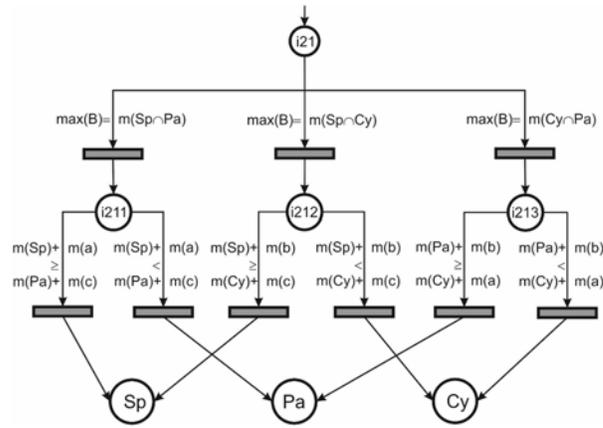

Fig. 6: Petri net for sub\_p2.

3) **sub\_p3** (figure 7) – this sub diagram deals with the uncertainty that the target object is:

- a 'sphere' or a 'parallelepiped';
- a 'sphere' or a 'cylinder';
- a 'cylinder' or a 'parallelepiped'.

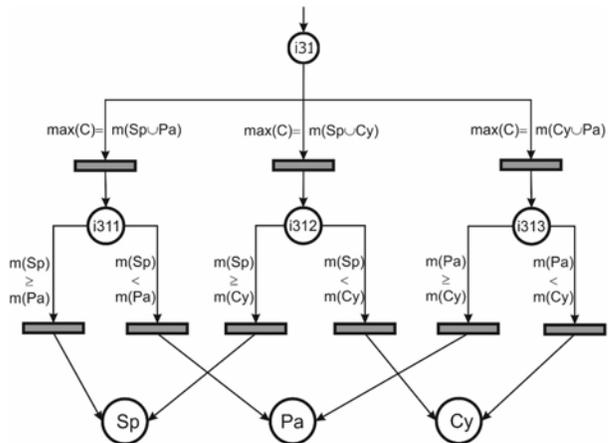

Fig. 7: Petri net for sub\_p3.

To not overload figures 4–7 we have used the following notations:

$$A = \{m(Sp \cap (Cy \cup Pa)), m(Pa(SpCy)), m(Cy \cap (Pa \cup Sp))\},$$

$$B = \{m(Sp \cap Pa), m(Sp \cap Cy), m(Cy \cap Pa)\},$$

$$C = \{m(Sp \cup Pa), m(Sp \cup Cy), m(Cy \cup Pa)\},$$

$$D = \{m(Sp), m(Pa), m(Cy)\},$$

$$a = m(Sp \cup Cy),$$

$$b = m(Pa \cup Sp),$$

$$c = m(Cy \cup Pa).$$

With the help of the Petri diagram (figure 4), we take the decision of sorting the target object in one of the three categories, as follows:

1) Determine

$$m^{\max} \triangleq \max(m(Sp \cap (CyPa)), m(Pa \cap (SpCy)), m(Cy \cap (PaSp))).$$

- If  $m^{\max} = m(Sp \cap (Cy \cup Pa))$ , the contradiction between the certainty value that the target object is ‘sphere’ and the uncertainty value that the target object is ‘cylinder’ or ‘parallelepiped’ is compared with a threshold determined through an experimental trial-error process. If this is higher or equal with the chosen threshold, the target object is a ‘sphere’.
- If  $m^{\max} = m(Pa \cap (Sp \cup Cy))$ , the contradiction between the certainty value that the target object is ‘parallelepiped’ and the uncertainty value that the target object is ‘sphere’ or ‘cylinder’ is compared with the threshold mentioned above. If this is higher or equal with the chosen threshold, the target object is a ‘parallelepiped’.
- If  $m^{\max} = m(Cy \cap (Pa \cup Sp))$ , the contradiction between the certainty value that the target object is ‘cylinder’ and the uncertainty value that the target object is ‘parallelepiped’ or ‘sphere’ is compared with the threshold mentioned above. If this is higher or equal with the chosen threshold, the target object is a ‘cylinder’.

If none of the three conditions are met, we proceed to the next step:

2) Determine

$$m^{\max} \triangleq \max(m(Sp \cap Pa), m(Sp \cap Cy), m(Cy \cap Pa)).$$

- If  $m^{\max} = m(Sp \cap Pa)$ , the contradiction between the certainty values that the target object is ‘sphere’ and ‘parallelepiped’ is compared with a threshold determined through an experimental trial-error process. If this is higher or equal with the chosen threshold, we check if  $m(Sp) + m(Sp \cup Cy) > m(Pa) + m(Cy \cup Pa)$ . If this condition is fulfilled, then the target objects is ‘sphere’. Otherwise, the target object is ‘parallelepiped’.

- If  $m^{\max} = m(Sp \cap Cy)$ , the contradiction between the certainty values that the target object is ‘sphere’ and ‘cylinder’ is compared with the threshold mentioned above. If this is higher or equal with the chosen threshold, we check if  $(Sp) + m(Sp \cup Pa) > m(Cy) + m(Cy \cup Pa)$ . If this condition is fulfilled, then the target objects is ‘sphere’. Otherwise, the target object is ‘cylinder’.
- If  $m^{\max} = m(Cy \cap Pa)$ , the contradiction between the certainty values that the target object is ‘cylinder’ and ‘parallelepiped’ is compared with the threshold mentioned above. If this is higher or equal with the chosen threshold, we check if  $m(Cy) + m(Sp \cup Cy) > m(Pa) + m(Sp \cup Pa)$ . If this condition is fulfilled, then the target objects is ‘cylinder’. Otherwise, the target object is ‘parallelepiped’.

If in none of the situations, the contradiction is not larger than the chosen threshold, we go to the next step:

3) Determine

$$m^{\max} \triangleq \max(m(Sp \cup Pa), m(Sp \cup Cy), m(Cy \cup Pa)).$$

- If  $m^{\max} = m(Sp \cup Pa)$ , the uncertainty probability that the target object is ‘sphere’ or ‘parallelepiped’ is larger than a threshold determined through an experimental trial-error process, we check if  $m(Sp) > m(Pa)$ . If the condition is fulfilled, the target object is ‘sphere’. Otherwise, the target object is ‘parallelepiped’.
- If  $m^{\max} = m(Sp \cup Cy)$ , the uncertainty probability that the target object is ‘sphere’ or ‘cylinder’ is larger than the threshold mentioned above, we check if  $m(Sp) > m(Cy)$ . If the condition is fulfilled, the target object is ‘sphere’. Otherwise, the target object is ‘cylinder’.
- If  $m^{\max} = m(Cy \cup Pa)$ , the uncertainty probability that the target object is ‘cylinder’ or ‘parallelepiped’ is larger than the threshold mentioned above, we check if  $m(Cy) > m(Pa)$ . If the condition is fulfilled, the target object is ‘cylinder’. Otherwise, the target object is ‘parallelepiped’.

If none of the hypotheses mentioned above are not fulfilled, we go to the next step:

4) Determine

$$m^{\max} \triangleq \max(m(Sp), m(Pa), m(Cy)).$$

- If  $m^{\max} = m(Sp)$ , the target object is a ‘sphere’.
- If  $m^{\max} = m(Pa)$ , the target object is a ‘parallelepiped’.
- If  $m^{\max} = m(Cy)$ , the target object is a ‘cylinder’.

## VI. DISCUSSION

As mentioned in the introduction chapter, the main goal of this paper is to find a way to grasp objects according to their shape. This is done by classifying the target objects into three main classes: sphere, parallelepiped and cylinder. To determine the shape of the target objects, the robot work environment was scanned with a stereovision system and a Kinect sensor, with the purpose of creating a 3D image of the surrounding space in which the robot must fulfill its task. From the two created images, the target object is selected and then it is compared with 3 templates, which represents a sphere, a cube and a cylinder. With a template matching algorithm the matching percentage is determined for each of the templates. These percentages (figure 8), represents the data gathered from the observers, for the fusion problem. Because we wanted to test and verify the decision-making algorithm for as many cases as possible, the observers' values were simulated using sine signals with different frequency and amplitude of 1 (figure 8). This amplitude represents the maximum probability percentage that a certain type of object is found by the template matching algorithm.

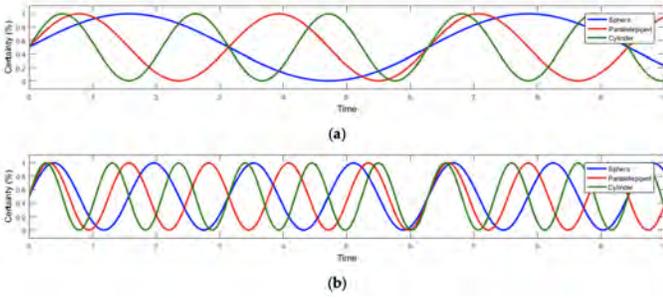

Fig. 8: Simulation of the information provided by the two sensors/observers: (a) first observer detection; (b) second observer detection.

On these input data we then apply a neutrosophication algorithm with the purpose of obtaining the generalized belief assignment values for each of the statements an observer is doing:

- The certainty probability that the object is a 'sphere' (figure 9.a, h)
- The certainty probability that the object is a 'parallelepiped' (figure 9.b, i)
- The certainty probability that the object is a 'cylinder' (figure 9.c, j)
- The uncertainty probability that the object is a 'sphere' or a 'parallelepiped' (figure 9.d, k)
- The uncertainty probability that the object is a 'sphere' or a 'cylinder' (figure 9.e, l)
- The uncertainty probability that the object is a 'cylinder' or a 'parallelepiped' (figure 9.f, m)
- The uncertainty probability that the object is a 'sphere' or a 'cylinder' or a 'parallelepiped' (figure 9.g, n)

After the belief values were computed for each statements of the observers, we go to the data fusion step (figure 10).

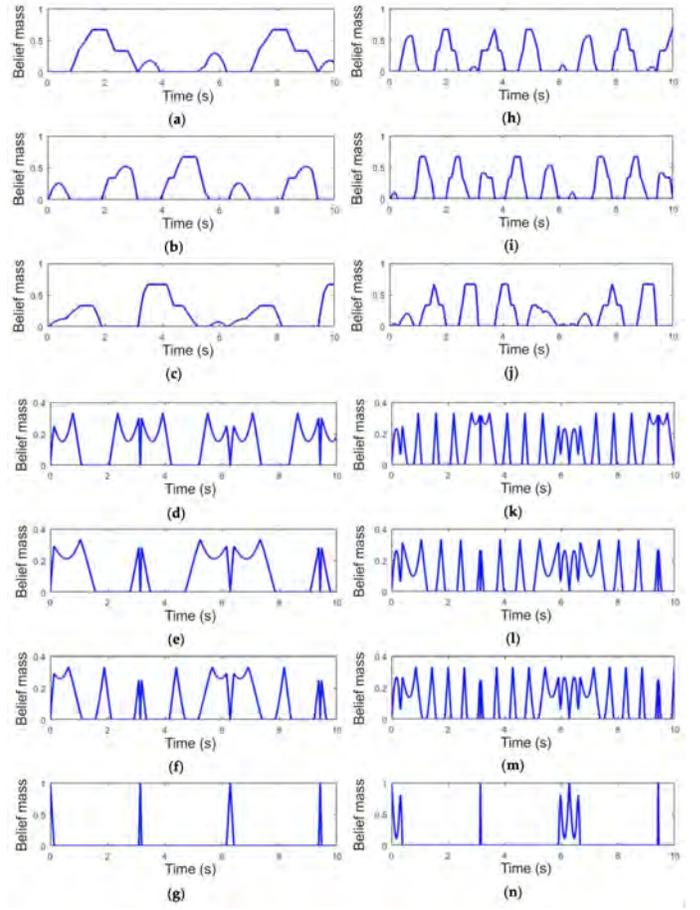

Fig. 9: Generalized trust values. From a to g correspond to observer 1 and from h to n for observer 2 as follows: (a)  $m_1(Sp)$ ; (b)  $m_1(Pa)$ ; (c)  $m_1(Cy)$ ; (d)  $m_1(Sp \cup Pa)$ ; (e)  $m_1(Sp \cup Cy)$ ; (f)  $m_1(Pa \cup Cy)$ ; (g)  $m_1(Sp \cup Pa \cup Cy)$ ; (h)  $m_2(Sp)$ ; (i)  $m_2(Pa)$ ; (j)  $m_2(Cy)$ ; (k)  $m_2(Sp \cup Pa)$ ; (l)  $m_2(Sp \cup Cy)$ ; (m)  $m_2(Pa \cup Cy)$ ; (n)  $m_2(Sp \cup Pa \cup Cy)$ .

With the help of belief values presented in figure 10 and computed using the neutrosophication algorithm described in section V-A, we find the fusion values, presented in figure 11. As one can see in figure 11, the fusion values for certainty, uncertainty and contradiction are minimum. The only exception is the fusion value for the uncertainty that the target object is 'sphere' or 'parallelepiped' or 'cylinder',  $m(Sp \cup Cy \cup Pa)$ , when the data received from the observers are identical and not contradicting, the uncertainty is maximum. This means:

$Obs_1$ : 33.33% sphere, 33.33% parallelepiped, 33.33% cylinder,

and

$Obs_2$ : 33.33% sphere, 33.33% parallelepiped, 33.33% cylinder.

Therefore, the system cannot decide on a single state. This is why the robotic hand will maintain its starting position until the system will decide the target object's category. This indecision period of time takes about 0.07 seconds. When the sensors values about the target object are changed from the

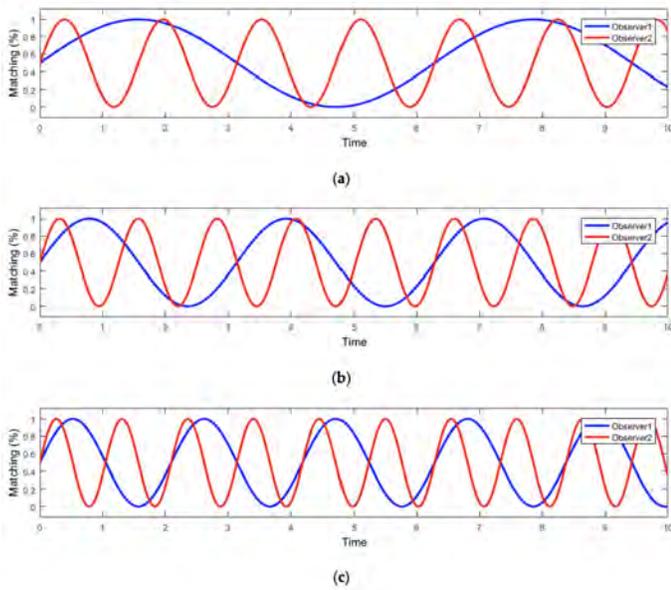

Fig. 10: Data fusion: (a) Observer 1 vs. Observer 2 for Sphere objects; (b) Observer 1 vs. Observer 2 for Parallelepiped objects; (c) Observer 1 vs. Observer 2 for Cylinder objects.

equal values presented above, the algorithm is able to provide a solution.

The indecision also reaches high values at the time 3.14s, 6.28s and 9.42s of the simulation, in the conditions that the observer's statements are close in value with the already presented case from above,

$Obs_1$ : 33.35% sphere, 33.46% parallelepiped, 33.19% cylinder

$Obs_2$ : 33.21% sphere, 33.10% parallelepiped, 33.69% cylinder

for the moment 3.14s,

$Obs_1$ : 33.44% sphere, 33.23% parallelepiped, 33.33% cylinder

$Obs_2$ : 33.44% sphere, 33.23% parallelepiped, 33.33% cylinder

for the moment 6.28s and

$Obs_1$ : 33.39% sphere, 33.70% parallelepiped, 32.91% cylinder

$Obs_2$ : 32.96% sphere, 32.64% parallelepiped, 34.40% cylinder

for the moment 9.42s.

In tables IV, V, and VI we present the percentage of the states' occurrence, the general belief assignment values, the fusion values, and the decision made by the algorithm for the situations previously mentioned.

TABLE IV: Percentages of states' occurrence for each source at different time steps.

state\time	$Obs_1$ 3.14s	$Obs_2$ 3.14s	$Obs_1$ 6.28s	$Obs_2$ 6.28s	$Obs_1$ 9.42s	$Obs_2$ 9.42s
$Sp$	33.35%	33.21%	33.44%	33.44%	33.39%	32.96%
$Pa$	33.46%	33.10%	33.23%	33.23%	33.70%	32.64%
$Cy$	33.19%	33.69%	33.33%	33.33%	32.91%	34.40%

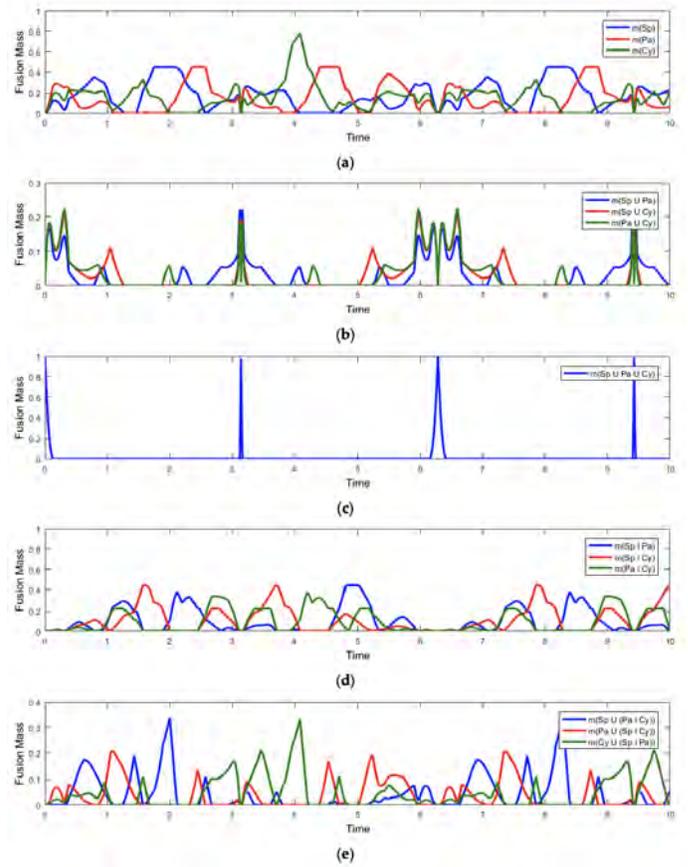

Fig. 11: Fusion values: (a) Fusion values of  $m(Sp)$ ,  $m(Pa)$  and  $m(Cy)$ ; (b) Fusion values of  $m(Sp \cup Pa)$ ,  $m(Sp \cup Cy)$ ,  $m(Pa \cup Cy)$ ; (c) Fusion value of  $m(Sp \cup Pa \cup Cy)$ ; (d) Fusion values of  $m(Sp \cap Pa)$ ,  $m(Sp \cap Cy)$ ,  $m(Pa \cap Cy)$ ; (e) Fusion values of  $m(Sp \cup (Pa \cap Cy))$ ,  $m(Pa \cup (Sp \cap Cy))$ ,  $m(Cy \cup (Sp \cap Pa))$ .

In all three cases, the uncertainty is quite large, and the algorithm ask for restarting the decision process and keeps the decision taken in previous decision process. In our case the decision was that the object is a 'cylinder', 'sphere' and 'cylinder' for the three analyzed points.

Analyzing figure 11(a), at the time of 4.08 seconds the object is decided to be a 'cylinder' because the probability that the target object is a cylinder is very high, but  $m(Cy) = 0.7777$ .

For the time interval of 4.3–4.9 seconds, where in figure 11(d) the contradiction between the target object being a 'sphere' or a 'parallelepiped' is larger than that the target object is a 'sphere' or a 'cylinder' respectively a 'cylinder' or a 'parallelepiped', the object is decided to be a 'parallelepiped' at first because the probability for it being a 'parallelepiped' is larger than the probability of it being a 'sphere' or a 'cylinder'. This situation is changed starting with second 5 of the simulation, when the probability that the target object is a 'sphere' increase, the probability that the same object is a 'cylinder' remains low and the probability that the target

object is a ‘parallelepiped’ decrease below the value of the sphere probability.

Using the fusion values and the decision-making diagram (figure 4), from section V-B, we can sort the desired object into the three categories: sphere, parallelepiped and cylinder. The obtained results are presented in figure 12.

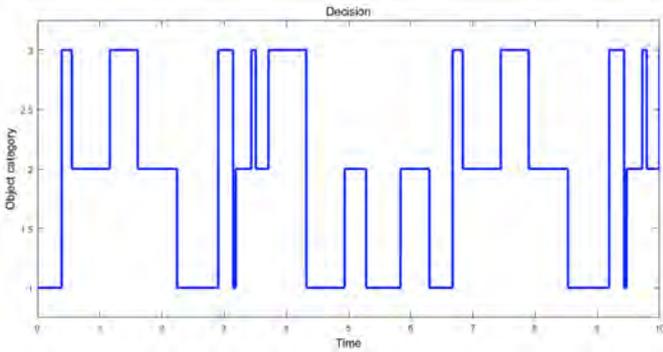

Fig. 12: Object category decision, obtained from the proposed algorithm. Value 1 represents decision for Sphere, value 2 represents decision for Parallelepiped and value 3 represents decision for Cylinder.

## VII. CONCLUSIONS

Any robot, no matter of its purpose, has a task to fulfill. That task can be either of grasping and manipulation or just a transport task. To successfully complete its task, the robot must be equipped with a number of sensors that will provide

enough information about the work environment in which the work is being done.

In this paper we studied the situation in which the robot is equipped with a stereovision system and a Kinect sensor, to detect the environment. The robot’s job was to grab and manipulate certain objects. With the help of two different systems, two 3D images of the environment can be created, each one for the two sensor type. In these images, we isolated the target object and it’s compared with three template images, obtained through similar methods as the environment images. The three template images represent the 3D virtual model of a sphere, a parallelepiped and a cylinder. The comparison is achieved with a template matching method, and following that we obtain a matching percentage for each template tested against the desired image. Because we wanted to develop the decision-making algorithm based on information received from certain template matching methods, we considered as known the information that these algorithms can provide. Moreover, to test different cases, we selected as input for our decision-making algorithm and output for the template matching methods, several sine signals that can provide all the different cases that can occur in practice.

The goal of this paper is in part a data fusion problem with the purpose of classifying the objects in visual range of a humanoid robot, so it can fulfill his grasping and manipulation task. We also wanted to label the target object in one of three categories mentioned above, so that during the approach phase on the target object, the robotic hand can prepare for grasping the object, lowering the time needed to complete the task.

The stereovision system and the Kinect sensor presented in

section III, represent the information sources, called in this paper, the observers, name taken from the neutrosophic logic. These observers specify the state in which the system is. One observer can specify 7 states for the searched object.

With the help of neutrosophic logic, we determine the generalized belief values for each of the 7 states. The neutrosophic algorithm is applied to information gathered from both of the sensors. We have chosen the neutrosophic logic, because it extends fuzzy logic, providing instruments for approaching also the uncertainty situations besides the truth and falsity ones.

Using these belief values, we compute the fusion values on which we apply the classic DSMT combination rule, and build the decision-making algorithm presented in section V. To help develop this decision-making algorithm we used a Petri net which provided us a clear method of switching through system states under certain conditions.

The decision-making algorithm analyzes the probability of completing all the possible tasks that may appear in sensor data fusion and tackles these possibilities so that for every input the system will have an output.

The presented method can be used successfully in real time applications, because it provides a decision in all the cases in a very short time (table VII). The algorithm can be extended so that it can use information received from multiple sources or provide a decision starting from a high number of system states. The number of observer/data sources is not limited nor is the system's states. But while increasing the number of observers and system's states, the data to be processed is increased and the decision-making algorithm design is becoming a highly difficult task to achieve.

TABLE VII: Average execution time of the presented algorithm.

Method	Execution time (s)
Data neutrosophication for Obs. 1	0.0026
Data neutrosophication for Obs. 2	0.0026
Data fusion using DSMT	0.0002
Data de-neutrosophication/decision-making	0.0092
<b>Total time</b>	<b>0.0146</b>

In the case of autonomous robots, these must be taught what to do and how to complete their tasks. From this the necessity of developing new intelligent and reasoning system arises. The developed algorithm in this paper can be used successfully for target identification applications, object sorting, image labeling, motion tracking, obstacle avoidance, edge detection, etc.

**Abstract**—The identification of the subsoil constitutive materials, as well as the detection of possible interfaces and anomalies, are crucial for many site characterization applications. During investigation campaigns, complementary geophysical and geotechnical methods are usually used. These two sets of methods yield data with very different spatial scales and different levels of incompleteness, uncertainty and inaccuracy. In this work, a mathematical combination of geophysical and geotechnical information is proposed in order to produce a better subsoil characterization. It is shown that belief functions can be used for such a fusion process. A specific methodology is developed in order to manage conflictual information and different levels of uncertainties and inaccuracies from different investigation methods. In order to test and validate this methodology, we focus on the use of two selected methods, Electrical Resistivity Tomography (ERT) and Cone Penetration Test. First, a synthetic model with artificial data is considered, taking advantage of the results obtained to conduct a comparative study (effect of parameters and noise level). Then, an experimental test bench is considered, in which a two-layered model is placed (plaster and saturated sands) and geophysical and geotechnical data are generated, using a mini-ERT device and insertion depth values. This work also aims at providing a better graphical representation of a subsoil section with associated degrees of belief. The results highlight the ability of this fusion methodology to correctly characterize the considered materials as well as to specify the positions of the interfaces (both vertical and horizontal) and the associated levels of confidence.

**Keywords:** data fusion, belief functions, geophysical data, geotechnical data, experimental test bench, electrical resistivity tomography.

## I. INTRODUCTION

For subsoils characterization, investigation campaigns are set up, usually consisting of geophysical and geotechnical methods. These two families of methods are complementary and are used for various issues such as the characterization of slope stability [1-4] the characterization of potentially dangerous sites [5], the characterization of sites at construction [6] or the characterization of river embankments [7].

On the one hand, geophysical methods are non-intrusive and provide physical information on large volumes of soils but with significant potential uncertainties. These uncertainties are

due in particular to the integrative and indirect aspects of the methods as well as to the resolution of the inverse problems. On the other hand, the geotechnical investigation methods are intrusive and provide more punctual information but also more accurate. An important issue for the assessment of subsoils is to be able to combine acquired geophysical and geotechnical data, while taking into account their respective uncertainties, inaccuracies and spatial distributions [8]. The complementarity of these two sets of methods is often underused since the uncertainty and inaccuracy associated with each method are rarely considered. Furthermore, the results are usually only graphically superimposed [9] instead of being mathematically merged.

To characterize a section of subsoil and its potentially risky areas, it is essential to distinguish the different materials in place. The horizontal and vertical interfaces, as well as possible anomalies, have to be located. For levee embankment, as an example, it is in these locations that internal erosion is likely to develop, which may lead to the complete rupture of the levee [10]. Such a section characterization, with associated confidence indexes, could be included in failure hazard models.

The use of belief functions [11-12] and different information combination rules to combine geotechnical and geophysical data is proposed. This makes it possible to take into account at the same time the uncertainties, inaccuracies and incompleteness of data related to each method. In the field of geosciences, belief functions have already been used and provide interesting results for slope instability mapping [13-14], detection of precious metal [15], groundwater [16] or flood susceptibility mapping [17]. To our best knowledge, no work has been proposed, considering the combination of two sources of information with different spatial distribution (spatialized and punctual) and for an investigation campaign in the vertical section.

Here, an innovative method of information fusion to combine electrical resistivity tomography results and cone penetrometer test data is proposed. First, work on data obtained from synthetic models is displayed. The obtained results allow

to conduct a comparative study, evaluating the effect of different parameters (like the data noise level) on the fusion result. The fusion methodology is then tested from data acquired on a test bench. In this work, the potential of such a methodology is shown by using insertion depth data, acquired by a laboratory penetration cone, and electrical resistivity data acquired by a mini Electrical Resistivity Tomography (ERT) device. The depth of penetration data corresponds to geotechnical information while the electrical resistivity data correspond to geophysical information. The main concern is to highlight the ability of this information fusion algorithm to characterize the interfaces between materials and to discriminate three different types of materials with variation in thickness of one of them, and to present the variation of the results according to the number and position of the simulated boreholes.

The main contributions of this work are as follows. First, this new methodology makes it possible to take into account the uncertainties, inaccuracies and incompleteness associated with the different methods of investigation used, proposing a modeling of the Basic Belief Assignments (BBAs) specifically adapted to the problematic. Then, the proposed graphic representation is innovative since it allows both to present the different geological sets that would be present in the subsoil and their layout, while presenting the confidence associated with these results. This methodology is particularly suitable for the characterization of interfaces and anomalous zones, which may correspond to areas where the risk of instability is potentially the greatest. This work also allows the implementation of a small physical model to validate the fusion approach with real data.

This article is organized as follows. In section II a presentation of the approach of fusion used in the methodology is given, which introduces the use of the evidence theory and the combination methods used here. In section III, a synthetic study will then present the fusion approach from artificial data. It will also present the comparative results associated to two parametric studies. Then, in section IV, a presentation of the investigation methods used in the introduced experiment (laboratory penetration cone and mini ERT device) is given. Finally, the test bench fusion results are presented in section V and discussed in section VI, in order to understand the interests, limitations and perspectives of such a methodology.

## II. FUSION METHODOLOGY

### A. Belief functions and combination rules

The belief functions have been introduced by Shafer [11] in 1976 in the development of his mathematical theory of evidence inspired by previous works of Dempster [12]. Shafer's theory is also referred as Dempster-Shafer theory (DST) in the literature. This theory (proposes a method to) calculate(s) the belief and the plausibility of an event (here a soil material class) from distinct source of evidence (measured data). The practical advantage of using such a theory lies in its ability to manage information from different sources, associated with variable uncertainties and inaccuracies. In this work, only two sources of information will be considered: geotechnical and

geophysical. Another advantage of this theory is its ability to assess the degree of conflict between sources (ex: contradictory information between data obtained from large scale geophysical campaign and from punctual geotechnical investigation). Uncertainties correspond to degrees of confidence that are given to a value, whereas inaccuracies correspond to intervals of values that can be directly associated with measurement errors related to the method. For example, the uncertainty of measuring a geotechnical parameter identical to the one measured in a borehole increases with the distance to that point. The inaccuracy can for its part, be associated with the error bar of the result. The belief functions allow to take into account the ignorance and incompleteness of the information. It is indeed possible to grant credit on all the possible results in order to quantify the ignorance. For the reader eager to learn more, the theory is detailed in [18].

A Bayesian approach as part of a subjective probability approach [19] could have been considered for geophysical and geotechnical data combination. However, the main limitation of such an approach is that probabilities essentially represent uncertainty and only very poorly the level of inaccuracy. Moreover, in the probabilistic modeling stage, the different decisions (events) are only represented on singletons (i.e. single events) and are necessarily considered exhaustive and exclusive. The exclusivity is implied by the assumption of the additivity of probabilities. However, this hypothesis may be too strong and limit the representation of the knowledge. Furthermore, with a Bayesian approach, it is difficult to model the lack of knowledge or the knowledge that is not expressed in probability distributions.

In order to define and to use the belief functions, it is necessary (i) to set a frame of discernment, (ii) to assign belief mass values to the events of this framework (Basic Belief Assignments - BBAs), (iii) to choose a fusion rule for combining information; and (iv) to represent the combined information.

The Frame of Discernment (FoD)  $\Theta$  is made of all the possible events about the problem under concern, the elements of the FoD are exclusive and exhaustive, so that for  $n$  events:

$$\Theta = \{\theta_1, \theta_2, \dots, \theta_n\}. \quad (1)$$

In the considered problematic, the possible events of the FoD correspond to intervals of values of geophysical and geotechnical parameters that can be associated with classes of geological materials (for example,  $\theta_1$ =clays,  $\theta_2$ =sands, ...). The space of belief mass functions, the set of all subsets of  $\Theta$ , written  $2^\Theta$ , is fixed by all the disjunctions and by the possible conflict between the sources of information (written  $\emptyset$ ) such that:

$$2^\Theta = \{\emptyset, \theta_1, \theta_2, \theta_1 \cup \theta_2, \theta_3, \theta_1 \cup \theta_3, \theta_2 \cup \theta_3, \theta_1 \cup \theta_2 \cup \theta_3, \dots, \theta_1 \cup \theta_2 \cup \theta_3 \cup \dots \cup \theta_n\}. \quad (2)$$

As in the probability theory, the belief mass function  $m_j$  is defined, for a source of evidence  $S_j$  (for  $j = 1, 2$ ), attributed

to  $A$  (defined on  $2^\Theta$ ) in  $[0, 1]$  such that the more  $m(A)$  tends to 1 and the more the confidence in  $A$  is important :

$$\sum_{A \in 2^\Theta} m(A) = 1. \quad (3)$$

The difference with the probability theory lies in the fact that  $A$  can represent the union of several events (for example, either  $\theta_1$  OR  $\theta_2$ ). It is therefore possible to model uncertainty and lack of knowledge. For instance, when no information is available about the achievement of an event member of  $\Theta$ , one can set  $m_j(\Theta) = 1$ , avoiding the uniform distribution that would have been considered in a probabilistic scheme. Combination rules, as part of the belief functions theory, can thus take different levels of uncertainty and imprecisions into account according to the source of information. If only defined on singletons, the belief mass function is similar to a probability distribution.

Smets fusion approach developed in his Transferable Belief Model (TBM) [20] (i.e. conjunctive fusion) allows the attribution of a mass of belief to the conflict, outside the FoD, so that (open-world assumption):

$$m_{12}(\emptyset) > 0. \quad (4)$$

Where  $m_{12}(\cdot)$  denotes the combined BBA resulting from the combination of information of sources 1 and 2. The belief mass resulting from the fusion of information from source 1 and 2 is written:

$$m_{12}(A) = \sum_{\substack{X, Y \subseteq \Theta \\ X \cap Y = A}} m_1(X)m_2(Y). \quad (5)$$

And the level of conflict between the two considered sources of information can therefore be quantified by:

$$m_{12}(\emptyset) = \sum_{\substack{X, Y \subseteq \Theta \\ X \cap Y = \emptyset}} m_1(X)m_2(Y), \quad (6)$$

with  $m_1(X)$  and  $m_2(Y)$  the belief masses respectively attributed to events  $X$  and  $Y$  by sources 1 and 2.

According to Shafer's approach and unlike Smets' rule, Dempster-Shafer's rule (DS) does not allow the attribution of a mass of belief to the conflict (closed-world assumption):

$$m_{12}^{DS}(\emptyset) = 0. \quad (7)$$

The conflict is there reallocated through a classical normalization factor. The mass of belief in  $A$ ,  $m_{12}^{DS}(A)$ , resulting from the fusion of information from sources 1 and 2 is written:

$$m_{12}^{DS}(A) = \frac{1}{1 - m_{12}(\emptyset)} \sum_{\substack{X, Y \subseteq \Theta \\ X \cap Y = A}} m_1(X)m_2(Y). \quad (8)$$

The disadvantage of this method is that the conflict between the sources is no longer represented and it is possible to obtain counterintuitive results if the conflict is important because of this normalization. Even more problematic, even if the distinct sources are both informative whatever the level of conflict is, Dempster-Shafer's fusion process can even not take into account the second source of information [21].

The disadvantage of this method is that the conflict between the sources is no longer represented and it is possible to obtain counterintuitive results if the conflict is important because of this normalization. Even more problematic, even if the distinct sources are both informative whatever the level of conflict is, Dempster-Shafer's fusion process can even not take into account the second source of information [21].

$$m_{12}^{PCR6}(A) = m_{12}(A) + \sum_{\substack{Y \in 2^\Theta \\ A \cap Y = \emptyset}} \left[ \frac{m_1(A)^2 m_2(Y)}{m_1(A) + m_2(Y)} + \frac{m_2(A)^2 m_1(Y)}{m_2(A) + m_1(Y)} \right]. \quad (9)$$

### B. Construction of BBAs from geophysical and geotechnical data

Belief masses have to be assigned to each considered event of the FoD, for both sources of information. The combination of the belief masses can only be initiated after this stage. In the following, the geophysical source of information will be identified as source 1 and the geotechnical source of information as source 2. A 2D model assumption will be made, corresponding to the  $x$  and  $z$  spatial axes, since vertical sections of subsoil are considered.

#### Geophysical data

The discretization of the considered subsoil section, as well as the depth of investigation and the resolution, depend on the acquisition method used [24]. It is the user who sets, using the inversion tool used, the shape and dimensions of the discretization grid used. It is about starting from this discretization and being able to associate for each cell, masses of beliefs for each event of the FoD.

The constitutive classes of the FoD are also fixed at the end of the inversion process by the geophysicist, with the help of a representation of the distribution of the set of inverted geophysical values, in the form of modal classes (Figure 1.a). The representation in this form makes it possible to highlight the centers, minima and maxima of the events considered in order to be able to fix the bounds of the intervals associated with the events of the FoD. The number of cells of the subsoil section are represented according to the geophysical parameter values. The infima and suprema must be fixed so that the intervals are of the same width in order to avoid the appearance of a bias when calculating Wasserstein distances (detailed under). To associate the belief masses with the FoD events, the intervals of inverted values of the physical parameter (in red, Figure 1.b) are considered. For some geophysical methods, these intervals can correspond to the value obtained at the end of the inversion with its associated inaccuracy.

It is then necessary to associate belief mass values  $m_1(\cdot)$  corresponding to each element of  $2^\Theta$ , for each cell of the inverted section. The masses are obtained from the calculation of Wasserstein distances [25], considering two geophysical intervals  $A = [a_1, a_2]$  and  $B = [b_1, b_2]$  with  $A$  and  $B$  belonging to  $\mathbf{R}$ ,  $A$  being the interval corresponding to an event

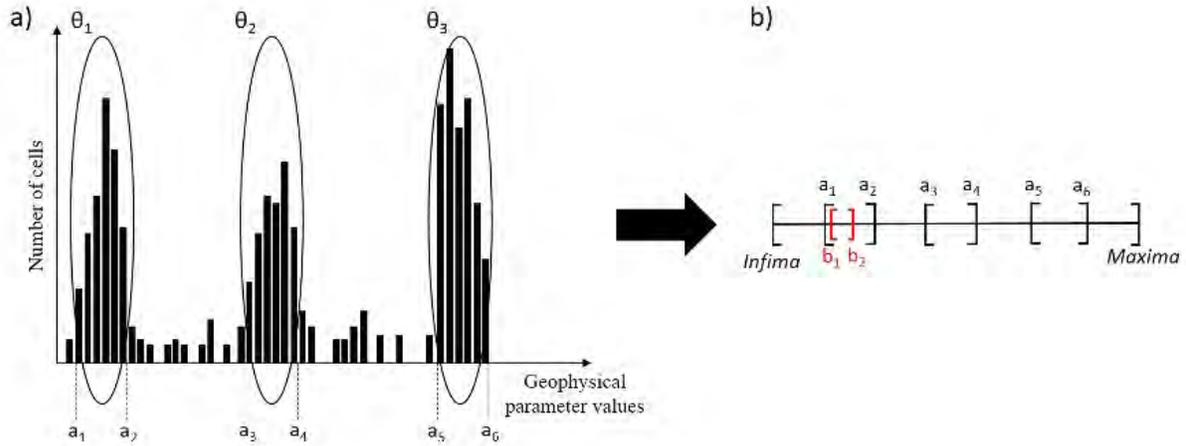

Fig. 1. a) Model classes' distribution of the geophysical parameter values from the considered subsoil section, allowing the selection of the geophysical classes in b). The red interval corresponds to an interval of inverted values, from one cell of a 2D section of subsoil, used for Wasserstein distances' calculation.

of the FoD and  $B$  being an interval of inverted values (Figure 1.b), Eq. (10):

$$d_{\text{Wass}}^2(A, B) = \left[ \frac{a_1 + a_2}{2} - \frac{b_1 + b_2}{2} \right]^2 + \frac{1}{3} \left[ \frac{a_2 - a_1}{2} - \frac{b_2 - b_1}{2} \right]^2 \quad (10)$$

This calculation estimates the distance between two intervals according to their size and the distance between them. The Wasserstein distances are calculated (using a logarithmic scale if the geophysical parameter requires it) between the inverted values with estimated inaccuracies, and the intervals associated with each event, chosen by the geophysicist. Each cell is finally associated with a standardized BBA respecting Eq. (3). This way, the more the distance of a geophysical interval resulting from the inversion is “close” to one event of the FoD, the more the mass of belief associated is important, and reciprocally.

### Geotechnical data

For the geotechnical part, the information proposed during an investigation campaign is spatially punctual (in the  $x$ - $z$  plane) and often contained in vertical soundings made from the surface. It is about associating masses of belief with the different events of the FoD for each cell of the considered vertical soundings. For this, the values proposed at each depth are considered with the associated inaccuracy, corresponding to the measurement error that could be attributed to the measuring device (Figure 2.a). Thus, as for the geophysical part, intervals of values are obtained.

The geotechnical mesh consisting of as many cells in depth as the number of geotechnical values (Figure 2.b) is generated. A mass of belief  $m_2(\cdot) = 1$  is assigned, in the drilling points,

to the events corresponding to the measured geotechnical parameter. A value of 1 is set since we are very confident in the information inside the boreholes unlike the spatialized geophysical information. A new mesh is then constructed (Figure 2.c), according to the size and depth of the boreholes. In order to characterize the entire section of the model, as does the geophysical method, and to associate mass values to each new cell (BBA), an exponential lateral decay of the belief mass is imposed, from the drilling point to the nearest borehole so that the decay rate is a function of the values proposed by the nearby borehole. So that, for a specific depth, Eq. (11):

$$BBA(x) = e^{-kC_v x} BBA(0), \quad (11)$$

with  $x$  being the distance from the considered cell to the reference borehole ( $x = 0$  in the borehole),  $k$  a decay factor fixed by the user to adjust the lateral decay rate,  $BBA(x)$  the belief mass values assigned to each event of the FoD for a position  $x$ , with  $BBA(0) = 1$ .  $C_v$  corresponds to the coefficient of variation expressed in Eq. (12), such as used in [26]:

$$C_v = \frac{\sqrt{\frac{1}{n_{\text{mesh}}-1} \sum_{i=1}^{n_{\text{mesh}}} (Q - Q_i)^2}}{Q}, \quad (12)$$

where  $Q$  is the geotechnical value of the reference cell in the considered borehole and  $Q_i$  the geotechnical value in the nearby borehole. For Figure 2.b,  $n_{\text{mesh}} = 3$  has been considered. If  $n_{\text{mesh}} = 5$  or  $7$ , the computation of the  $C_v$  will take into account 5 or 7 cells in the nearby borehole. Indeed, for two consecutive boreholes with similar values, at similar depth, the decay of the confidence is slower than for two consecutive boreholes presenting radically different

values. This decay of belief mass is carried out to the left and to the right, from each drilling.

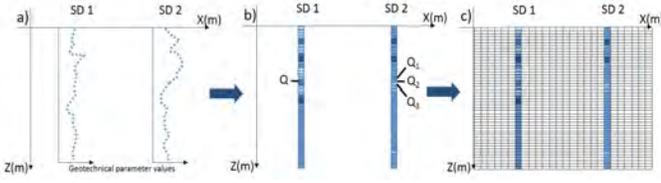

Fig. 2. Construction of a geotechnical discretization mesh from two vertical boreholes acquisition (SD1 and SD2). a) Representation of the geotechnical values for SD1 and SD2 according to the depth. b) The boreholes are divided in cells associated with belief mass equal to 1 for the considered event. c) Construction of a new mesh according to the size and depth of the boreholes.

If, between two boreholes, the mass of belief associated with a hypothesis  $A$  is less than 1 ( $m_2(A) < 1$ ), then the remainder of mass to be allocated to satisfy Eq. (3), is reported on the proposition “any type of material” represented by the union of all events, such as Eq. (13):

$$m_2(\theta_1 \cup \theta_2 \cup \theta_3 \cup \theta_4) = 1 - m_2(A). \quad (13)$$

### C. Dimensioning of the mesh prior to the fusion

Each source of information imposes its own mesh but in order to combine the belief masses from the geophysical information source (source 1) and the geotechnical source (source 2), it is necessary to have a common mesh containing, for each cell, the geophysical and geotechnical BBAs. In order to not alter the quality of the information, no interpolation is carried out. It is decided to superimpose the geophysical discretization grid resulting from the 2D inversion to the geotechnical division, depending on the number and the borehole positions. Thus, an irregular mesh is obtained but without any approximation (Figure 3).

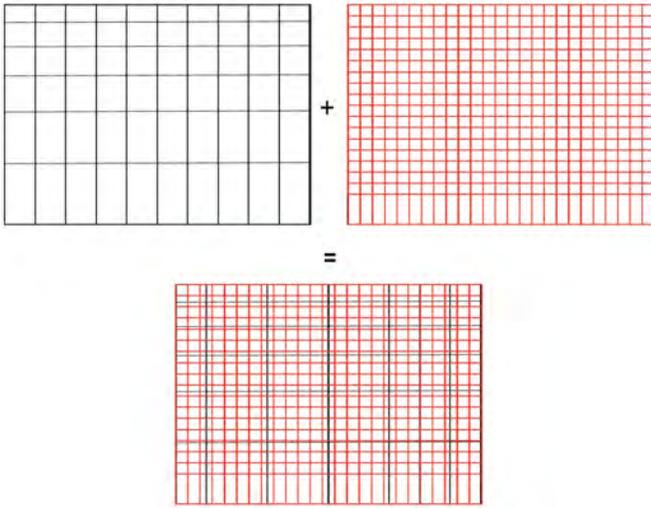

Fig. 3. Example of a geophysical mesh (in black) and a geotechnical mesh (in red) superimposed to propose a new irregular mesh to carry out the combination calculations and present the fusion results.

## III. SYNTHETIC STUDY

Below, a synthetic study based on artificial data is proposed in order to test this new proposed methodology. It is the opportunity to show the impact of different levels of noise on the geophysical information as well as the influence of the lateral decay factor  $k$  (Eq.11) on the results of the fusion in order to be able to choose a value for the use of such a methodology from real data.

### A. Considered methods

For this study, the electrical resistivity tomography (ERT) method stands for the geophysical information source and the Cone Penetrometer Test (CPT) method for the geotechnical information source.

The basic principle of DC-resistivity methods consist in injecting an electric current of known intensity [A] by means of two “current” electrodes and measuring a voltage [V] between two “potential” electrodes. Depending on the electrode layout, the topography, the properties of the materials and their distribution, apparent resistivity values can be computed. The depth of investigation depends on the spacing of the electrodes, the configuration of the electrodes and the nature of the soil [27]. By generalizing this principle, a two dimensional (2D) ERT consists in aligning a series of electrodes and acquiring a large number of measurements based on four electrodes configuration. The apparent resistivity data acquired are then inverted using an inversion code or software to reconstruct a complete 2D-section of electrical resistivity [ $\Omega \cdot m$ ]. Here the Res2Dinv software (ver 3.71.118) [27] has been used.

In order to obtain an artificial resistivity section of subsoil, a two steps procedure is followed. First, resistivity data are simulated using the Res2Dmod software [28], on the section that we want to consider. Second, apparent electrical resistivity values are inverted with Res2Dinv, considering a L1 norm [29] and an extended model discretization, to obtain the synthetic inverted section of electrical resistivity.

The CPT method consists in pushing rods into the soil, at a constant speed, with a conical tip at the end [30]. This test is often used for the determination of the soils mechanical resistance properties. The two measured parameters are the tip resistance  $q_c$  [MPa] and sleeve friction  $f_s$  [MPa]. Although the method uses two parameters, only  $q_c$  will be considered as the study parameter.

### B. FoD and considered model

For this synthetic study, a two-layer model is considered, composed of materials that can be likened to silts for the upper layer and clays for the underlying layer. The FoD therefore contains three material class hypotheses, such as:

$$\Theta = \{\theta_1, \theta_2, \theta_3\}, \quad (14)$$

with  $\theta_1$  the event corresponding to the clayey material,  $\theta_2$  to the silty material and  $\theta_3$  to unknown materials. The latter is associated with the union of the geophysical and geotechnical value ranges that do not correspond to those associated with  $\theta_1$  and  $\theta_2$ . This event  $\theta_3$  allows us in a certain way, to quantify

the lack of knowledge of the environment since it does not include the two first sets. The construction of the BBAs then consists in associating the data of the two considered sources to the events of the FoD. Figure 4 shows the two-layer model based on events from the FoD, used for this synthetic study.

Fig. 4. Representation of the events of the FoD in the imposed model of subsoil of the synthetic study.

### C. Construction of BBAs from geophysical and geotechnical data

#### Geophysical data

The electrical acquisition is simulated with a Wenner acquisition mode and with 96 electrodes interspaced from one meter. An electrical resistivity of  $100 \Omega\cdot\text{m}$  is considered for the upper material and a resistivity of  $30 \Omega\cdot\text{m}$  for the underlying one [31] (Figure 4). Electrical acquisitions are simulated with different noise levels (5, 10 and 15%). The results of this inversion (with 10% noise, figure 5.a) allow to highlight the presence of two layers but the interface between these two layers is not perfectly identified. A variation of thickness in the center of the model is visible. The interface is not straightforward and anomalies are present on the surface even though they are not part of the initial model.

From these inversion results, it is possible to define the ranges of electrical resistivities that will be associated with the different events considered for the fusion process. A distribution in modal classes is used to visualize the number of cells, in the discretized section of the 2D inversion, associated with specific range of resistivities (Figure 5.b). This distribution allows to highlight the two large material classes of the model. Thanks to it, the bounds of the considered events can thus be defined (in  $\Omega\cdot\text{m}$ ), so that the intervals have the same length (in logarithmic scale):

$$\begin{aligned}\theta_1 &= [25; 45], \\ \theta_2 &= [83; 149.4], \\ \theta_3 &= [13.89; 25 \cup 45; 83 \cup 149.4; 268.92].\end{aligned}\quad (15)$$

As explained in II.B., it is possible to associate belief masses with each cell of the mesh thanks to the values resulting from the inversion. As part of the construction of geophysical BBAs, the values presented Figure 6 are obtained. This figure highlights the association of the values of Figure 5.a with the events of the FoD, Eq. (15). The presence of a top layer ( $\theta_2$ ) and a base layer ( $\theta_1$ ) can be detected (Figure 6.a). It appears that there is a variation in the thickness of the layers in the center of the model, but the interface is not well characterized. Moreover, the intermediate values of electrical resistivity resulting from the inversion (Figure 5.a) between

$\theta_2$  and  $\theta_1$  layers induce the representation of a third material ( $\theta_3$ ) which has no reality in the model that has been fixed. The belief masses are maximum when the resistivity values correspond to the center of the resistivity classes set for each event (Eq. (15)).

#### Geotechnical data

Concerning the source of geotechnical information, the simulation of four vertical CPT soundings interspaced from 19 meters is proposed (Figure 7). 20 cm wide and up to 15 m deep boreholes are considered, and a value of  $q_c$  is recorded every 50 cm from the surface. An inaccuracy of  $10^{-2}$  MPa on the measurements is considered. For a fixed normalized friction ratio of 3%, a value of  $q_c$  of 20 MPa is considered for the upper silty material and a value of 0.2 MPa for the underlying clay material, as proposed in the Robertson diagram [32].

In order not to have uniform values of  $q_c$  for the materials and to try to represent the noisy reality of an acquisition in the field, values are drawn following a normal distribution defined for each event. Mean  $q_c$  values of 0.2 and 20 MPa are respectively used to define the normal distributions of the material classes. Standard deviation values equal to 10% of the mean values are associated, echoing the 10% noise used for the geophysical data. Keeping the minimum and maximum values, these random draws, make it possible to define the limits, in MPa, of the intervals associated with the elements (i.e. material classes) of the FoD:

$$\begin{aligned}\theta_1 &= [0.14; 0.27], \\ \theta_2 &= [13.5; 23.5], \\ \theta_3 &= [0.1; 0.14 \cup 0.27; 13.5 \cup 23.5; 100].\end{aligned}\quad (16)$$

The minimum and maximum values are fixed at 0.1 and 100 respectively because they are the minimum and maximum values in Robertson's diagram [32].

There are two types of sounding results according to their position (Figure 8). Once the values associated with the meshes of the sounding are obtained, it is possible to associate masses of belief to the whole section by extending the geotechnical information, as explained in II.B. In the framework of the construction of geotechnical BBAs and for  $k = 0.1$  (Eq.11), the obtained values are proposed in Figure 9. This figure highlights the fact that the confidence is maximum in the soundings. This method allows us to characterize the material  $\theta_2$  on the first 5 meters of the model and the material  $\theta_1$  from 10 to 15 meters deep.

The greater thickness of the material  $\theta_2$  in the center of the model is also well characterized. On the other hand, a great doubt appears in yellow (Figure 9.a) in certain areas, not allowing the determination of a specific material ( $\theta_1 \cup \theta_2 \cup \theta_3$ ). For the model base area, this can be explained by the fact that the soundings stop at 15 meters depth. Regarding the areas between 5 and 10 meters to the right and left of the first and last sounding, this is related to the fact that for these two soundings, the closest soundings propose different values at the same depths, the confidence attributed to the presence of

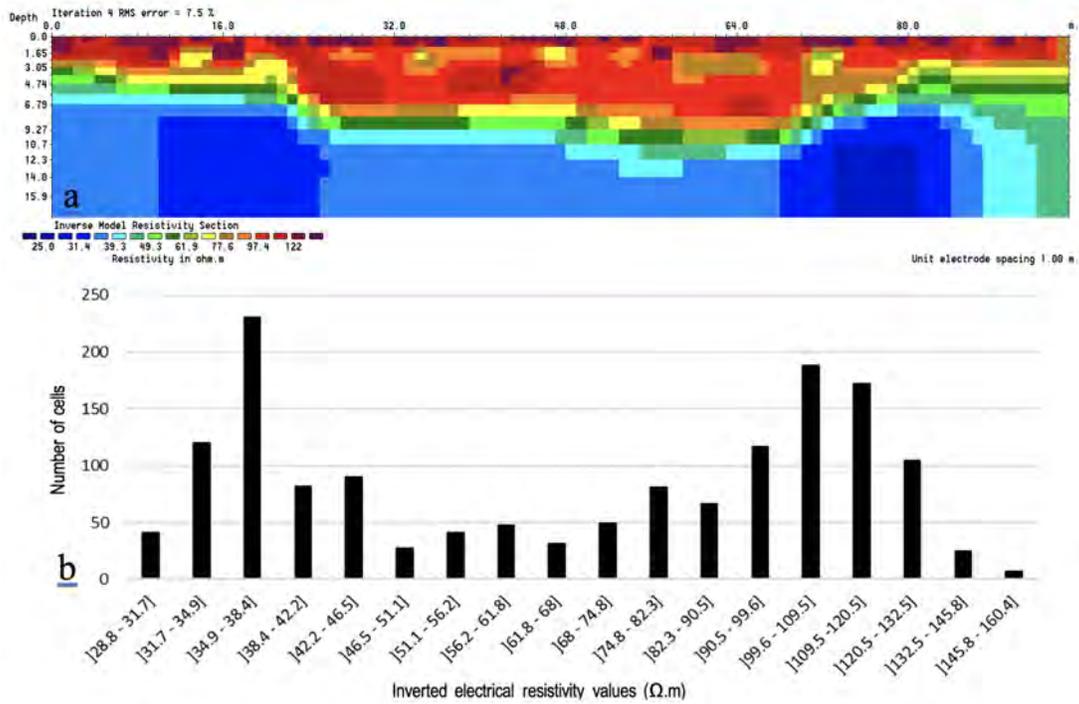

Fig. 5. a) Subsoil section displaying inverted electrical resistivity values from 10% noise data acquisition and b) model classes' distribution of the cells presented in a), according to the electrical resistivity values ( $\Omega.m$ ).

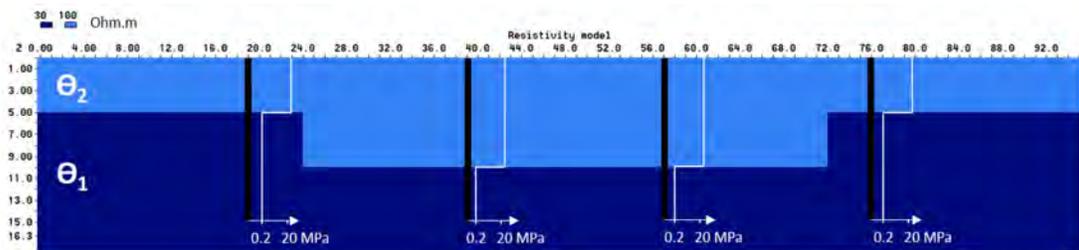

Fig. 7. 2D section of subsoil displaying true ER distribution with boreholes positions in black and associated tip resistance vertical profiles in white.

$\theta_1$  therefore decreases very quickly laterally. This decay is also high towards the edges of the model because no other

sounding is present at the ends to constrain the information.

*D. Effect of lateral decay factor and noise level on the fusion results*

We examine in this part the results of the fusion of belief masses established for the proposed synthetic model by varying the noise level of the geophysical information, as well as the value of the lateral decay factor  $k$  (Eq.11) influencing the lateral decay rate of geotechnical information.

Figure 10 shows the fusion results with different values of  $k$  ( $10^{-2}$ ,  $5 \cdot 10^{-2}$ ,  $10^{-1}$ ,  $5 \cdot 10^{-1}$  and 1) for a simulated noise of 10% on the acquired geophysical information. Noise was set at 10% since the electrical resistivity classes of the FoD were defined from the modal classes of the inverted 10% noise image, Figure 5.b. For each value of  $k$ , Figures 10.a and 10.b represent the results obtained by Smets fusion whereas Figures 10.c and 10.d represent the results obtained by PCR6

fusion. While Figures 10.a and 10.c show the material classes having the greatest mass of belief at the end of the fusion process, Figures 10.b and 10.d correspond to the values of these respective belief masses, between 0 and 1. These figures, display the events (materials) potentially present within the section, as well as their attached level of confidence.

The higher the value of  $k$  is, the higher the rate of confidence in geotechnical information is. This can be seen, for example, from the last borehole to the right end of the section (Figures 10.b) or between the 2nd and 3rd boreholes (Fig 10.d). The increase of  $k$  implies that for two soundings offering similar values at the same depth, the confidence associated with the corresponding type of material will tend to decrease. On the other hand, for two soundings proposing different values at the same depth, the increase of  $k$  will hardly have any impact on the belief masses associated with the selected events (e.g.

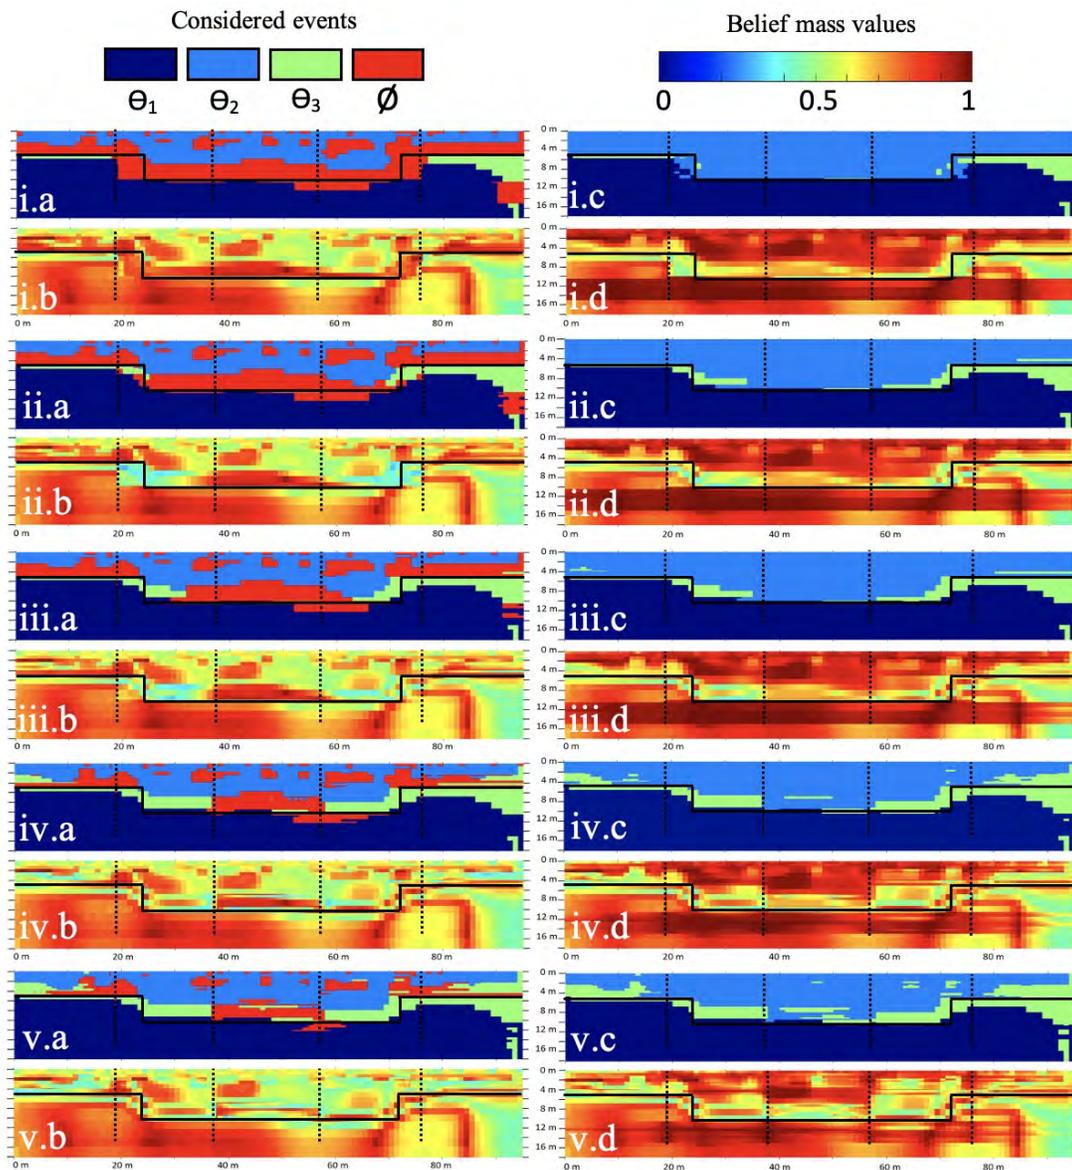

Fig. 10. Representation of the events having the highest belief mass in a) and c) and their associated mass values in b) and d), considering a 10% noise. In i)  $k = 0.01$ , ii)  $k = 0.05$ , iii)  $k = 0.1$ , iv)  $k = 0.5$  and v)  $k = 1$ . Figures on the left side are results for Smets fusion while figures on the right side are results for PCR6 fusion. The sounding positions are in dashed lines while the black lines represent the position of the interface.

between 5 and 10 m of depth between the boreholes 1 and 2, Figures 10.d).

With regard to the material classes identified after the fusion process, the more  $k$  increases, the more the quantity of conflict decreases (in red, Figures 10.a). This is explained by the fact that when there is little trust in the geotechnical data, there is little conflict with the geophysical data. In the meantime, an increase in the proportion of  $\theta_3$  is observed (Figures 10.c) close to the interface. This observation is explained by a larger mass attributed to the union of events and by geophysical data which propose intermediate values at the interface level.

In the following of this work, an intermediate value of  $k$  will be retained, equal to 0.1. With such parameter value, a good

confidence in information repeating between two successive soundings is obtained, but it also leaves room for doubt by having enough unknown material ( $\theta_3$ ) at the interfaces. The obtained fusion results with different noise levels added to the geophysical information (5, 10 and 15%) are shown in Figures 10.iii and 11 with  $k = 0.1$ .

The greater the amount of noise is, the less clear the interfaces proposed by the inversion are (Figures 5.a, 11.i.a, 11.ii.a). A greater number of anomalies are also present when the noise level increases. The noise level finally impacts the level of inaccuracy associated with the geophysical data used in the fusion process. Larger data inaccuracies induce wider value ranges considered for calculating Wasserstein distances,

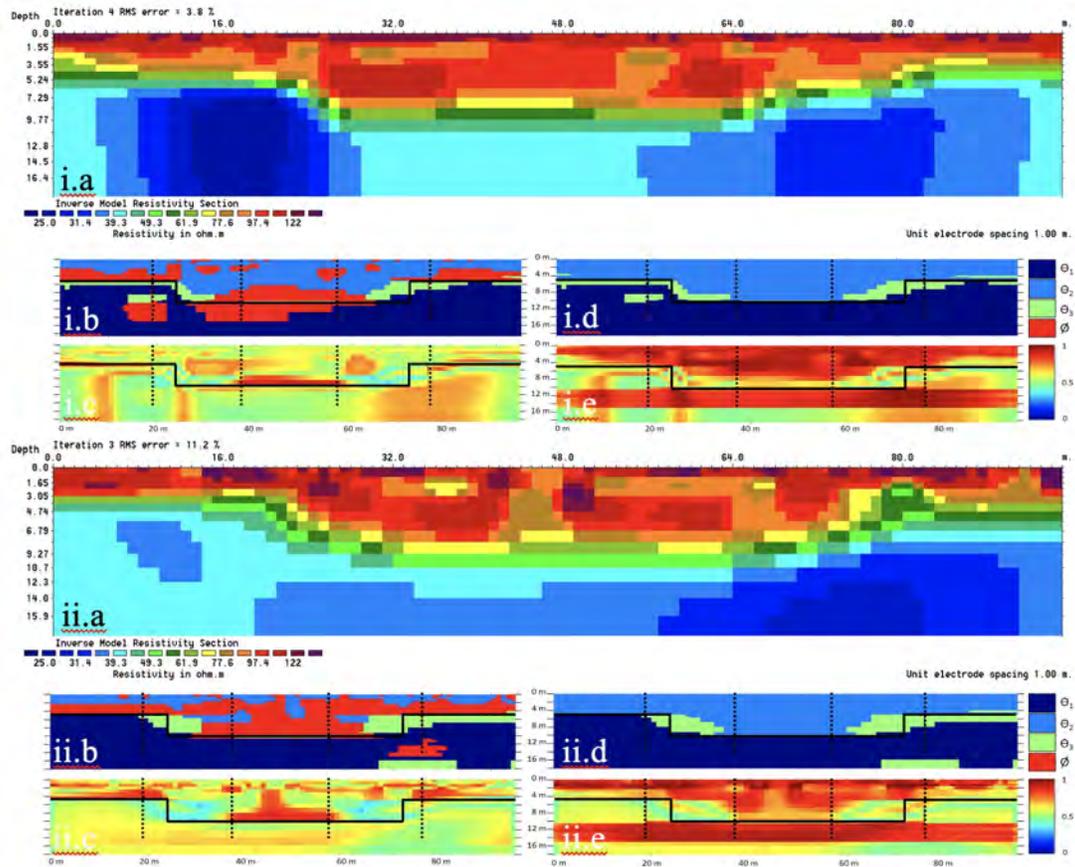

Fig. 11. a) Subsoil section displaying inverted electrical resistivity values from i) 5% noise and ii) 15% noise data acquisition. Representation of the events having the highest belief mass in b) and d) and their associated mass values in c) and e). Figures on the left side are results for Smets fusion while figures on the right side are results for PCR6 fusion. The sounding positions are in dashed lines while the black lines represent the position of the interface.

which in turn can bring to consider belief masses on more events of the FoD.

Since the classes associated with FoD elements were fixed from the values with 10% noise (section III.C and Figure 4.b), it is “reasonable” to have a higher confidence (higher belief masses) on these results than on the results with 5% and 15% noise (Figures 11.c, 11.e, 10.iii.b, 10.iii.d). The fusion process allows to override the noise effects, whether the noise level is 5 or 15%. This can be imputed to the computation of Wasserstein distances, taking into account the data inaccuracies and considering all geophysical classes.

#### IV. SETTING UP A TEST BENCH FOR REAL GEOTECHNICAL AND GEOPHYSICAL ACQUISITIONS

##### A. Materials

In order to be able to assess the validity of the developed fusion methodology, two methods of data acquisition were retained: (i) a mini-ERT device acting as the geophysical source of information and (ii) a laboratory penetration cone acting as the geotechnical source of information. Before setting up the test bench, it was necessary to select the materials that could be put in place in a tank in order to carry out the study. This selection implies that the materials used meet

several conditions in order to validate the methodology: they must have (i) distinct electrical resistivity ranges, (ii) distinct penetration depths and (iii) a certain homogeneity in the space to limit uncontrolled anomalous values.

1) *Mini ERT device*: Expressly for the purposes of this study, a mini ERT device (Figure 12) has been set up. This device consists of 48 electrodes of 6 mm length, positioned at regular intervals of one centimeter. It can be moved along the test bench to make multiple acquisitions and to cover a longer section.

2) *Laboratory penetration cone*: The laboratory penetration cone method is described in the French standard NF P 94-052-1 [33]. It consists in measuring a penetration depth of a cone, in millimeters, subjected to its own weight (Figure 13). The materials are tested individually, repeatedly, to determine an average value and a standard deviation of penetration depth for each material. These values can be used later in the study to simulate different drilling positions within the test bench. This method can be likened to the CPT method which is one of the most popular in situ geotechnical tests.

3) *Test bench and used materials*: For the validation of the methodology, we wanted to build a test bench that could be easily set up and controlled, with two or three layers and

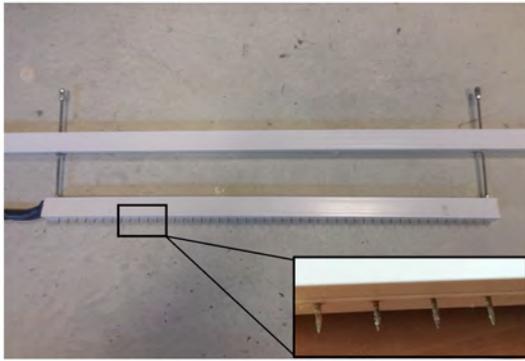

Fig. 12. Mini ERT device with 48 electrodes spaced 1 cm, adjustable height, used for electrical acquisitions in the test bench.

Fig. 13. Laboratory penetration cone.

variation of the interface positions. Fast-hardening natural fine-grained plaster as well as Hostun fine sand [34] are the retained constituents. These two materials meet the three conditions listed above. They were placed in a transparent PVC tank of  $100 \times 30 \times 17 \text{ cm}^3$  as shown in Figure 14 with an underlying layer of 5 cm of plaster (setting time = 69 h) overlaid by a layer of 2.5 cm of water saturated sand.

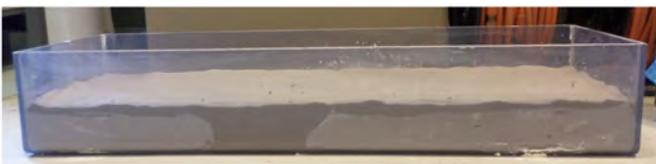

Fig. 14. Transparency view of the test bench.

A formwork was made during the placement of the plaster so that a 20 cm long anomaly could be inserted in. Saturated sand of 7.5 cm thickness is present instead of plaster. The contact between the materials and the bottom of the tank is at the origin of an interface that will be interesting to detect with the help of the methodology. 16 kg of plaster were mixed with 8 kg of water to obtain the material finally put in place. The electrical resistivity of the plaster was measured before and after the placement of the saturated sand to verify that the presence of water had a negligible impact on the electrical properties of the plaster.

TABLE I  
VALUES OF ELECTRICAL RESISTIVITY AND DEPTH OF PENETRATION OF THE MATERIALS SET UP WITHIN THE TEST BENCH.

	Plaster before pluviation	Saturated Hostun sands
<b>Electrical resistivity (<math>\Omega \cdot \text{m}</math>)</b>		
Mean	31.28	78.15
Standard deviation	3.23	11.18
Number of measures	12	52
<b>Penetration depth (mm)</b>		
Mean	0.11	17.31
Standard deviation	0.04	1.61
Number of measures	8	10

For the Hostun sand, 15.82 kg were pluviated in 5.8 kg of water, above the plaster to reach saturation. Trials had been carried out in advance to determine the proportions of water and sand required to achieve such a state as well as to validate the repeatability of such installation by pluviation. The values of electrical resistivities and penetration depths are displayed in Table I.

### B. FoD and BBA modeling

1) *FoD and target model*: A FoD consisting of four elements (material classes) is considered so that:

$$\Theta = \{\theta_1, \theta_2, \theta_3, \theta_4\}, \quad (17)$$

with  $\theta_1$  the element corresponding to the plaster material;  $\theta_2$  corresponding to saturated sand;  $\theta_3$  corresponding to the hard and electrically insulating bottom of tank simulating a substrate and  $\theta_4$  corresponding to unknown materials, being the union of the ranges of values not corresponding to those associated with the 3 previously described materials. Figure 15 presents the target model in the form of events constituting the FoD, following the disposition of the materials within the test bench. Although the tank used is 1 m long, the ERT acquisition only covered a 83 cm long section, on the central line of the model, and allowed us to image up to 18 cm of depth.

2) *Construction of BBAs from geophysical and geotechnical data*: The electrical acquisition was carried out on 83 cm long, on the central line of the model, with a first acquisition on 47 cm, and three next acquisitions done after respective displacements of 12 cm (roll along method). The results obtained from the inversion of the acquired data are displayed in Figure 16.a. These results make it possible to highlight the existence of three distinct sets, at depths relatively close to the target model

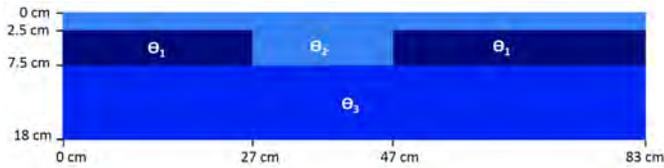

Fig. 15. Scheme of the idealized section model (with vertical exaggeration), including the FoD constituent events associated with the materials of the test bench.

(Figure 15) but presenting vertically slightly shifted interfaces, gradual rather than sharp. In addition, the variation in saturated sand thickness is poorly evaluated. Indeed, the anomalous zone is recognized but associated here, in its lower part, with values of electrical resistivities much larger than what they really are.

The proposed values, although in the same order of magnitude, do not exactly match the ranges of values measured on the materials independently (Table I). In order to characterize the events (materials) of the FoD, a distribution in modal classes (Figure 16.b) is used to visualize the number of cells of the discretized section for the 2D inversion, associated with their corresponding ranges of resistivities. This distribution makes it possible to highlight the three large sets of materials in the model. Thanks to it, the bounds of the events considered can thus be defined, in  $\Omega \cdot m$ , so that the intervals are the same length, as presented Eq. (18):

$$\begin{aligned} \theta_1 &= [10; 35], \\ \theta_2 &= [40; 140], \\ \theta_3 &= [9500; 33250], \\ \theta_4 &= [2.85; 10 \cup [35; 40 \cup [140; 9500 \cup [33250; 116375]. \end{aligned} \quad (18)$$

In contrast to information from the geophysical source, geotechnical data were obtained beforehand by laboratory penetration cone testing, and then numerically simulated prior to fusion. Several simulations proposing various positions of survey points were carried out. In order to simulate drilling points, the associated mean depth values (mm) and associated standard deviations (Table I) were used to draw values, following a normal distribution defined for each event. An average penetration depth value of 0 mm is used for  $\theta_3$  (bottom of tank) and an associated standard deviation of 0.01 mm, meaning that negative values may be drawn. These random draws, make it possible to define the limits, in mm, of the intervals associated with the events of the FoD as presented Eq. (19):

$$\begin{aligned} \theta_1 &= [0.04; 0.19], \\ \theta_2 &= [13; 21], \\ \theta_3 &= [-0.02; 0.02], \\ \theta_4 &= [-0.05; -0.02 \cup [0.02; 0.04 \cup [0.19; 13 \cup [21; 100]. \end{aligned} \quad (19)$$

Thus, 2 mm wide boreholes are simulated, down to 15 cm and acquiring every 5 mm with an associated inaccuracy of 0.01 mm. The values of penetration depth obtained can then be associated with the different materials of the model.

## V. TEST BENCH DATA FUSION RESULTS

The results of the geophysical and geotechnical information fusion, are proposed in Figure 17. The simulations were carried out according to four distinct vertical drill positioning configurations, represented in dashed lines in the figures and at regular intervals: i) 8 holes inter-spaced of 10 cm (Figure 17.i) ( $x = 10; 20; 30; 40; 50; 60; 70; 80$  cm), ii) 5 holes inter-spaced of 18 cm (Figure 17.ii) ( $x = 4, 22, 40, 58, 76$  cm), iii) 3 holes inter-spaced of 25 cm (Figure 17.iii) ( $x = 15, 40, 65$  cm), iv) 2 holes inter-spaced of 50 cm (Figure 17.iv) ( $x = 15, 65$  cm). The fusion results carried out are presented, respecting i) the hypothesis of Smets (Figures 17.a and 17.b), ii) the hypothesis of a closed-world (section II.1) with PCR6 rule (Figures 17.c and 17.d). Figures 17.b and 17.d represent the belief mass values associated with events having the largest mass, represented respectively in Figures 17.a and 17.c. The fusion results are analyzed and discussed in the next section.

## VI. FUSION RESULTS ANALYSIS AND DISCUSSION

### Different rules of combinations

Let us discuss and compare the results obtained by the 2 different combination rules used in an 8-boreholes simulation (Figure 17.i). In the framework of a model as rich in geotechnical information, the section proposed by the PCR6 method (Figure 17.i.c) is very close to the target model set up (Figure 15). The three sets are well characterized and the interfaces at 2.5 cm deep (sands-plaster) and at 7.5 cm deep (plaster-PVC tank and sand-PVC tank) are much better defined than by ERT alone (Figure 16.a). Moreover, thanks to this geotechnical information, the sand thickness anomaly could be correctly characterized as saturated sands (2) and not as a more resistive anomaly, in continuity with the insulating material from below, as suggested by the results of the inversion. The lateral extension of this anomaly is, moreover, well estimated (20 cm). The combination of Smets highlights the significant conflict existing between the two considered sources of information (Figure 17.i.a) concerning the two first layers.

Whatever method is used, the presence of a hypothesis 4 is found at the vertical and horizontal interfaces (Figures 17.i.a, i.c). This hypothesis does not correspond to any material set up in the test bench. The belief masses attributed to such a hypothesis, highlight the transition zones not conform to reality, proposed by the inversion of the electrical resistivity data (Figure 16.a). In comparison to the belief masses associated with the other hypotheses of the model, the belief masses associated with 4 are the lowest (Figures 17.i.b, i.d), showing that the confidence granted to such a material remains quite relative. An overall confidence drop is also observed from 15 cm depth. This corresponds to the maximum depth reached by the simulated boreholes. As confidence is extended laterally, the belief masses are constrained only by geophysical information to such a depth and therefore rely only on one source of information.

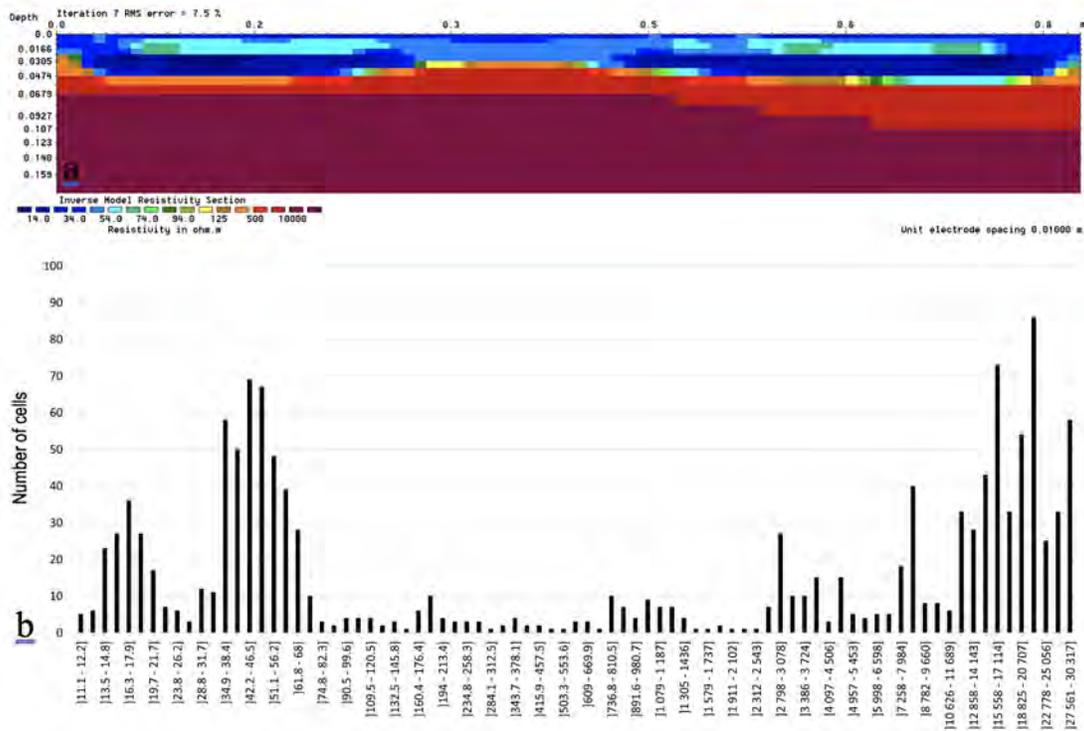

Fig. 16. a) inverse model resistivity section obtained by roll along acquisitions in the central line of the model and b) model classes' distribution of the cells presented in a), according to the electrical resistivity values ( $\Omega\cdot m$ ).

### Influence of the number of boreholes and positions

The first intuition would be to assume that the more the number of boreholes decreases, the more the method should be put in difficulty to properly characterize the section of the set up test bench. Although this is partly true, the quality of the results is not based as much on the number as on the positions of the drillings. Indeed, the anomaly of saturated sands contained between the two banks of plaster (Figure 15) is as well characterized in terms of lateral extension with three or five soundings (Figures 17.ii.c, iii.c). It also has an equivalent associated trust (Figures 17.ii.d, iii.d). It turns out that the belief masses associated with the event 1 (plaster) are even smaller for a fusion including three soundings (Figures 17.iii.d) than for a simulation of only two (Figures 17.iv.d).

The explanation of such results lies in the fact that being in the presence of consecutive boreholes, informing about the occurrence of different materials, at an equivalent depth, induces a rapid decrease in the confidence attributed to the boreholes. Therefore, more credibility is given to the geophysical information source, explaining the greater presence of 4, which reflects the gradual transitions in electrical resistivities. The masses associated with this event, however, remain relatively small. On the other hand, if two consecutive boreholes have the same geotechnical values, for a specific depth, the lateral decay rate will be low and no priority can be given to a different material existing between these two boreholes. That is why the sand anomaly in the center of the model does not appear in the results fusion with two soundings (Figures 17.iv.c) : no

borehole pass through the anomaly and the geophysical source is unable to characterize this material as saturated sand. The strength of these results is that they suggest the presence of 4 in this location, suggesting that the survey campaign should be reinforced (with a new borehole position for example).

The conflict presented by Smets combination (results in Figures 17.i.a, ii.a, iii.a and iv.a) is neither a function of the number of geotechnical soundings. In this study, the cases of fusion bringing the highest amount of conflict are in fact the ones with eight and two soundings. Nor is it to be confused with a lack of knowledge of the subsoil. Conflict zones highlight contradictory information between the two sources. These zones are generally between two consecutive boreholes providing the same information, but going against the available geophysical information. These are therefore potentially anomalous zones where the geophysical information must be considered carefully, in particular if the belief mass associated with the event retained after normalization is too low.

### Important considerations and potential in the application

It is important to consider that the effectiveness of this fusion methodology has been assessed by comparing the fusion results with a target model (Figure 15). However, this remains an idealized representation of the test bench set up and could be, in some places, quite far from reality (real interfaces not perfectly horizontal or vertical, materials not perfectly homogeneous, 3D effects neglected, ...). The approach is different from the one of the synthetic study (Figure 4) where the

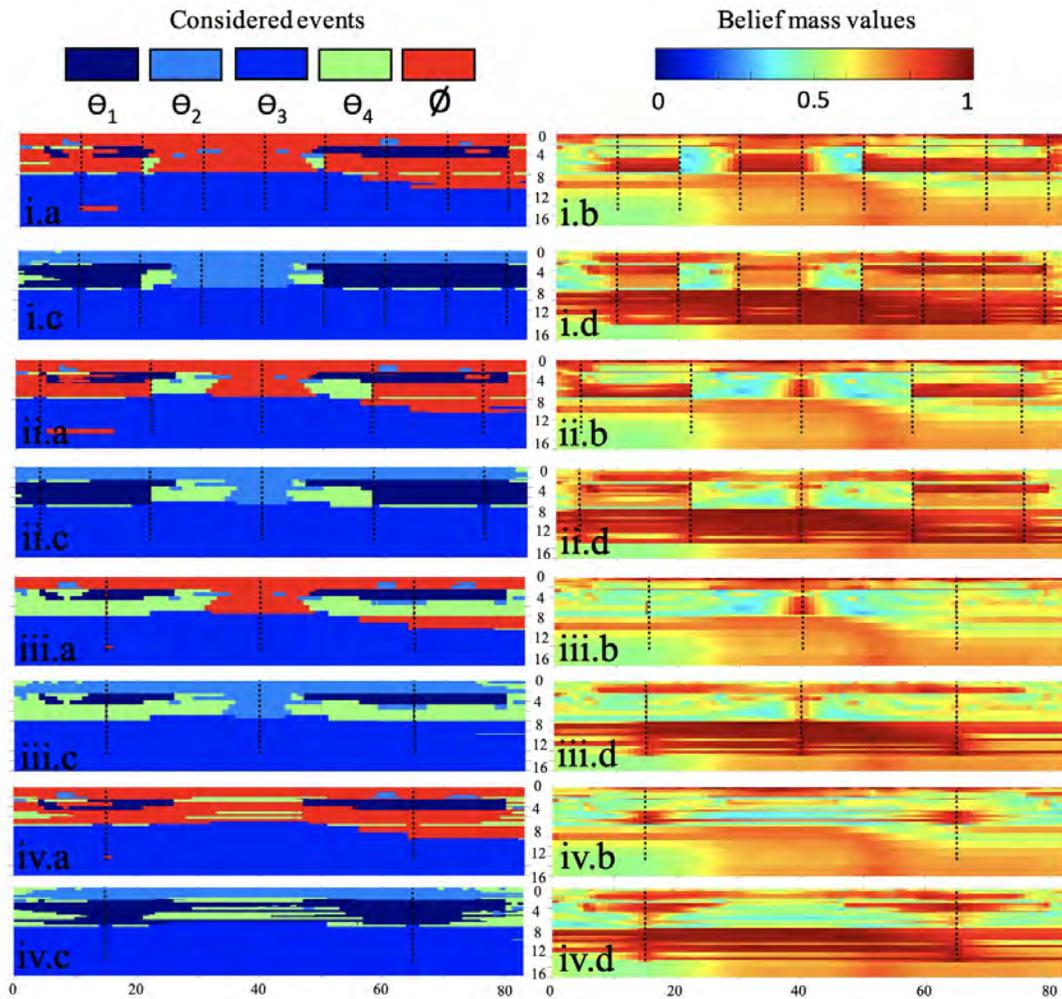

Fig. 17. Representation of the events having the highest belief mass in a) and c) and their associated mass values in b) and d). For i) 8 boreholes, ii) 5 boreholes, iii) 3 boreholes, iv) 2 boreholes are considered. For each case, (a,b) figures are results of Smets fusion, while (c,d) figures are results of PCR6 fusion. The borehole positions are in dashed lines.

model shown corresponds to the true model. In order to control the effectiveness of the fusion methodology, it was envisaged to carry out ex post verifications of the constituent materials. Unfortunately, for practical reasons, this could not be done (reworking of materials modifying their physical properties, interaction with water, delicate cutting and extraction, ...).

Regarding the fusion methodology developed, two aspects are debatable. First, the choice to set a mass of belief equal to 1 on the geotechnical information in the boreholes. Second, the effect of different random draw results on the fusion results. The choice of a maximum punctual confidence ( $m = 1$ ) in boreholes is defended in order to give a full and local confidence to geotechnical information as it is currently done during investigation campaigns. Excessive risks are not taken since the test bench is relatively well known and the synthetic model is perfectly well known. Thus, it is sure that simulated borehole values refer to the right materials. Furthermore, a value of  $m = 0.99$  instead of  $m = 1$ , for instance, does not significantly change the results and does

not change the interpretation and the resulting discussion. Regarding the effect of random draws, these draws were done following a normal distribution, the variations from one draw to another are minimal and the results of fusion differ little.

Such an information fusion algorithm, dedicated to the combination of data from geophysical and geotechnical sources, should prove useful for processing of data acquired during investigation campaigns for many different kinds of issues. It is possible to envisage its use with a larger number of materials, but also, and especially, with a larger number of data types from geophysical methods (seismics, ground penetrating radar) and geotechnical testing methods (penetration cone, core sampling with laboratory identification, permeability tests, ...) associated.

In the framework of a recognition campaign, the conflict zones, or zones with a low associated confidence, would make it possible to specify the locations where the investigation must be reinforced. The ultimate goal is to obtain a more robust and cost-effective diagnosis of the investigated structure, more

targeted for geotechnical investigation. This methodology has particularly shown its ability to correctly characterize interfaces, which corresponds to areas where the risk of instability is potentially the greatest. For a levee embankment issue, for example, the results from such a methodology could come to feed into models of breakage risks (ex: CARDigues [35]).

## VII. CONCLUSION

In this work, a new methodology has been presented, based on belief functions to take benefit and to combine two different and complementary kinds of information: geophysical and geotechnical. Each one having its own spatial distribution and related uncertainties and inaccuracies. A new representation of the information has been proposed, taking into consideration two different investigation methods, associated with degrees of belief. This representation is more informative than data superposition of different physical parameters.

In the first place, this new approach has been validated with a synthetic study, simulating data acquired by ERT and a CPT method, considering a 2D model with two layers and thickness variation. The results were obtained with different noise ratios applied to the geophysical data and different values of lateral decay coefficient for the geotechnical information. The most appropriate value to pick up for the coefficient has been pointed out and it has been showed that this approach was able to manage the noise ratio, thanks to the use of Wasserstein distances.

In order to address the problem of combining information acquired by geophysical and geotechnical methods during investigation campaigns, and to acquire values from real devices, a test bench composed of plaster and saturated sands was set up. The methods used to characterize such a physical model were the ERT method (geophysical) and the laboratory penetration cone method (geotechnical). While the data has been acquired by a dedicated small scale ERT device, on the surface and on the central line of the complete model, borehole were simulated respecting the penetration depth ranges previously established.

Fusion results were proposed following 2 combination rules (Smets and PCR6) as well as for four different simulations of number and positions of boreholes. The results highlighted the ability of this fusion approach to correctly characterize the test bench materials as well as to specify the positions of the interfaces (vertical and horizontal) between the materials. Moreover, for each result, thanks to a graphical representation, the associated confidence is proposed.

Further research should include cases of material mixtures and cases of different materials sharing common ranges of physical properties in order to test the ability of this methodology to differentiate them. We also wish to test this new methodology in real investigation campaigns in order to improve the available knowledge and strengthen the characterization. The level of confidence associated with the proposed results may be very relevant for decision support (eg models of failure hazards). The results of such a methodology should make it possible to propose the most relevant borehole

positions (that are a function of conflictual and anomalous areas), in order to make the quality of the information more cost-effective.

## ACKNOWLEDGMENTS

We would like to thank Quiterie Forquenot de la Fortelle and Gautier Gugole for their precious help throughout the experimental phase and also would like to thank the *Région Pays de la Loire* for their financial support.

**Abstract**—In this paper, a dual iris authentication using Dezert-Smarandache theory is presented. The proposed method consists of three main steps: In the first one, the iris images are segmented in order to extract only half iris disc that contains relevant information and is less affected by noise. For that, a Hough transform is used. The segmented images are normalized by Daugman rubber sheet model. In the second step, the normalized images are analyzed by a bench of two 1D Log-Gabor filters to extract the texture characteristics. The encoding is realized with a phase of quantization developed by J. Daugman to generate the binary iris template. For the authentication and the similarity measurement between both binary irises templates, the hamming distances are used with a previously calculated threshold. The score fusion is applied using DSMT combination rule. The proposed method has been tested on a subset of iris database CASIA-IrisV3-Interval. The obtained results give a satisfactory performance with accuracy of 99.96%, FAR of 0%, FRR of 3.89%, EER of 2% and processing time for one iris image of 12.36 s.

**Keywords:** Biometric, Iris, Authentication, Dezert-Smarandache theory.

## I. INTRODUCTION

When individuals log onto computers, or access an ATM, or pass through airport security, they have to reveal their identities. For this, individuals use passwords, ATM cards, and passports to prove their identities. However, passwords can be forgotten, and ATM cards or passports can be lost or stolen. In contrary, the biometric modalities (Fingerprint, face, iris, etc) speak to what and they also allow to prove our identity.

However, the unimodal biometric systems using one biometric modality for recognition cannot guarantee at present an excellent recognition rate. Furthermore, these systems suffer from limitations such as sensitivity to noise, data quality, non-universality, and spoof attacks. To overcome these problems, Multimodal biometric systems, which combine multiple biometric modalities, have been developed on purpose to achieve a better recognition rate.

The popular fusion method of the biometric traits can be done at two stages of recognition system:

### A. Fusion at feature extraction level

The data is acquired from each sensor is utilized to generate a feature vector. Then, the features are fused to form one feature vector.

### B. Fusion at matching score level

The matching score of each system is combined and compared with the stored template.

We use as a modality for recognition of individuals: iris, since their texture is

- Stable throughout the life of a person, unlike the fingerprint.
- Unique for each person, unlike a facial feature in identical twins.
- Unfalsifiable contrary to the characteristics of the voice.
- Iris is an internal organ well protected from the external environment, but nevertheless measurable, in a rather little invasive way, by simple image acquisition.

Daugman's algorithm [1] is one of the best iris algorithm known in biometrics. The algorithm consists of segment iris using Integro-Differential Operator and iris normalization is implemented using Daugman's polar representation. Then, iris encoding is applied using 2D Gabor filters to extract a binary code of 256 bytes. The Matching is processed by computing similarity between two iris codes using Hamming distance. The more Hamming distance is small, the more both codes are similar. A distance of 0 corresponds to a perfect match between both iris images, while two iris images of different person will have a Hamming distance close to 0.50. In 1997, Wildes [2] proposed a novel iris recognition system compared to Daugman algorithm [1]. The acquisition of iris is done by a CCD Camera in low luminosity. Then, the iris is segmented using Circular and Elliptic Hough transform and is normalized using a transformation function of pixels. After that, the iris is filtered by Laplacian of Gaussian filters with four different resolution levels. A normalized correlation is calculated for every resolution levels. The median of the values of correlations is computed for the filtered image. The fusion of four values is applied using Fisher's linear discriminant.

In 1998, W. Boles and B. Boashash [3], presented a new algorithm for recognition of individuals from iris images. The algorithm is insensitive to variation in the lighting conditions and noise levels. A Median filter is used for preprocessing. The advantage of this technique is to extract a features vector from 1D signals rather than 2D images analyzed in [1], [2] using zero-crossings of the dyadic wavelet transform at various resolution levels. Only a few selected intermediate resolutions

are used for matching. The matching is applied using different dissimilarity functions. Thus, make the algorithm faster and less sensitive to noise and quantification error.

In 2004, Ma et al. [4] presented an efficient algorithm for iris recognition. The iris is segmented by Canny filter and Hough transform. Then, the iris is normalized by histogram equalization. After that, A 1D Wavelet Transform is used to represent resulting 1D intensity signals. The position of local sharp variation points is registered as features. The matching is effectuated using the similarity function (exclusive or operation). This algorithm is efficient and faster than Daugman's algorithm [1].

In [5], the researchers proposed a modified Masek approach and a comparative study of the performance of the following methods: radial segmentation, Masek segmentation approach, modified Masek approach. The proposed method tested on Casia Iris Database V3 showed a good performance in terms of accuracy and processing time.

R. Biswas [6] has introduced an iris recognition system that includes different steps: segmentation, normalization, feature extraction, and classification. The segmentation of the pupil is performed by the Hough transform. Experimental results showed a recognition rate of 92%.

In [7], the authors proposed an iris recognition system based on "Fractal dimension of the box-counting method". First, the iris is segmented by Hough transform and is normalized by Daugman's rubber sheet model. Then, the feature extraction is processed by box counting. Finally, the matching is established using K-nearest Neighbor and Euclidean distance. Experiments tested on Casia Interval V4 database showed a good recognition rate equal to 92.63%.

D. Bobeldyk and A. Ross [8] have developed a method for predicting eye color from NIR iris images. Researchers have shown that a texture based approach based on the BSIF is more efficient than the intensity based approach based on raw pixel values. Experiments tested on the BioCOP database showed a good recognition rate of 90%. The BSIF distinguished "light color iris" and "dark color irides" using the SVM classifier.

The authors [9] presented a new method of classifying faked iris images of different patterns such as printed irises, contact lenses. The new classification method learns different characteristics of faked iris images by CNN and identifies legitimate and faked iris images using "Hierarchical Multi-Class". The tests carried out on the different databases: ND-contact, Casia-Iris-Interval and Casia-Iris-Syn, LivDet-Iris-2017-Warsaw showed a recognition rate equal to 100% and FAR = 0%, FRR = 0%.

H.G. Daway et al. [10] presented a new method for detecting the pupil. The method involves several steps, the most important of which depends on the difference in color and intensity between the pupil and its neighborhood. These characteristics are very important to locate and extract the pupil. Thus, the pupil is a region of very high intensity (color) compared to its neighborhood. The experimental results showed a recognition rate equal to 100%.

In purpose to improve overall performance in terms of recognition rate and mitigate errors, the researchers have used more than one biometric trait, and thus, the multibiometric systems have emerged. Numerous multi-biometric systems have been developed, which fusion is made at Matching score.

In [11], the researchers proposed a new approach for recognition using both irises. The iris is segmented using the Canny filter and Hough transform, then the segmented iris is normalized by J. Daugman's rubber sheet model. The iris feature extraction is carried out using convolution of the normalized iris with 1D Log-Gabor filters then the phase of filtered iris is quantized in order to generate a binary code. The Hamming distance is used for Matching. The Matching operation consists in comparing the two iris feature vectors of a person with the others; if the Hamming Distances are less than the threshold then the person is identified. The experimental results showed a good recognition rate equal to 99.92% with an FRR = 9.96%, while for unimodal systems (left iris and right iris) the recognition rate is equal to 99.87% with an FRR = 14.62% and FPR = 15.68%.

In [12], the authors presented the framework for multi-modal biometric fusion based on the uncertainty concept of Dempster-Shafer theory. A combination of quality measures and the accuracy of classifiers (equal error rate) are proposed to encode the uncertainty concept to improve the fusion. The proposed method revealed a good performance with an EER equal to 1%.

R. Dwivedi and S. Dey [13] proposed a cancelable multi-biometric system using score level fusion. The fusion of scores was applied by MC weighting at first level and RA weighting at the second level. The comparative analysis shows that the proposed fusion method outperforms the existing weighting approaches.

In this works, we extract only the interior half of the iris disc rather than the whole iris disc, which contains the most relevant information and it is less affected by noise. In addition, we combined two sources of information (left iris and right iris) with a high degree of conflict using Dezert-Smarandache Theory, which solves the problem of highly re-distributed masses conflicts arising under the Dempster Shafer theory.

The reminder paper is organized as follows: the research method is described in section II, Results and Analysis are presented in section III, conclusions are provided in section IV.

## II. RESEARCH METHOD

The key idea of our work is to extract only the discriminant information from iris texture and proposes Dezert-Smarandache Theory (DSMT) at score level fusion to operate under uncertainty in goal to achieve a good performance.

The proposed method is composed of four main stages: preprocessing, feature extraction, fusion, and matching.

### A. Preprocessing stage

First, the iris images require going through the preprocessing phase including segmentation and normalization.

1) *Iris segmentation*: The segmentation of iris is realized by commonly Edge detector method: Hough transform.

- HOUGH TRANSFORM ALGORITHM
- Generate edge map using the Canny filter.
- Canny parameters: the standard deviation of Gaussian smoothing filter:  $\sigma = 2$ ; weighting for vertical gradients = 0; weighting for horizontal gradients=1.
- Increase contrast in dark iris region. image gamma value: enhance the contrast of bright regions:  $\gamma = 1.9$ .
- Detect pixel corresponding to the local maxima Distance in pixel units to be looked at on each side of each pixel when determining, whether it is a local maximum or not:  $d = 1.5$ .
- Binarize iris image using Hysteresis thresholding. Low threshold  $T_1 = 0.19$ . High threshold  $T_2 = 0.20$ .

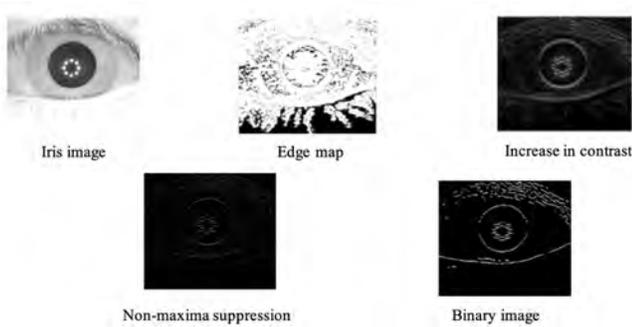

Figure 1. Different step of Hough Transform.

Then, a Circular Hough Transform detects at first the iris/sclera boundary and the iris/pupil boundary. The eyelashes are detected by global thresholding ( $T = 100$ ).

In this work, the objective is to extract only relevant information from iris, which is represented by the structural variation of the iris texture (high gradient areas), only the internal half of the iris disc is exploited rather than whole, because it contains the most relevant information [14] and it is less affected by the noise as shown in Figure 2. Indeed, the proposed technique decreases the complexity and the computation load without losing information (as shown in Table I).

$$r_{\text{half of iris disc}} = r_{\text{pupil}} + (r_{\text{iris}} - r_{\text{pupil}})/2 \quad (1)$$

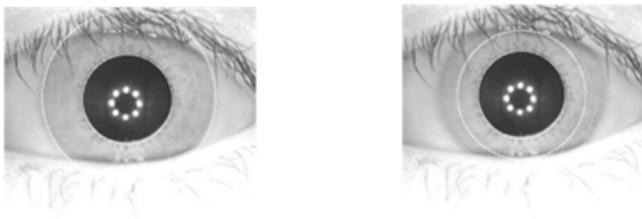

Figure 2. Delimitation of only the internal half of iris disc.

Table I  
COMPARISON: TOTAL IRIS DISC VS HALF IRIS DISC.

	Accuracy (%)	Processing time for one iris image (s)
Total iris disc	99.87	22.88
Half iris disc	99.96	12.36

From Table I, we denote that treatment using only half iris disc is more efficient with an accuracy of 99.96% and processing time for one iris image of 12.36 s than the treatment using a whole iris disc with accuracy 99.87% of and processing time of 22.88 s.

2) *Iris normalization*: The iris disc does not always have the same dimension, even for eye images of the same person; this is due to various problems as follows:

- a) Different acquisition conditions of the eye images. Dilation and contraction of the pupil due to the variation of the illumination level.
- b) The circles of iris and pupil are not concentric.

In order to overcome these problems, a stage of normalization is applied. It consists of transforming the region of the iris disc to rectify the dimensions of all the iris discs, by using the homogenous rubber sheet model proposed by Daugman [1]. It transforms each point in the iris area to the polar coordinates  $(r, \theta)$ , where  $r$  is on the interval  $[0, 1]$ , and  $\theta$  is an angle in  $[0, 2\pi]$ , as illustrated in Figure 3.

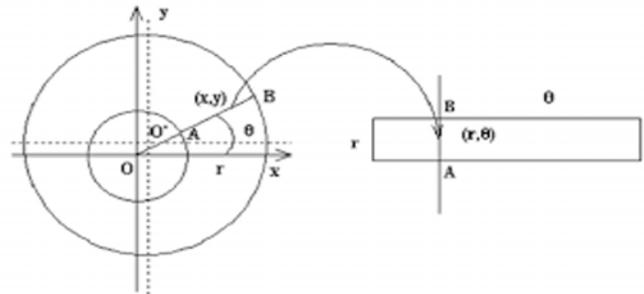

Figure 3. Daugman rubber sheet model [1].

In our system,  $(20 \times 240)$  points were used, but only  $(10 \times 240)$  points corresponding to the internal half of the iris disc that contains the most relevant information and which is less affected by noise, are retained for the next steps of the processing, as shown in Figure 4.

Figure 4. Normalization of the segmented iris.

### B. Feature extraction stage

After that, the feature extraction stage is applied in purpose to extract the most discrimination information present in the iris region. For this reason, a bench of two 1 D Log-Gabor filter is used.

### 1) 1D Log-Gabor filter:

- The Fast Fourier Transform is applied for each line of the normalized matrix image (FFT to 1D signals).
- Then, the Inverse Fast Fourier Transform IFFT is applied on the multiplication FFT (1D signals) by a 1D Log-Gabor Filter.
- The frequency response of a 1D Log-Gabor filter is given by:

$$G(f) = \exp\left(-\frac{\log(f/f_0)^2}{2 \times \log(\sigma/f_0)^2}\right) \quad (2)$$

#### Parameter setting:

- A bench of two 1D Log-Gabor filters is used.
- The standard deviation of the 1D Log-Gabor wavelet is given by  $\sigma = 2$ .
- The center frequency of the 1D Log-Gabor wavelet is given by  $f_0 = 0.05$ .

Indeed, the phase of a filtered image was quantized using four-quadrants of Daugman [1], when going from one quadrant to an adjacent quadrant, one bit is changed as shown in Figure 5.

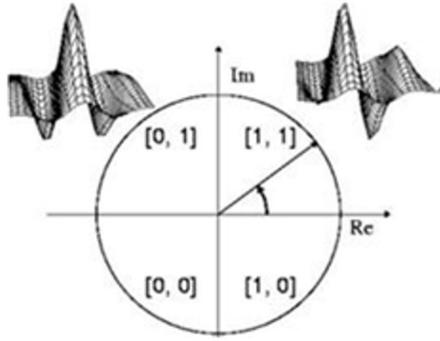

Figure 5. Quantization Phase [1].

The encoding process produces a bitwise template containing a number of information bits (as shown in Figure 6), the total number of bits in the template (9600 bits) will be the angular resolution (240) times the radial resolution (10), times 2, times the number of filters used (2).

Figure 6. Quantization Phase [1].

### C. Matching stage

The matching score comes before Fusion stage. It consists in comparing two iris code using Hamming distance. The Hamming Distance (HD) is defined by:

$$HD = \sum_{j=1}^N X_j \oplus Y_j \quad (3)$$

where  $X_j$  and  $Y_j$  are the two bitwise iris code,  $N$  is the number of bits in each iris code, and  $\oplus$  is xor operation.

Literally, the Hamming distance calculates the number of different and valid bits for the two iris code between  $X_j$  and  $Y_j$ .

The number of translation bits that compensates the rotation of the iris needs to be fixed. We applied a translation of the iris code in an interval  $[-3,+3]$  bits. We take into consideration the minimum Hamming distance.

### D. Fusion stage

In this stage, score level fusion using Dezert-Smarandache theory (DSMT) was applied on a goal to improve the performance of the dual iris system.

1) *Score level fusion:* Matching score level fusion combines the scores generated by multiple classifiers relating to the left and right iris to affirm the veracity of the claimed identity.

The Dezert-Smarandache theory operates under hyperpower set  $D^\Theta$ . Thus, DSMT is able to function properly not only with the unions but also with intersections. DSMT Classic has combination rule [15],[16] and [17]:

$$m(C) = \sum_{A \cap B = C} m_1(A)m_2(B); A, B \in D^\Theta, \forall C \in D^\Theta \quad (4)$$

#### Example

$$\Theta = \{S_{\text{left}}, S_{\text{right}}\},$$

$$\Theta = \{\emptyset, S_{\text{left}}, S_{\text{right}}, S_{\text{left}} \cup S_{\text{right}}, S_{\text{left}} \cap S_{\text{right}}\},$$

where

$\emptyset$ : Empty set;

$S_{\text{left}}$ : Hypothesis assuming that two individuals have same left iris;

$S_{\text{right}}$ : Hypothesis assuming that two individuals have a same right iris;

$S_{\text{left}} \cup S_{\text{right}}$ : Hypothesis assuming that two individuals have the same iris;

$S_{\text{left}} \cap S_{\text{right}}$ : Hypothesis assuming that two individuals have different iris.

### E. Decision

The decision is made by fixing a threshold. The two irises compared will be considered as belonging to the same person if the calculated score is inferior to a threshold.

## III. RESULTS AND ANALYSIS

### A. Simulation environment

The proposed method has been tested on a subset of iris database CASIA-IrisV3-Interval [18] in order to evaluate its performance in authentication mode. The subset contains 1180 eye images of 118 individuals (classes), and each individual has five iris samples for the left eye and five iris samples for the right eye.

**B. Performance metrics**

- False Reject Rate (FRR): also known as Type I error, is the measure of the probability that the biometric security system will incorrectly reject an access attempt by an authorized user;
- False Accept Rate (FAR): also known as Type II error, is the measure of the probability that the biometric security system will incorrectly accept an access attempt by an unauthorized user;
- EER (Equal Error Rate): The EER is the operating point for which the False Reject Rate (FRR) is equal to the False Accept Rate (FPR).

**C. Decidability**

Decidability [1] is the best metric which indeed takes into account the mean and standard deviation of the intra-class and inter-class distributions:

$$d' = \frac{|\mu_s - \mu_d|}{\sqrt{\frac{\sigma_s^2 + \sigma_d^2}{2}}} \tag{5}$$

Decidability  $d'$  is a distance in standard deviations calculated using (7), which is a function of the magnitude of the difference between the mean of the intra-class distribution  $\mu_s$ , and the mean of the inter-class distribution  $\mu_d$ , the standard deviation of the intra-class and inter-class distributions,  $\sigma_s$ , and  $\sigma_d$  respectively.

Table II  
DECIDABILITY TABLE FOR VARIOUS NUMBERS OF BIT-SHIFTS.

Numbers of shifts	$\mu_s$	$\sigma_s$	$\mu_d$	$\sigma_d$	$d'$
0	0.3300	0.0723	0.4914	0.0284	3.4314
1	0.3137	0.0697	0.4860	0.0279	3.8149
2	0.3072	0.0668	0.4812	0.0269	4.0264
3	0.3044	0.0653	0.4772	0.0258	4.0742
4	0.3032	0.0646	0.4738	0.0247	4.0431
5	0.3028	0.0642	0.4709	0.0238	3.9907
6	0.3025	0.0639	0.4684	0.0230	3.9362
7	0.0637	0.0642	0.0223	0.0216	3.8862
8	0.3023	0.0635	0.4645	0.0216	3.8303
9	0.3022	0.0634	0.4629	0.0211	3.7999
<b>10</b>	<b>0.2758</b>	<b>0.0639</b>	<b>0.4643</b>	<b>0.0201</b>	<b>4.3960</b>

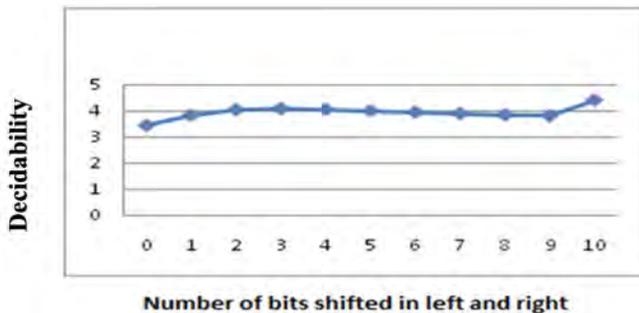

Figure 7. Decidability curve for various numbers of bit-shifts.

Using Equation (7), several different decidabilities are found out using 0-bit shift to 10-bit shift towards both left and right iris templates.

The higher decidability is equal to 4.3960 at 10 bit shift (as shown in Table II and Figure 7) that guarantees good separation of intra-class and inter-class distributions, which allows for more accurate recognition.

**D. Score level fusion**

In fact, we calculated the fusion score  $S_f$  using Hamming distances obtained by comparing the individuals from their iris

- $HD_L$ : Hamming distance obtained by comparing the individuals from their left iris;
- $S_L$ : Score obtained by comparing the individuals from their left iris;
- $HD_R$ : Hamming distance obtained by comparing the individuals from their right iris;
- $S_R$ : Score obtained by comparing the individuals from their right iris.

Accuracy=100*((TP+TN)/(nbintera+nbinter))
    
```

where \* is the product operator of two numbers.

The dual iris system using DSMT at score level fusion reaches an accuracy rate of 99.96% and FAR of 0%, FRR of 3.89%, EER of 2% as shown in Figure 8 and Figure 9.

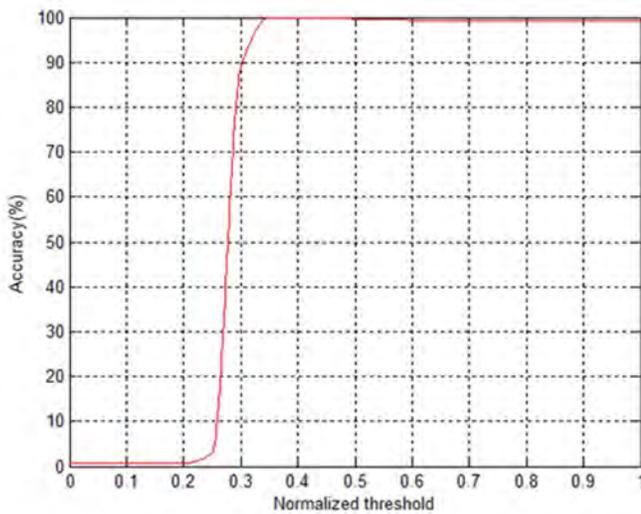

Figure 8. The accuracy of the dual iris system.

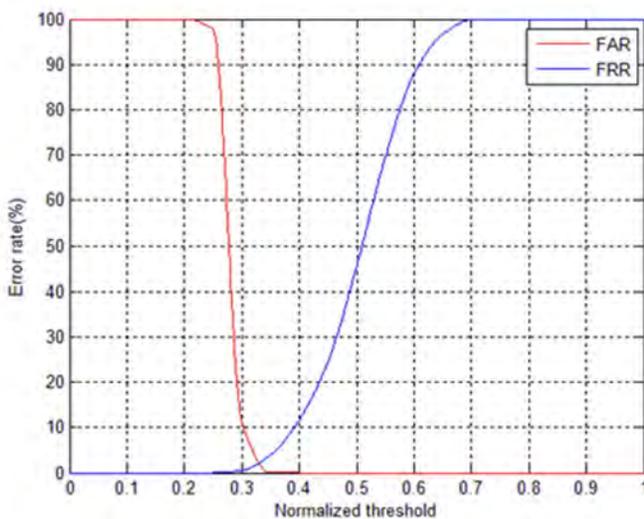

Figure 9. FRR and FAR of the dual iris system.

We conclude from Figure 10 that the ROC (Receiver Operating Characteristic) of dual iris system using DSMT at score level fusion fit the origin, which proves the performance of our method.

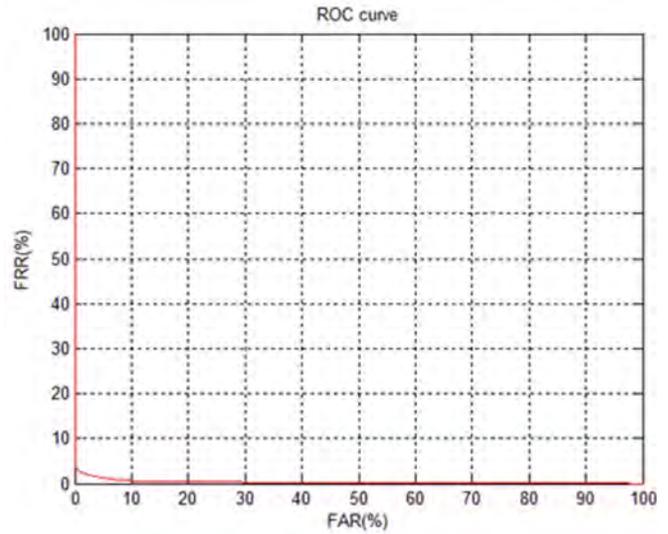

Figure 10. ROC of the dual iris system.

#### E. Comparison of various approaches

We denote from Table III, that the proposed dual iris authentication system gives a competitive performance with an accuracy of 99.96%, FAR of 0%, FRR of 3.89%, EER of 2% in comparison with other approaches. The problem of Dempster Shafer theory used in DST approach [12] (EER of 1%) that consists of combining two sources of information with a high degree of conflict is resolved. The proposed method is based on Dezert-Smarandache Classic rule (DsmC) that solves this problem. Iftakhar and al [11] used the fusion method based on the AND rule that gives an accuracy of 99.92%, FAR of 0%, FRR of 9.96%, which is more drastic and leads to improve the FAR. R. Dwindi and S. Dey obtained less performance in term of accuracy equal to 98.89%, EER of 0.69%, which used a score fusion methods likes MC weighting and RA weighting. These two methods using for optimization gives a little improvement to the performance of the system.

#### IV. CONCLUSION

The purpose of this work was to find out a dual iris authentication system that guarantees good performance and to make sure that there is no false acceptance rate, which promises useful security applications. The proposed method consists in segmenting, to normalizing, characterizing and encoding the iris. For the segmentation part, the detection of the iris/pupil circles was performed by Hough circular transform. Only the interior half of the iris disc containing the most relevant information and less affected by noise, which reduces time complexity was extracted. Iris normalization part was performed by the Daugman rubber sheet model with a

Table III  
DECIDABILITY TABLE FOR VARIOUS NUMBERS OF BIT-SHIFTS.

Iris Reco. System	Accuracy (%)	FAR (%)	FRR (%)	EER (%)
Iftakhar & Ashraful approach [11]	99.92	0	9.96	-
DST [12]	-	-	-	1
Dwivedi & Dey approach [13]	98.89	-	-	0.69
Proposed dual iris authentication system	99.96	0	3.89	2

resolution of  $10 \times 240$ . This stage was analyzed by the bench of two 1D Log-Gabor filters to extract the texture characteristics and the encoding was realized with a phase of quantization developed by J.Daugman to generate the binary iris template. For the authentication and the similarity measurement between both binary irises templates, the hamming distances are used with a previously calculated threshold. The score fusion is applied using Dezert-Smarandache Classic (DSmC) rule. The experiment tested on Casia-iris v3-interval shows that the proposed system gives a good performance compared to others approaches with an accuracy of 99.96%, FAR of 0%, FRR of 3.89%, EER of 2% and processing time for one iris image of 12.37 s.

Originally published as: M. Fidali, W. Jamrozik, *Method of Classification of Global Machine Conditions Based on Spectral Features of Infrared Images and Classifiers Fusion*, Quantitative InfraRed Thermography Journal, Vol. 16(1), pp. 129–145, 2019, and reprinted with permission.

**Abstract**—This paper describes an original method of global machine condition assessment for infrared condition monitoring and diagnostics systems. This method integrates two approaches: the first is processing and analysis of infrared images in frequency domain by the use of 2D Fourier transform and a set of  $F$ -image features, the second uses fusion of classification results obtained independently for  $F$ -image features. To find the best condition assessment solution the two different types of classifiers,  $k$ -nearest neighbours and support vector machine (SVM), as well as data fusion method based on Desert Smarandache theory have been investigated. This method has been verified using infrared images recorded during experiments performed on laboratory model of rotating machinery. The results obtained during the research confirm that the method could be successfully used for identification of operational conditions that are difficult to be recognized.

**Keywords:** classification, decision fusion, PCR6, infrared image analysis, Fourier Analysis, infrared thermography, condition base monitoring.

## I. INTRODUCTION

Infrared thermography is a modern and popular technique for thermal condition monitoring of machinery, apparatus and industrial processes [1].

Infrared cameras can be used in continuous condition monitoring systems for contactless detection and identification of object faults at its early stage, which is useful for planing object maintenance and overhauls.

Continuous condition monitoring system based on infrared device should include infrared image processing and recognition to classify the current operation condition of the object. Research connected with the application and development of infrared image processing and analysis, as well as artificial intelligence methods, to continuous thermographic objects monitoring and diagnostics has been carried out in several different academic and research centres [2], [3] and also by the authors [4]. In this article an original method of object condition identification, which can be used in continuous condition monitoring and diagnostics systems, has been proposed.

The method can be generalised to any diagnostic data acquired during continuous monitoring of different objects or industrial processes.

## II. METHOD

It has been assumed that the assessment of the general condition of an object could be determined on the basis of the analysis of infrared images that are acquired continuously by monitoring system during an object operation.

For a clear description of the method, let us assume that diagnosed object is a complex machinery containing several sub-assemblies (e.g. motor, couplings, journal bearing, pump, etc.).

Having acquired an infrared image of machinery in any moment of its operation, it is possible to define regions of interests (ROIs) containing only important parts of the diagnosed object. In such a way, the rest of the image content could be treated as an unwanted background that is not considered during the diagnostic process.

In the proposed method, whose brief algorithm is presented in (Fig. 1), each defined region of interest contained a sub-

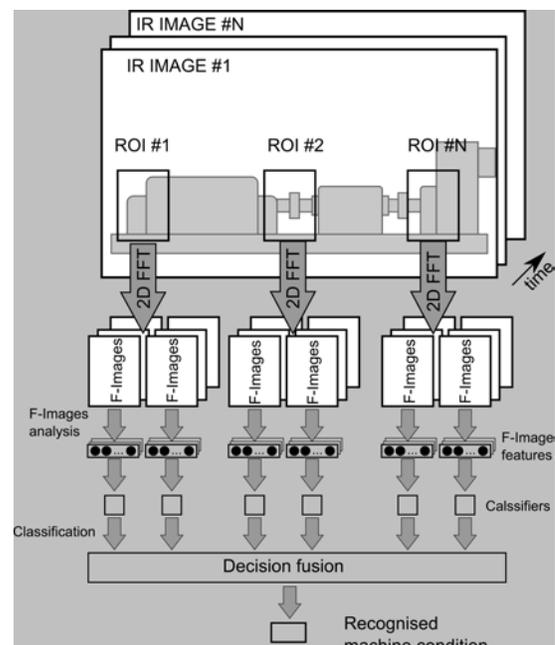

Figure 1: Idea of the method of identification of object conditions based on infrared images.

assembly of the machinery that could be treated as a kind of sub-image. Each sub-assembly in a different way reflects the machine's conditions, thus analysis of the sub-images of sub-assemblies allows us to acquire partial diagnostic information about global conditions of an object. Process of analysis of each sub-image gives sets of features that represent the condition of each machine sub-assembly at the moment of its operation corresponding to the time of infrared image acquisition. The local conditions of the sub-assemblies are related to the machine's global condition.

Having determined the feature vectors for infrared images acquired during machine operation in different conditions (including faults), it is possible to design a set of local classifiers that allow us to identify conditions of the machinery. At this stage, the classifiers could be treated as local experts.

Local diagnostic information provided by each classifier can be joined together to get information about global (overall) machinery condition. In the elaborated method, to aggregate diagnostic decisions and maximize final classification performance, application of decision fusion methods were used.

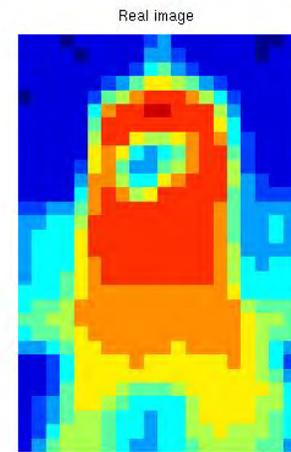

#### A. Processing and analysis of infrared images

The versatile nature of developed method allows us to apply different image processing and analysis methods to obtain a features set. For method verification purposes, the authors decided to use spectral representation of infrared images. Spectral representation of infrared images is obtained by use of the two-dimensional Fourier transform. One of the reasons of application of the 2D Fourier transform is a shift invariant property [5], which makes the method less sensitive to deviation in location of imaging device while observing an object. Spectral representation of infrared image could also emphasises diagnostic information that could be hidden in the real image.

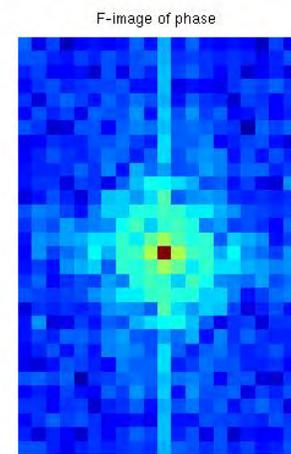

The result of Fourier transform of an infrared image is a two-dimensional spectrum, which could be represented by two images of magnitude and phase called also  $F$ -images. Frequency components on the  $F$ -images are distributed symmetrically and in many cases of the analysis it is enough to consider one quarter of the magnitudegrams and/or two adjacent quarters of the phasegrams. In most considered cases, the entire  $F$ -image is shown and analysed [4], [5]. This approach is most convenient for  $F$ -image interpretation purposes because frequency components generates specific symmetrically distributed patterns (similar to stars) (c.f. Fig. 2), whose shapes and locations depend on a content of the original infrared image.

To analyse the  $F$ -images, the three following features are defined:

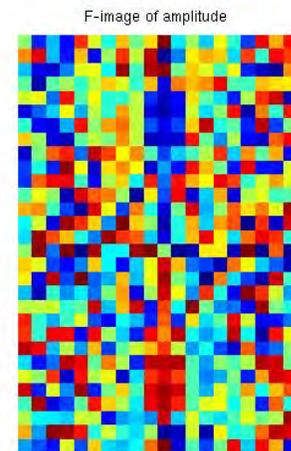

- HFP* Horizontal  $F$ -image Parameter,
- VFP* Vertical  $F$ -image Parameter,
- CFP* Circular  $F$ -image Parameter.

(a) Infrared image

(b)  $F$ -image of magnitude

(c)  $F$ -image of phase

Figure 2: An exemplary infrared image (a) and its  $F$ -images of magnitude (b) and phase (c) obtained on the basis of 2D Fourier analysis.

The features are mean values of  $F$ -images frequency components calculated over rectangular and circular areas, placed in the centers of the  $F$ -images in the way presented in Fig. 3. The dimensions of areas that were used to calculation of feature values were set experimentally (c.f. III-A)

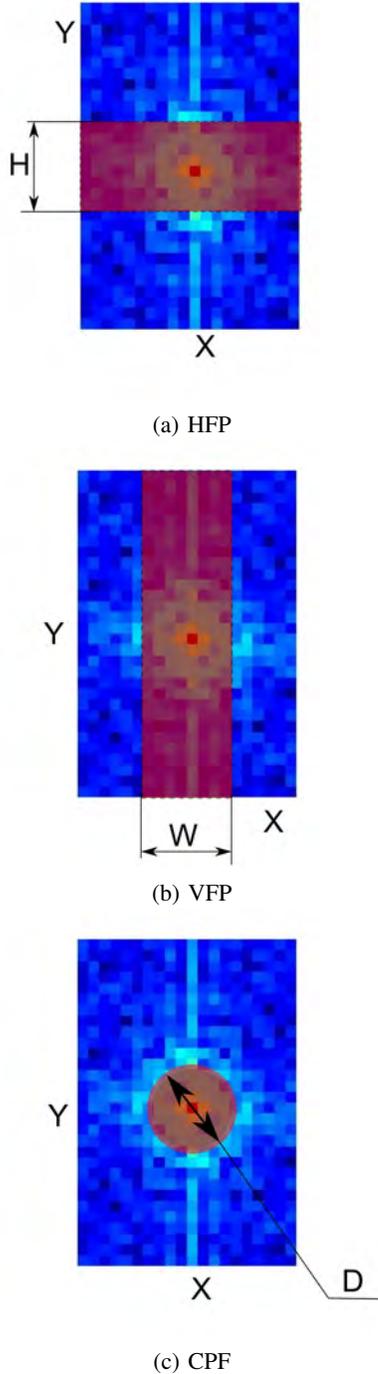

Figure 3: Graphical illustration of considered features of  $F$ -images.

### B. Classification of the machine's conditions

To classify machine operation conditions, a number of possible approaches could be chosen [6]. In practice, the choice of a classifier is a difficult problem and it is often based on a data specificity, as well as a researcher's experience.

The authors decided to apply two classifiers: a simple  $k$ -Nearest Neighbour ( $k$ -NN) classifier [7] and Support Vector Machine (SVM) [8], which is recognised as a very effective classification solution.

The author's intention was to show how to use the method and how the different classifiers behave.

To obtain a reliable and certain classification efficiency, the *leave-one-out* cross-validation (LOOCV) algorithm [9] has been applied.

The LOOCV validation method has a high variance but estimates of generalization error are comparable with other partitioning schemes used for classification efficiency evaluation [10].

The classifier accuracy measure that we used was the relative number of misclassification, which is calculated as follows:

$$err = N_e/N, \quad (1)$$

where  $N$  was the number of considered samples and  $N_e$  was the number of misclassified samples. On the basis of the  $err$  measure, the classifier efficiency was calculated in the following way:

$$eff = (1 - err) \cdot 100 \%. \quad (2)$$

### C. Decision fusion

In the elaborated method, joining of the classification results is proposed. There are some methods which allow treatment of the data jointly [11]. One of the interesting approaches is a decision fusion.

Decision fusion, which is also called classifier fusion, is the method that combines results of classification obtained from different classifiers trained over different types of data gathered from the same object. In this approach, classifiers are treated as "local experts", who make decision about the machine's condition.

The use of classifiers in technical diagnostic is connected with the uncertainty of the data on which those classifiers are trained. The sources of uncertainty could take the following form, for example, [12]: random events, measurement deviations, incompleteness of the set of considered diagnostic parameters and lack of knowledge about diagnosed object or process.

In general, most types of uncertainty could be characterised by the use of classical probability theory based on the Bayesian theorem [13], [14].

An alternative to the Bayesian methods is the Dempster-Shafer Theory (DST), also called the mathematical theory of evidence. The DST can deal with imprecise or incomplete data. In addition, DST can be interpreted as a generalisation of probability theory where probabilities are assigned to multiple

possible events (e.g. sets of events) as opposed to mutually exclusive singletons [15], [16].

The DST theory offers very important mechanisms of information aggregation coming from multiple sources by the use of rules for combining evidences. A lot of rules have been developed since establishing the DST.

Several interesting examples, including a detailed analysis of validity of Dempster's combination rule in different contexts, can be found in [17]–[19].

A generalisation and in some points an extension of the Dempster-Shafer evidence theory is The Dezert-Smarandache Theory (DSmT) [20] of plausible and paradoxical reasoning. DSmT overcomes some limitations of DST [20], [21] because it allows us to formally combine any kind of information. DSmT bases itself on similar terms as DST. The DSmT introduces the generalised frame of discernment  $\Theta$ , which contains  $n$  exhaustive elements  $(\theta_1, \dots, \theta_n)$ . In the classification case, elements of  $\Theta$  are all considered classes (class labels).

On the basis of the generalised frame of discernment, hyper-power set  $D^\Theta$  can be created of all single class labels but also of allowed class labels logical combinations. This means that classification can not only be made for single classes but the tested sample can also be assigned simultaneously to several classes ( $\theta_i \cap \theta_k \neq \emptyset$ ) or there can be some uncertainty in the reasoning process and the same test sample can be member of one or other class ( $\theta_i \cup \theta_k \neq \emptyset$ ). Each of these combinations is called focal element. For each element of  $D^\Theta$ , a Generalized Basic Belief Assignment (GBBA) is possible. In other words, as the result of classification some belief is assigned for test sample  $x$  that is a member of certain classes, several classes or there is some doubt to which class it should be assigned. From the formal site:  $m(\cdot) : D^\Theta \rightarrow [0, 1]$  so GBBA can take values from 0 to 1, and if  $m_x(A) = 1$  there is 100% belief that test element  $x$  belongs to class  $A$ . In contrast, for empty set - e.g.. unknown class  $m(\emptyset) = 0$ . Belief assigned to all elements of  $D^\Theta$  should sum up to 1:  $\sum_{A \in D^\Theta} m(A) = 1$ . This means that in the frame of discernment,  $D^\Theta$  tested elements are for sure member of one of classes or class combinations defined by  $D^\Theta$ ; so, no other unknown classes are allowed.

Similarly to DST, the DSmT also allows to aggregate information with the use of combination rules. For this purpose, many combination rules have been elaborated [20], [22]. During the research, a PCR6 rule was used. The key idea of the PCR6 rule is to transfer the partial conflicting Basic Belief Assignment *BBA* proportionally to the individual *BBA* of non-empty elements involved in the conflict [23].

#### D. GBBA calculation

The calculation of evidence is crucial for classifier fusion based on the methods demanding the *BBA* or the *GBBA* for each class [24], [25].

A simple method, which is ideal for research at the preliminary stage, has been developed for the evidence calculation from *k*-NN classifiers [26]. To obtain the output for a given sample, a set of distance measures to a number of known samples is calculated and it can be regarded as a class

distribution. Identification of  $k$  nearest neighbours of a element  $x$  irrespective of class label is made. Then, the number of neighbours  $k_i$  supporting assignment of element  $x$  to class  $C_i$  is calculated. Accordingly, the *GBBA* function of class  $C_i$  is calculated as follows [26]:

$$m(\{C_i\}) = k_i/k \quad (3)$$

In case of SVM classifier, which unfortunately gives only class labels, the probabilities of class distribution were obtained applying extension introduced by Wu [27]. In the presented research, we deal with only one occurring condition at the time, therefore probabilities are very useful. It can be assumed that SVM classifier outputs are degrees of support for each class representing identified machine conditions. These outputs can be directly transformed into mass assignments:  $p_i \rightarrow m(i)$ , where  $p_i$  is the probability of condition  $i$  occurrence and  $m(i)$  is the belief that condition  $i$  occurred provided by single SVM classifier on the basis of available evidence (in a form of feature space).

### III. METHOD VERIFICATION

Our method verification considers several different aspects of the method's application. First of all, verification should confirm that method can be useful in condition monitoring of machinery. The second important task of verification was to indicate what kind of classifier should be used and what is the best way to perform data fusion. To do this, we use two earlier described classifiers and compare results of classification obtained by use of single classifiers with results of classifier fusion, as well as results of classification obtained for multidimensional space of features. Investigation helps us to find the best solution to an answer the question: is fusion of simple classifiers a better solution than application of the classifier to single or multidimensional space of features?

The method was verified on the basis of digital infrared images taken during diagnostic experiments. All of our computations were performed using Matlab 2007b software.

#### A. Considered experimental data

The experiments have been performed using a laboratory stand that consists of a laboratory model of rotating machinery and an infrared imaging system (Fig. 4).

During the experiment, a sequence of 840 infrared images of resolution  $320 \times 480$  pixels has been recorded. The thermographic images have been taken every 30 s. The images have represented the machine operating in the conditions presented in the table I.

For reference, condition S1 decided to record two times more images to make it easier to recognise by classifiers. It should be pointed out that conditions S2, S3 and S4 are difficult to distinguish and have been simulated intentionally to check whether it was possible to notice a small change in operational condition. Such small changes were also desirable for testing the ability of the classifiers to recognise nearly indistinguishable changes in the machine's condition.

Table I: Description of conditions simulated during the experiment.

Condition Id	Description of fault	No of acquired images
S1	machine without faults	240
S2	50% throttling of air pump	120
S3	90% throttling of air pump	120
S4	90% throttling of air pump and clearance of second bearing mounting	120
S5	load of disk brake	120
S6	faulty bearing no 2	120

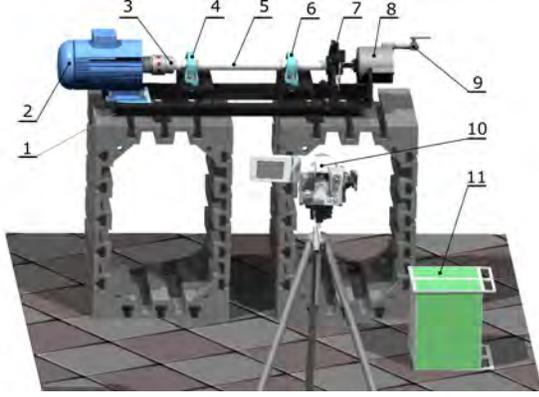

Figure 4: Visualisation of the laboratory stand. 1-frame, 2-motor (1.5 kW, 2500 rpm), 3-coupling, 4-bearings set no 1, 5-shaft, 6-bearings set no 2, 7-break set, 8-air pump, 9-throttle valve, 10-infrared camera connected to PC, 11-motor controller.

The infrared images acquired during the experiment have been pre-processed. The first step of the pre-processing was the selection of two Regions of Interest of size  $20 \times 30$  pixels (ROI1 and ROI2) (Fig. 5). These ROIs represented the bearing housings. It was expected that changes in the machine's condition would affect changes of bearing temperature and should be revealed in the infrared images.

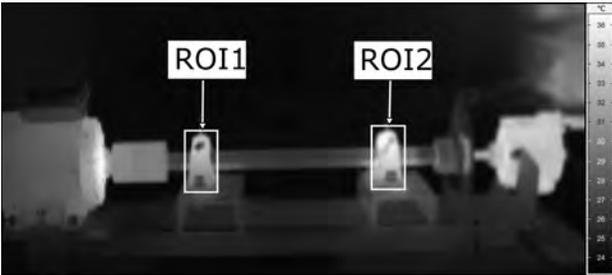

Figure 5: Infrared image of the operating laboratory stand, with marked ROIs of the first (left, ROI1) and the second (right, ROI2) bearings.

According to the proposed method (c.f. II), sub-images corresponding to regions of interest (ROI1 and ROI2) were transformed to frequency domain using Fast Fourier Transform (FFT) algorithm.  $F$ -images (magnitude and phase) obtained after transformation was analysed and image features were

calculated. Each infrared image was represented by 12 features, whose names were coded in the following way:

EstimatorId\_FImageType\_ROIID

e.g. HFP\_P\_R1 means that the value of the feature HFP was calculated for  $F$ -image of phase determined in ROI1.

It is obvious that values of presented  $F$ -image features depend on dimensions and content of the region of interest (ROI), as well as type of  $F$ -image (magnitude and phase). To consider a variety in content of each type of  $F$ -images, each of the proposed feature could be fitted to the image content by setting a value of the feature parameter  $W$ ,  $H$ , and  $D$ .

To find the optimal values of  $F$ -image feature parameters  $W$ ,  $H$ , and  $D$  an exhaustive search of feature space based on criterion of the maximum machine conditions classifier performance has been performed. Features have been calculated for each acceptable value of the feature parameters (from 1 to the maximal value  $H_{\max} = 30$ ,  $W_{\max} = 20$ , and  $D_{\max} = 20$ ). Constrains followed from the size ( $20 \times 30$  pixels) of the considered  $F$ -images.

For optimisation purposes, a k-Nearest Neighbour ( $k$ -NN) classifier was used. A number of nearest neighbours parameter was set to  $k = 10$  according to recommendations presented in [28]. Classification efficiency was calculated in the way presented in the theoretical background (c.f. II-B) and *leave-one-out* cross-validation (LOOCV) algorithm was used. Optimal values of feature parameters are presented in Tab. II.

Table II: Optimal values of feature parameters and basic statistics of classification efficiencies.

feat. num.	feat. name	estimator parameter name	estimator parameter value	mean eff [%]
1	ROI1_VFP_A	H	20	59.6
2	ROI2_VFP_A	H	18	80.6
3	ROI1_VFP_P	H	2	23.9
4	ROI2_VFP_P	H	7	25.2
5	ROI1_HFP_A	W	29	56.9
6	ROI2_HFP_A	W	26	80.8
7	ROI1_HFP_P	W	9	28.3
8	ROI2_HFP_P	W	9	24.3
9	ROI1_CFP_A	D	14	62.3
10	ROI2_CFP_A	D	20	75.6
11	ROI1_CFP_P	D	6	37.1
12	ROI2_CFP_P	D	6	43.4

The feature values, calculated using determined optimal parameters of  $F$ -image features, were data source for classification of machine conditions.

*B. Classification results for one and multidimensional feature space*

The first step of the method verification was assessment of application of one and multidimensional *F*-images feature space for purposes of classification of machine condition. As mentioned earlier, k-NN and SVM classifiers were applied. In case of k-NN classifier, a  $k = 10$  neighbours was used. The Euclidean distance function was used as a distance metric in k-NN classifier. In case of SVM classifier, one-against-all strategy is implemented for multi-class classification. A Gaussian kernel was applied. Mean classifier efficiencies of considered machine conditions as a function of feature space dimension were shown in Fig. 6. As one can expect, classification efficiency increase with size of feature space and for almost all conditions reach efficiency above 80% for size of feature space equal to 4 and more.

A detailed analysis of maximal classifier efficiencies is presented in Table III. The results show that in case of conditions S1, S3, S4, S5 and S6 maximum efficiencies could be achieved for one dimensional space of feature vales for both types of applied classifiers. Values of maximal classification efficiencies are given in bold. The highest classification effi-

ciency values have been obtained on the basis of CFP feature, which indicates its usefulness in analysing the *F*-images. The greatest number of maximum classification efficiency (100%) was obtained using the SVM classifier. SVM gave the best results for features of *F*-images of phase whereas k-NN gave good results for *F*-images of magnitude within the region of interest ROI2. Region ROI2 covered more load bearing support, which affected its highest temperature and thus intensive infrared radiation.

A plot of classification efficiencies for condition S2 presented in Fig. 6 and values in Table III clearly show that condition S2 is poor recognizable. Analysis of classification efficiencies for condition S2 shows that application of one dimensional feature space allowed to obtain maximal efficiency equals 58.3% with application of k-NN classifier. The SVM classifier was unable to correctly recognize condition S2, where SVM allowed to obtain maximal efficiency equal 8.3%.

Looking at feature values distribution for condition S2 presented in Figure 7, it is clear that SVM was unable to find proper global decision boundaries. Exemplary decision boundary for condition S2 vs all other conditions can be

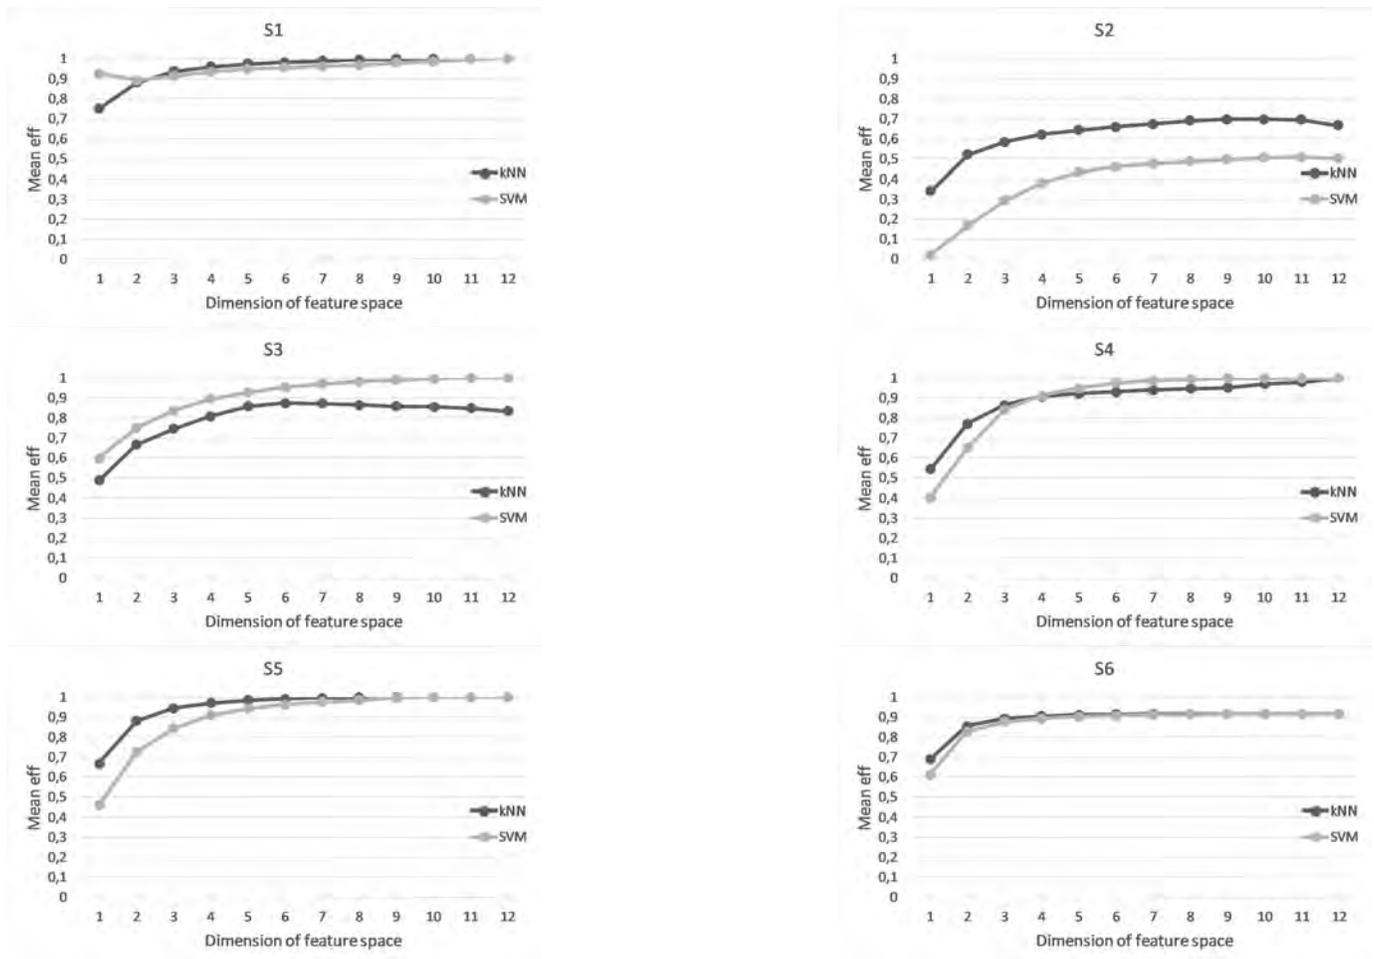

Figure 6: Evolution of the belief in a cell crossed by an obstacle observed by a sensor.

seen in Fig. 7. Taking into consideration the distribution of feature values for condition S2, the strategy of classification using SVM classifier with linear boundaries is insufficient to distinguish between S2 and other classes. Application of feature spaces dimensionality of 3-8 increase maximal classification performance of condition S2 which was, respectively, 83% for k-NN and 75% for SVM classifiers. Minimal space giving maximal classification performance with use of k-NN classifier was constructed with use of the following two sets of features:

$VFP\_P\_R2, HFP\_A\_R2, HFP\_P\_R2$  and  $VFP\_A\_R1, HFP\_P\_R2, CFP\_A\_R1$

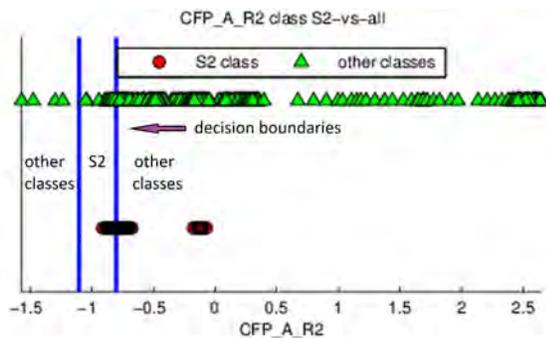

Figure 7: Distribution of CFP\_A\_R2 feature for condition S2.

To assess which classes are most similar a confusion matrix was prepared (Fig. 8). In each column there is percentage fraction of each class that was assigned to various predicted classes. Taking into consideration only single kNN classifiers, that were trained over 1D data set it can be seen, that conditions S2 and S3 are most difficult to distinguish. It is connected

with the way in which those conditions were simulated, when only degree throttling of air pump was changed.

Predicted class	Actual class					
	1	2	3	4	5	6
1	92.3	0.0	0.0	0.0	0.0	0.0
2	7.7	58.4	30.0	0.0	0.0	0.0
3	0.0	41.3	70.0	0.0	0.0	0.0
4	0.0	0.0	0.0	100.0	0.0	0.0
5	0.0	0.0	0.0	0.0	85.7	0.0
6	0.0	0.0	0.0	0.0	14.3	100.0

#### IV. CLASSIFIER FUSION RESULTS

Results of the classification of machine conditions shown in Section II-B, (Tab. III) indicate that the proposed features of the  $F$ -images are useful for assessing machine conditions. For the majority of concerned machine conditions, it was possible to obtain the maximum classification efficiency on the basis of selected individual features of  $F$ -images. However, for condition S2, reliable condition assessment was not possible. To increase classification efficiency, fusion of classifiers was applied. We carried out an exhaustive computation considered all combinations of two, three and four k-NN and SVM classifiers of all considered  $F$ -image features.

Mean classification efficiencies after classifier fusion as a function of number of fused classifier for all considered conditions are presented in Fig. 9. Table IV presents the highest classification efficiencies obtained for all condition after fusion of two, three and four combinations of different individual k-NN and SVM classifiers. Our results show that fusion of two classifiers is sufficient to obtain maximal classification almost for all conditions. Classifier fusion also allowed us to raise the highest classification efficiency for condition S2 by the 8.3% (from 58.3% to 66.7%) in comparison to the results obtained for the individual classifiers. The maximum efficiency of the classification was obtained as a result of the fusion of k-NN classifiers only. Fusion of the SVM classifiers does not ensure an increase of the classification efficiency for this class.

The most interesting observation made after the analysis of classification performances is the lack of an increase of the efficiency for the condition S2 according to the number of fused single classifiers. This is caused by the presence of the classifiers that assign the high degree of belief to the wrong states. Fusing more than two classifiers did not cause an increase of the relative number of classifier combinations giving maximal performance. These results find confirmation

Table IV: Comparison of maximal classification efficiencies for all conditions after fusion different numbers of single kNN and SVM classifiers using PCR6 rule.

Fuzz. Class. #	Class. Type	Simulated machine conditions					
		S1	S2	S3	S4	S5	S6
2	kNN(.)	100	66.7	100	100	100	100
	SVM(.)	100	8.3	100	100	100	100
3	kNN(.)	100	66.7	100	100	100	100
	SVM(.)	100	8.3	100	100	100	100
4	kNN(.)	100	66.7	100	100	100	100
	SVM(.)	100	8.3	100	100	100	100

in [29], which showed that adding additional experts at some point leads to obtaining totally conflicted and useless classifier combinations. Analysis of classifiers combinations giving the highest performances indicates that they are composed from complementary rather than individually best performing classifiers. Taking into account the obtained results, it can be concluded that the fusion of two selected classifiers is sufficient. In case of the considered data, a pair of classifiers assuring highest efficiency 66.7% was *HFP\_A\_R2, CFP\_A\_R1*.

Taking into consideration the very good results of

classification obtained for multidimensional feature spaces decided to perform fusion of kNN classifiers calculated for two dimensional feature spaces. As could have been expected, the results were very good (Table V). Maximal classification efficiency for condition S2 was increased to 83.3% for four following combination of classifiers and feature spaces:

- PCR6{kNN{VFP\_A\_R2,CFP\_A\_R2}},
- kNN{HFP\_P\_R2,CFP\_A\_R1}},
- PCR6{kNN{HFP\_P\_R2,CFP\_A\_R1}},
- kNN{HFP\_P\_R2,CFP\_A\_R2}},
- PCR6{kNN{HFP\_P\_R2,CFP\_A\_R1}},
- kNN{HFP\_P\_R2,CFP\_P\_R2}},
- PCR6{kNN{HFP\_P\_R1,CFP\_P\_R1}},
- kNN{HFP\_P\_R2,CFP\_A\_R1}}.

Its worth mentioning that maximal classification efficiency using single k-NN classifier for condition S2 with the use of three and four dimensional (3D and 4D) space of feature was also 83.3%. The presented results confirm the ability of decision fusion algorithms to identify machinery conditions which are difficult to be recognised. In contrast, the SVM classifier results for the 2D feature space was maximally

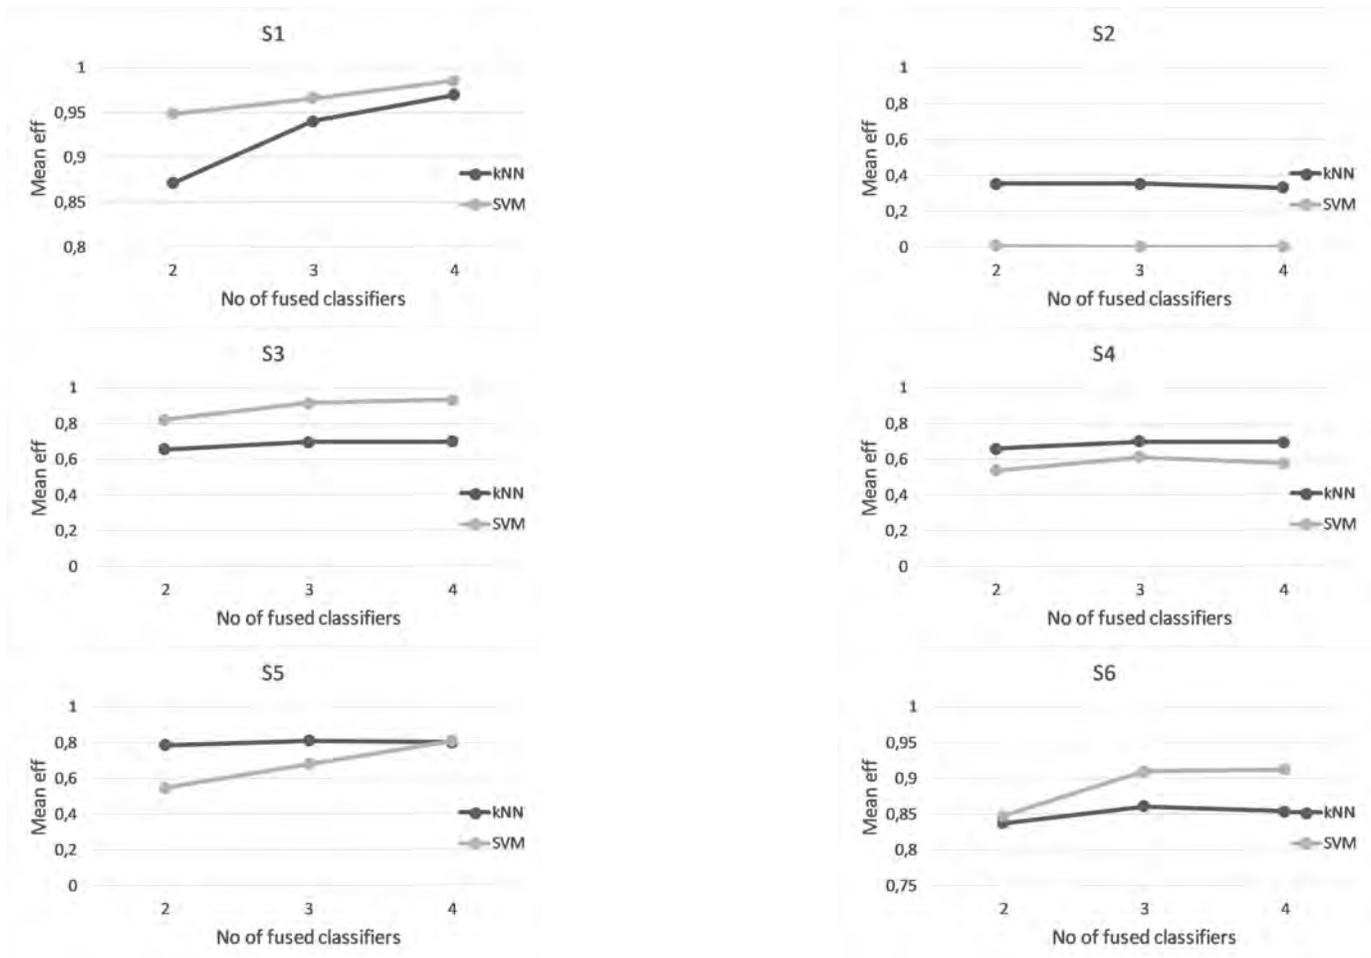

Figure 9: Plots of mean classification efficiencies as a function of different number of fused classifiers for considered machine conditions.

62.5%. Accordingly, the increase of classification performance in comparison to single feature space is visible and in this the kNN classifier was proven to be better than the SVM classifier.

Table V: Comparison of maximal classification efficiencies for all conditions fusion of 2 classifiers trained over 2D feature space.

Fuzz. Class. #	Class. Type	Simulated machine conditions					
		S1	S2	S3	S4	S5	S6
2	kNN(.)	100	83.3	100	100	100	100
	SVM(.)	100	62.5	100	100	100	100

## V. CONCLUSIONS

In this paper, the method of object condition assessment using multiple classifiers fusion approach based on the generalised evidence theory is proposed. Fused classifiers have been trained over the data represented by three parametric spectral features of  $F$ -images. The  $F$ -images were the result of the 2D Fourier transform of infrared images acquired during object observation. During the research, optimal parameters of the features were evaluated and  $F$ -image features were computed. Based on the spectral features of the infrared images the classification process was performed. For comparison purposes k-NN and SVM classifiers were used. The results of the classification have shown that the proposed features of an  $F$ -image of thermograms could be useful for the evaluation of a machine's condition. Circular Fourier Power (CFP) seemed to be suitable enough for the estimation of magnitude, as well as phase  $F$ -images.

The proposed approach of classifier fusion is suitable for the assessment of machine global condition on the basis of pre-selected features of spectral infrared images. Classification efficiencies obtained using classifier fusion are higher than those calculated taking into consideration a single classifier. It must be mentioned that features chosen for the member classifiers in fusion process should be heterogeneous to assure high classification efficiency. Moreover, the increase of the number of considered ROIs should entail a reduction of the uncertainty of the information, which is used in the decision making about the machine's global condition. Although the connection between diversity of features and the classification performance is not always straightforward, the analysis of the obtained results leads to the statement that in the considered case, the influence of feature heterogeneity degree on the fusion results is quite noticeable.

The problem of high homogeneity of data could be resolved by classification of multidimensional space of homogeneous feature values and the next application of the fusion of such a classifier. This strategy was verified during the presented research and the obtained results confirmed the ability of classifier fusion to increase classification efficiency of condition S2, which was difficult to recognise.

It can be expected that conclusions made from the research could be generalised to data represented by other infrared image features and diagnostic signals. However, it needs further investigation.

**Abstract**—In this paper we present an application of a new Belief Function-based Inter-Criteria Analysis (BF-ICrA) approach for Global Positioning System (GPS) Surveying Problems (GSP). GPS surveying is an NP-hard problem. For designing Global Positioning System surveying network, a given set of earth points must be observed consecutively. The survey cost is the sum of the distances to go from one point to another one. This kind of problems is hard to be solved with traditional numerical methods. In this paper we use BF-ICrA to analyze an Ant Colony Optimization (ACO) algorithm developed to provide near-optimal solutions for Global Positioning System surveying problem.

**Keywords:** Inter-Criteria Analysis, BF-ICrA, GPS surveying, PCR6, belief functions.

## I. INTRODUCTION

In our previous work [1] we did apply classical Atanassov's Inter-Criteria Analysis (ICrA) to examine some relations between considered GSP's and ACO algorithm performance. In this paper we consider a recent improved version of ICrA based on belief functions [2] and show how to apply it in same GSP problematic to revise and refine our previous analysis.

After a short presentation of GSP problematic and ACO in the next section, and brief basics of BF in section III, we recall the classical Atanassov's ICrA method in section IV and we present the new ICrA method based on Belief Functions, called BF-ICrA, in section V. In section VI, we show how to apply BF-ICrA for GSP problematic. Concluding remarks are given in Section VII.

## II. PRESENTATION OF ACO AND GSP PROBLEMATIC

### A. GPS surveying problem description

GPS satellites continuously transmit radio signals to the Earth while orbiting it. A receiver, with unknown position on Earth, has to detect and convert the signals received from all of the satellites into useful measurements. These measurements would allow a user to compute a three-dimensional coordinate position: location of the receiver. Any GPS observation is proven to have biases, hence, in order to survey an appropriate combination of measurement processing strategies must be used to minimize their effect on the positioning results. Differencing data collected simultaneously from two or more GPS receivers to several GPS satellites allows to eliminate or significantly reduce most of the biases. The GPS network

can be defined as set of stations  $(a_1, a_2, \dots, a_n)$ , which are co-ordinated by placing receivers  $(X_1, X_2, \dots)$  on them to determine sessions  $(a_1a_2, a_1a_3, a_2a_3, \dots)$  among them. The problem is to search for the best order in which these sessions can be organized to give the best schedule. Thus, the schedule can be defined as a sequence of sessions to be observed consecutively. The solution is represented by linear graph with weighted edges. The nodes represent the stations and the edges represent the moving cost. The objective function of the problem is the cost of the solution which is the sum of the costs (time) to move from one point to another one,  $C(V) = \sum C(a_i, a_j)$ , where  $a_i a_j$  is a session in solution  $V$ . For example if the number of points (stations) is 4, a possible solution is  $V = (a_1, a_3, a_2, a_4)$  and it can be represented by linear graph  $a_1 \rightarrow a_3 \rightarrow a_2 \rightarrow a_4$ . The moving costs are as follows:  $C(a_1, a_3), C(a_3, a_2), C(a_2, a_4)$ . Thus the cost of the solution is  $C(V) = C(a_1, a_3) + C(a_3, a_2) + C(a_2, a_4)$ . In practice, determining how each GPS receiver should be moved between stations to be surveyed in an efficient manner taking into account some important factors such as time, cost etc. The problem is to search for the best order, with respect to the time, in which these sessions can be observed to give the cheapest schedule or to minimize  $C(V)$ . The initial data is a cost matrix, which represents the cost (time, or distance) of moving a receiver from one point to another. Solving such problems - GSPs - to optimality requires a very high computational time. Therefore, meta-heuristic methods are used to provide near-optimal solutions for large networks within acceptable amount of computational effort. In this paper, we consider the Max-Min Ant System (MMAS) meta-heuristic [3] and we present it briefly in the next subsection.

### B. Ant colony optimization for GPS surveying problem

Real ants foraging for food lay down quantities of pheromone (chemical cues) marking the path that they follow. An isolated ant moves essentially at random but an ant encountering a previously laid pheromone will detect it and decide to follow it with high probability and thereby reinforce it with a further quantity of pheromone. The repetition of the above mechanism represents the auto-catalytic behavior of real ant colony where the more the ants follow a trail, the more attractive that trail becomes.

The ACO algorithm uses a colony of artificial ants that behave as cooperative agents in a mathematics space where they are allowed to search and reinforce pathways (solutions) in order to find the optimal ones. The problem is represented by graph and the ants walk on the graph to construct solutions. The solution is represented by path in the graph. After initialization of the pheromone trails, ants construct feasible solutions, starting from random nodes, then the pheromone trails are updated. At each step ants compute a set of feasible moves and select the best one (according to some probabilistic rules) to carry out the rest of the tour. The transition probability  $p_{ij}$ , to choose the node  $j$  when the current node is  $i$ , is based on the heuristic information  $\eta_{ij}$  and pheromone trail level  $\tau_{ij}$  of the move, where  $i, j = 1, \dots, n$ .

$$p_{ij} = \frac{\tau_{ij}^\alpha \eta_{ij}^\beta}{\sum_{k \in U_{\text{unused}}} \tau_{ik}^\alpha \eta_{ik}^\beta}. \quad (1)$$

The higher value of the pheromone and the heuristic information, the more profitable is to select this move and resume the search. In the beginning, the initial pheromone level is set to a small positive constant value  $\tau_0$  and then ants update this value after completing the construction stage. ACO algorithms adopt different criteria to update the pheromone level.

In our implementation we use MAX-MIN Ant System (MMAS) [3], [4], which is one of the best ant approaches. In MMAS the main is using fixed upper bound  $\tau_{max}$  and lower bound  $\tau_{min}$  of the pheromone trails. Thus accumulation of big amount of pheromone by part of the possible movements and repetition of same solutions is partially prevented. The main features of MMAS are:

The aim of using only one solution is to make solution elements, which frequently occur in the best found solutions, get large reinforcement. Pheromone trail update is given by:

$$\tau_{ij} \leftarrow \rho \tau_{ij} + \Delta \tau_{ij}, \quad (2)$$

where

$$\Delta \tau_{ij} = \begin{cases} 1/C(V_{best}) & \text{if } (i, j) \in \text{best solution,} \\ 0 & \text{otherwise,} \end{cases}$$

and  $V_{best}$  is the iteration best solution and  $i, j = 1, \dots, n$ .

To avoid stagnation of the search, the range of possible pheromone value on each movement is limited to an interval  $[\tau_{min}, \tau_{max}]$ .  $\tau_{max}$  is an asymptotic maximum of  $\tau_{ij}$  and  $\tau_{max} = 1/(1 - \rho)C(V^*)$ , while  $\tau_{min} = 0.087\tau_{max}$ . Where  $V^*$  is the optimal solution, but it is unknown, therefore we use  $V_{best}$  instead of  $V^*$ .

When all ants have completed their solutions, the pheromone level is updated by applying the global update rule. Only the pheromone corresponding to the best found solution is increased by the similar to the MMAS way. The global update rule is intended to provide a greater amount of pheromone on the paths of the best solution. It is a kind of intensification of the search around the best found solution.

We use heuristic information equals to one over the cost of the session.

### III. BASICS OF THE THEORY OF BELIEF FUNCTIONS

Let consider a finite discrete frame of discernment (FoD)  $\Theta = \{\theta_1, \theta_2, \dots, \theta_n\}$ , with  $n > 1$ , and where  $\theta_i \cap \theta_j = \emptyset$  for  $i \neq j$ . The power-set of  $\Theta$  (i.e. the set of all subsets of  $\Theta$ ) is denoted  $2^\Theta$ . A basic belief assignment (BBA) associated with a given source of evidence is defined [5] as the mapping  $m(\cdot) : 2^\Theta \rightarrow [0, 1]$  satisfying  $m(\emptyset) = 0$  and  $\sum_{A \in 2^\Theta} m(A) = 1$ . The quantity  $m(A)$  is called the mass of  $A$  committed by the source of evidence. Belief and plausibility functions are usually interpreted respectively as lower and upper bounds of unknown (possibly subjective) probability measure [6]. They are defined by<sup>1</sup>

$$Bel(A) \triangleq \sum_{B \subseteq A, B \in 2^\Theta} m(B), \quad \text{and} \quad Pl(A) \triangleq 1 - Bel(\bar{A}). \quad (3)$$

If  $m(A) > 0$ ,  $A$  is called a focal element of  $m(\cdot)$ . When all focal elements are singletons then  $m(\cdot)$  is called a *Bayesian BBA* and its corresponding  $Bel(\cdot)$  function is homogeneous to a probability measure. Historically the combination of BBAs is accomplished by Dempster's rule in Dempster-Shafer Theory (DST) [5]. Because of serious problems of Dempster's rule<sup>2</sup>, we recommend the Proportional Conflict Redistribution rule no. 6 (PCR6) proposed by Martin and Osswald in [10] (Vol. 3) which remains the most appealing alternative rule for BBA combination so far.

### IV. ATANASSOV'S INTER-CRITERIA ANALYSIS (ICRA)

Based on Intuitionistic Fuzzy Sets (IFS) [11], the Inter-Criteria Analysis (ICrA) has been introduced in 2014 by Atanassov et al. in [12], and then improved in [13], [15]. ICrA aims to identify the possible links between the criteria involved in a process of evaluation of multiple objects against multiple criteria. The aim of ICrA is to discover any existing correlations between the criteria themselves. Such analysis can permit (when possible) to reduce the complexity of large multiple criteria decision-making (MCDM) problems [2]. Until now the classical<sup>3</sup> ICrA has been applied in different fields: medicine [16], [17], optimization [18]–[21], workforce planning [22], competitiveness analysis [23], radar detection [24], ranking [25]–[27], etc. In this section we just recall the basic principles of classical ICrA.

Let consider a set of alternatives (or objects)  $\mathbf{A} \triangleq \{A_1, A_2, \dots, A_M\}$  ( $M > 2$ ), and a set of criteria  $\mathbf{C} \triangleq \{C_1, C_2, \dots, C_N\}$  ( $N \geq 1$ ). The available information is expressed by a  $M \times N$  score matrix<sup>4</sup>  $\mathbf{S} \triangleq [S_{ij} = C_j(A_i)]$ , and (eventually) the importance factor  $w_j \in [0, 1]$  of each criterion  $C_j$  with  $\sum_{j=1}^N w_j = 1$ . The ICrA method consists to build an  $N \times N$  Inter-Criteria (IC) matrix  $\mathbf{K}$  from the score matrix  $\mathbf{S}$ . The elements of the IC matrix  $\mathbf{K}$  consist of all Intuitionistic Fuzzy (IF) pairs  $(\mu_{jj'}, \nu_{jj'}) \in [0, 1] \times [0, 1]$  whose

<sup>1</sup>In the notations, the symbol  $\triangleq$  means *equal by definition*.

<sup>2</sup>that is: 1) insensitivity to the level of conflict between sources in some cases and dictatorial behavior [7], [8], and 2) inconsistency of Shafer's belief conditioning [9] with bounds of conditional probabilities.

<sup>3</sup>We refer Atanassov's ICrA as the classical approach in the sequel.

<sup>4</sup>also called benefit or payoff matrix in Multi-Criteria Decision-Making framework.

components express respectively the degree of agreement and the degree of disagreement between criteria  $C_j$  and  $C_{j'}$  for  $j, j' \in \{1, 2, \dots, N\}$ . For a given column  $j$  (i.e. criterion  $C_j$ ), it is always possible to compare with  $>$ ,  $<$  and  $=$  operators all the scores  $S_{ij}$  for  $i = 1, 2, \dots, M$  because the scores of each column are expressed in same unit. The construction of IC matrix  $\mathbf{K}$  can be used to search relations between the criteria because the method compares homogeneous data relatively to a same column. Atanassov in [14] prescribes<sup>5</sup> the normalization of the element  $S_{ij}$  of score matrix  $\mathbf{S}$  by taking

$$S_{ij}^{\text{norm}} = (S_{ij} - S_j^{\min}) / (S_j^{\max} - S_j^{\min}) \in [0, 1], \quad (4)$$

where

$$\begin{cases} S_j^{\min} = \min\{S_{1j}, \dots, S_{Mj}\}, \\ S_j^{\max} = \max\{S_{1j}, \dots, S_{Mj}\}. \end{cases} \quad (5)$$

The construction of the  $N \times N$  IC matrix  $\mathbf{K}$  is based on the pairwise comparisons between every two criteria along all evaluated alternatives. More precisely in [14] the degree of agreement between criteria  $C_j$  and  $C_{j'}$   $\mu_{jj'}$ , and their degree of disagreement  $\nu_{jj'}$  are calculated by

$$\mu_{jj'} \triangleq \frac{2K_{jj'}^{\mu}}{M(M-1)}, \quad \text{and} \quad \nu_{jj'} \triangleq \frac{2K_{jj'}^{\nu}}{M(M-1)}, \quad (6)$$

where  $K_{jj'}^{\mu}$  be the number of cases in which the inequalities  $S_{ij} > S_{i'j}$  and  $S_{i'j'} > S_{ij'}$  hold simultaneously, and  $K_{jj'}^{\nu}$  be the number of cases in which the inequalities  $S_{ij} > S_{i'j}$  and  $S_{i'j'} < S_{ij'}$  hold simultaneously.

By construction the IC matrix  $\mathbf{K}$  is always a symmetric matrix. Atanassov provides explicit formulas in [14] for  $K_{jj'}^{\mu}$  and  $K_{jj'}^{\nu}$ , which depend on a particular choice of the signum function. Because of this the results of  $K_{jj'}^{\mu}$  and  $K_{jj'}^{\nu}$  are disputable and that is why some authors [22], [28] propose other methods to calculate  $K_{jj'}^{\mu}$  and  $K_{jj'}^{\nu}$  values for making the Inter-Criteria Analysis.

Once the IC matrix  $\mathbf{K} = [K_{jj'}]$  of intuitionistic fuzzy pairs is calculated one needs to analyze it to decide which criteria  $C_j$  and  $C_{j'}$  are in strong agreement (or positive consonance) reflecting the correlation between  $C_j$  and  $C_{j'}$ , in strong disagreement (or negative consonance) reflecting non correlation between  $C_j$  and  $C_{j'}$ , or in dissonance reflecting the uncertainty situation where nothing can be said about the non correlation or the correlation between  $C_j$  and  $C_{j'}$ .

At the beginning of ICRA development it was not very clear how these intuitionistic fuzzy (IF) pairs  $(\mu_{jj'}, \nu_{jj'})$  had to be used and that is why Atanassova [29], [30] proposed to handle both components of the IF pair. For this, she interpreted pairs  $(\mu_{jj'}, \nu_{jj'})$  as points located in the elementary  $TFU$  triangle, where the point  $T$  of coordinate  $(1, 0)$  represents the maximal positive consonance (i.e. the true consonance), the point  $F$  with coordinate  $(0, 1)$  represents the maximal negative consonance (i.e. the falsity), and the point  $U$  with coordinates  $(0, 0)$  represents the maximal dissonance (i.e. the uncertainty). From this interpretation it becomes quite easy to identify the

top of consonant IF pairs  $(\mu_{jj'}, \nu_{jj'})$  that fall in bottom right corner of  $(TFU)$  triangle limited by vertical line from  $x$ -axis  $x = \alpha$ , and horizontal line from  $y$ -axis  $y = \beta$ , where  $\alpha$  and  $\beta$  are two ad-hoc threshold values in  $[0, 1]$ . The set of consonant IF pairs are then ranked according to their (Euclidean) distance  $d_{C_j C_{j'}}^T$  with respect to  $T$  point of coordinate  $(1, 0)$  defined by

$$d_{C_j C_{j'}}^T = d((1, 0), (\mu_{jj'}, \nu_{jj'})) = \sqrt{(1 - \mu_{jj'})^2 + \nu_{jj'}^2}. \quad (7)$$

It is worth noting that  $\mu_{jj'}$  and  $\nu_{jj'}$  values are in fact linked with belief function through the following formulas

$$Bel_{jj'}(\theta) = \mu_{jj'} \quad (8)$$

$$Pl_{jj'}(\theta) = 1 - \nu_{jj'}, \quad (9)$$

$$U_{jj'}(\theta) = Pl_{jj'}(\theta) - Bel_{jj'}(\theta) = 1 - \nu_{jj'} - \mu_{jj'}, \quad (10)$$

where  $\theta$  means: the criteria  $C_j$  and  $C_{j'}$  are totally positively consonant (i.e. totally correlated), whereas  $\bar{\theta}$  means: the criteria  $C_j$  and  $C_{j'}$  are totally negatively consonant (uncorrelated). The FoD is defined as  $\Theta \triangleq \{\theta, \bar{\theta}\}$ .  $U_{jj'}(\theta)$  represents the dissonance (the uncertainty about the correlation) of the criteria  $C_j$  and  $C_{j'}$ . From this, one can easily define any BBA  $m_{jj'}(\theta)$ ,  $m_{jj'}(\bar{\theta})$  and  $m_{jj'}(\theta \cup \bar{\theta})$  of  $2^\Theta$  by taking

$$m_{jj'}(\theta) = \mu_{jj'}, \quad (11)$$

$$m_{jj'}(\bar{\theta}) = \nu_{jj'}, \quad (12)$$

$$m_{jj'}(\theta \cup \bar{\theta}) = 1 - \mu_{jj'} - \nu_{jj'}. \quad (13)$$

**Remark 1:** The construction of the Inter-Criteria Matrix  $\mathbf{K}$  is not unique and depends on the choice of algorithm of construction of  $\mu_{jj'}$  and  $\nu_{jj'}$  (and the choice of the signum function) as reported in [28]. This can yield different ICRA results in general.

**Remark 2:** The construction of  $\mu_{jj'}$  and  $\nu_{jj'}$  appears to be only a crude approximation of true values because they are only based on counting the valid " $>$ " or " $<$ " inequalities. In fact, their calculations do not exploit how bigger and how smaller the scores values are in each comparison done. So it yields a lack of precision on estimation of  $\mu_{jj'}$  and  $\nu_{jj'}$  values.

ICRA can be very useful for verification of algorithm correctness. When the optimization problem have a lot of constraints with ICRA we can find if some of the constrain is subconstrain of some other and to exclude it. With the help of ICRA we can divide constraints to two or more groups, more sensitive and less sensitive and to solve problem first according more sensitive constraints and later to less sensitive ones. To circumvent the aforementioned drawbacks, we present succinctly in the next section a new ICRA approach based on belief functions which is presented in more details with examples in [2].

## V. A NEW ICRA METHOD BASED ON BELIEF FUNCTIONS

The new Belief Function based ICRA method, called BF-ICRA for short, presented in this section improves Atanassov's ICRA. It provides a more precise construction of  $\mu_{jj'}$  and  $\nu_{jj'}$  values because it exploits all available information included in the score matrix.

<sup>5</sup>Although this normalization is not very necessary in fact for ICRA making.

BF-ICrA starts with the construction of an  $M \times N$  BBA matrix  $\mathbf{M} = [m_{ij}(\cdot)]$  from the score matrix  $\mathbf{S} = [S_{ij}]$ . The elements  $m_{ij}$  of the BBA matrix  $\mathbf{M}$  are obtained as follows - see [31] for details and justification.

$$m_{ij}(A_i) = Bel_{ij}(A_i), \quad (14)$$

$$m_{ij}(\bar{A}_i) = Bel_{ij}(\bar{A}_i) = 1 - Pl_{ij}(A_i), \quad (15)$$

$$m_{ij}(A_i \cup \bar{A}_i) = Pl_{ij}(A_i) - Bel_{ij}(A_i), \quad (16)$$

where<sup>6</sup>

$$Bel_{ij}(A_i) \triangleq Sup_j(A_i)/A_{\max}^j, \quad (17)$$

$$Bel_{ij}(\bar{A}_i) \triangleq Inf_j(A_i)/A_{\min}^j, \quad (18)$$

with

$$Sup_j(A_i) \triangleq \sum_{k \in \{1, \dots, M\} | S_{kj} \leq S_{ij}} |S_{ij} - S_{kj}|, \quad (19)$$

$$Inf_j(A_i) \triangleq - \sum_{k \in \{1, \dots, M\} | S_{kj} \geq S_{ij}} |S_{ij} - S_{kj}|, \quad (20)$$

and

$$A_{\max}^j \triangleq \max_i Sup_j(A_i), \quad (21)$$

$$A_{\min}^j \triangleq \min_i Inf_j(A_i). \quad (22)$$

For another criterion  $C_{j'}$  and the  $j'$ -th column of the score matrix we will obtain another set of BBA values  $m_{ij'}(\cdot)$ . Applying this method for each column of the score matrix we are able to compute the BBA matrix  $\mathbf{M} = [m_{ij}(\cdot)]$  whose each component is in fact a triplet  $(m_{ij}(A_i), m_{ij}(\bar{A}_i), m_{ij}(A_i \cup \bar{A}_i))$  of BBA values in  $[0, 1]$  such that  $m_{ij}(A_i) + m_{ij}(\bar{A}_i) + m_{ij}(A_i \cup \bar{A}_i) = 1$  for all  $i = 1, \dots, M$  and  $j = 1, \dots, N$ .

The next step of BF-ICrA approach is the construction of the  $N \times N$  Inter-Criteria Matrix  $\mathbf{K} = [K_{jj'}]$  from  $M \times N$  BBA matrix  $\mathbf{M} = [m_{ij}(\cdot)]$  where elements  $K_{jj'}$  corresponds to the BBA  $(m_{jj'}(\theta), m_{jj'}(\bar{\theta}), m_{jj'}(\theta \cup \bar{\theta}))$  about positive consonance  $\theta$ , negative consonance  $\bar{\theta}$  and uncertainty between criteria  $C_j$  and  $C_{j'}$  respectively. The construction of the triplet  $K_{jj'} = (m_{jj'}(\theta), m_{jj'}(\bar{\theta}), m_{jj'}(\theta \cup \bar{\theta}))$  is based on two steps:

- **Step 1 (BBA construction):** Getting  $m_{jj'}^i(\cdot)$ .

For each alternative  $A_i$  for  $i = 1, \dots, M$ , we first compute the BBA  $(m_{jj'}^i(\theta), m_{jj'}^i(\bar{\theta}), m_{jj'}^i(\theta \cup \bar{\theta}))$  for any two criteria  $j, j' \in \{1, 2, \dots, N\}$ . For this, we consider two sources of evidences (SoE) indexed by  $j$  and  $j'$  providing the BBA  $m_{ij}$  and  $m_{ij'}$  defined on the simple FoD  $\{A_i, \bar{A}_i\}$  and denoted  $m_{ij} = [m_{ij}(A_i), m_{ij}(\bar{A}_i), m_{ij}(A_i \cup \bar{A}_i)]$  and  $m_{ij'} = [m_{ij'}(A_i), m_{ij'}(\bar{A}_i), m_{ij'}(A_i \cup \bar{A}_i)]$ . We also denote  $\Theta = \{\theta, \bar{\theta}\}$  the FoD about the relative state of the two SoE, where  $\theta$  means that the two SoE agree,  $\bar{\theta}$  means that they disagree and  $\theta \cup \bar{\theta}$  means that we don't know. Hence, two SoE are in total agreement if both commit their maximum belief mass to the same element  $A_i$  or to

the same element  $\bar{A}_i$ . Similarly, two SoE are in total disagreement if each one commits its maximum mass of belief to one element and the other to its opposite, that is if one has  $m_{ij}(A_i) = 1$  and  $m_{ij'}(\bar{A}_i) = 1$ , or if  $m_{ij}(\bar{A}_i) = 1$  and  $m_{ij'}(A_i) = 1$ . Based on this very simple and natural principle, one can now compute the belief masses as follows:

$$m_{jj'}^i(\theta) = m_{ij}(A_i)m_{ij'}(A_i) + m_{ij}(\bar{A}_i)m_{ij'}(\bar{A}_i), \quad (23)$$

$$m_{jj'}^i(\bar{\theta}) = m_{ij}(A_i)m_{ij'}(\bar{A}_i) + m_{ij}(\bar{A}_i)m_{ij'}(A_i), \quad (24)$$

$$m_{jj'}^i(\theta \cup \bar{\theta}) = 1 - m_{jj'}^i(\theta) - m_{jj'}^i(\bar{\theta}). \quad (25)$$

$m_{jj'}^i(\theta)$  represents the degree of agreement between the BBA  $m_{ij}(\cdot)$  and  $m_{ij'}(\cdot)$  for the alternative  $A_i$ ,  $m_{jj'}^i(\bar{\theta})$  represents the degree of disagreement of the two BBAs and  $m_{jj'}^i(\theta \cup \bar{\theta})$  the level of uncertainty (i.e. how much we don't know if they agree or disagree). By construction  $m_{jj'}^i(\cdot) = m_{jj'}^i(\cdot), m_{jj'}^i(\theta), m_{jj'}^i(\bar{\theta}), m_{jj'}^i(\theta \cup \bar{\theta}) \in [0, 1]$  and  $m_{jj'}^i(\theta) + m_{jj'}^i(\bar{\theta}) + m_{jj'}^i(\theta \cup \bar{\theta}) = 1$ . This BBA modeling permits to build a set of  $M$  symmetrical Inter-Criteria Belief Matrices (ICBM)  $\mathbf{K}^i = [K_{jj'}^i]$  of dimension  $N \times N$  relative to each alternative  $A_i$  whose components  $K_{jj'}^i$  correspond to the triplet of BBA values  $m_{jj'}^i = (m_{jj'}^i(\theta), m_{jj'}^i(\bar{\theta}), m_{jj'}^i(\theta \cup \bar{\theta}))$  modeling the belief of agreement and of disagreement between  $C_j$  and  $C_{j'}$  based on  $A_i$ .

- **Step 2 (fusion):** Getting  $\mathbf{m}_{jj'}(\cdot)$ .

In this step, one needs to combine the BBAs  $\mathbf{m}_{jj'}^i(\cdot)$  for  $i = 1, \dots, M$  altogether to get the component  $K_{jj'} = (m_{jj'}(\theta), m_{jj'}(\bar{\theta}), m_{jj'}(\theta \cup \bar{\theta}))$  of the Inter-Criteria Belief matrix (ICBM)  $\mathbf{K} = [K_{jj'}]$ . For this, we recommend to use the PCR6 fusion rule [10] (Vol. 3) because of known deficiencies of Dempster's rule. Because of computational complexity of PCR6 fusion rule when  $M$  becomes large, one may prefer to approximate the fusion result by using the simple averaging rule. Simple Matlab™code for PCR6 rule can be found in [32] for convenience.

The computational complexity of BF-ICrA is of course higher than the complexity of ICrA because it makes a more precise evaluation of local and global inter-criteria belief matrices with respect to IF inter-criteria matrices of ICrA. The overall reduction of the computational burden of the original MCDM problem thanks to BF-ICrA depends highly on the problem under concern, the complexity and cost to evaluate each criteria involved in it, as well as the number of redundant criteria identified by BF-ICrA method.

Once the global Inter-Criteria Belief Matrix (ICBM)  $\mathbf{K} = [K_{jj'} = (m_{jj'}(\theta), m_{jj'}(\bar{\theta}), m_{jj'}(\theta \cup \bar{\theta}))]$  is calculated, we can identify the criteria that are in strong agreement, in strong disagreement, and those on which we are uncertain. For identifying the criteria that are in strong agreement, we evaluate the distance of each component of  $K_{jj'}$  with the BBA representing the best agreement state and characterized

<sup>6</sup>assuming that  $A_{\max}^j \neq 0$  and  $A_{\min}^j \neq 0$ . If  $A_{\max}^j = 0$  then  $Bel_{ij}(A_i) = 0$ , and if  $A_{\min}^j = 0$  then  $Pl_{ij}(A_i) = 1$ .

by the specific BBA<sup>7</sup>  $m_T(\theta) = 1$ . From a similar approach we can also identify, if we want, the criteria that are in very strong disagreement using the distance of  $m_{jj'}(\cdot)$  with respect to the BBA representing the best disagreement state characterized by the specific BBA  $m_F(\bar{\theta}) = 1$ . We use the  $d_{BI}(\cdot, \cdot)$  distance presented in [33] for measuring the distance  $d(m_1, m_2)$  between the two BBAs<sup>8</sup>  $m_1(\cdot)$  and  $m_2(\cdot)$  over the same FoD. It is defined by

$$d_{BI}(m_1, m_2) \triangleq \sqrt{N_c \cdot \sum_{X \in \mathcal{E}^\Theta} d_W^2(BI_1(X), BI_2(X))}, \quad (26)$$

where the *Belief-Intervals* are defined by  $BI_1(X) \triangleq [Bel_1(X), Pl_1(X)]$  and  $BI_2(X) \triangleq [Bel_2(X), Pl_2(X)]$  and computed from  $m_1(\cdot)$  and  $m_2(\cdot)$  thanks to formula (3).  $d_W(BI_1(X), BI_2(X))$  is Wasserstein's distance between intervals calculated by

$$d_W([a_1, b_1], [a_2, b_2]) = \sqrt{\left[ \frac{a_1 + b_1}{2} - \frac{a_2 + b_2}{2} \right]^2 + \frac{1}{3} \left[ \frac{b_1 - a_1}{2} - \frac{b_2 - a_2}{2} \right]^2},$$

and  $N_c = 1/2^{|\Theta|-1}$  is a normalization factor to get  $d_{BI}(m_1, m_2) \in [0, 1]$ .

## VI. APPLICATION OF BF-ICRA TO GSP

In this section, we analyze the experimental results obtained using MMAS algorithm described in the previous section. For this, we use real data from Malta and Seychelles GPS networks composed of 38 sessions and 71 sessions respectively denoted GSP1 and GSP2. We use also 6 larger test problems range from 100 to 443 sessions denoted GSP3, ..., GSP8. The results are obtained by performing 30 independent runs, for every experiment. The details of our MMAS implementation are given in [1]. So in our GSP example we consider 8 GSP criteria  $C_i = GSP_i$ ,  $i = 1, \dots, 8$  and six average costs as results  $A_1, \dots, A_6$ , where  $A_1$  is the cost average for the first 5 runs,  $A_2$  the cost average for the first 10 runs,  $A_3$  for the first 15 runs, ... and finally  $A_6$  for all the 30 runs. Table I shows the values of averaged costs obtained for this problem. It corresponds to the transpose of the score matrix  $\mathbf{S}$ .

	$A_1$	$A_2$	$A_3$	$A_4$	$A_5$	$A_6$
$C_1 = GSP1$	899.00	898.00	898.33	898.50	899.40	899.50
$C_2 = GSP2$	916.40	915.60	922.47	924.80	924.72	922.07
$C_3 = GSP3$	41336.40	41052.40	40991.93	40935.90	40832.20	40910.60
$C_4 = GSP4$	3244.80	3303.30	3327.00	3344.55	3345.60	3341.93
$C_5 = GSP5$	1656.20	1660.80	1663.93	1664.95	1666.96	1665.90
$C_6 = GSP6$	1673.60	1683.50	1690.73	1688.75	1690.24	1692.67
$C_7 = GSP7$	3420.00	3430.70	3433.13	3426.85	3429.44	3428.57
$C_8 = GSP8$	3758.20	3755.70	3758.73	3760.50	3760.80	3765.80

Table I

TRANSPOSE OF THE SCORE MATRIX  $\mathbf{S} = [S_{ij}]$  OF GSP PROBLEM.

<sup>7</sup>We use the index  $T$  in the notation  $m_T(\cdot)$  to refer that the agreement is true, and  $F$  in  $m_F(\cdot)$  to specify that the agreement is false.

<sup>8</sup>Here we will take  $m_1(\cdot) = m_{jj'}(\cdot)$  and  $m_2(\cdot) = m_T(\cdot)$ , or  $m_2(\cdot) = m_F(\cdot)$

Hence in this problem  $M = 6$  and  $N = 8$ , and  $\mathbf{S} = [S_{ij}]$  is a  $6 \times 8$  score matrix. Based on classical ICRA approach, one gets the following IC matrices<sup>9</sup>

$$\mathbf{K}^\mu = \begin{matrix} & C_1 & C_2 & C_3 & C_4 & C_5 & C_6 & C_7 & C_8 \\ \begin{matrix} C_1 \\ C_2 \\ C_3 \\ C_4 \\ C_5 \\ C_6 \\ C_7 \\ C_8 \end{matrix} & \begin{bmatrix} 1 & 0.60 & 0.27 & 0.67 & 0.73 & 0.67 & 0.33 & 0.87 \\ 0.60 & 1 & 0.27 & 0.80 & 0.73 & 0.53 & 0.47 & 0.73 \\ 0.27 & 0.27 & 1 & 0.07 & 0 & 0.20 & 0.40 & 0.13 \\ 0.67 & 0.80 & 0.07 & 1 & 0.93 & 0.73 & 0.53 & 0.80 \\ 0.73 & 0.73 & 0 & 0.93 & 1 & 0.80 & 0.60 & 0.87 \\ 0.67 & 0.53 & 0.20 & 0.73 & 0.80 & 1 & 0.67 & 0.80 \\ 0.33 & 0.47 & 0.40 & 0.53 & 0.60 & 0.67 & 1 & 0.47 \\ 0.87 & 0.73 & 0.13 & 0.80 & 0.87 & 0.80 & 0.47 & 1 \end{bmatrix} \end{matrix}$$

$$\mathbf{K}^\nu = \begin{matrix} & C_1 & C_2 & C_3 & C_4 & C_5 & C_6 & C_7 & C_8 \\ \begin{matrix} C_1 \\ C_2 \\ C_3 \\ C_4 \\ C_5 \\ C_6 \\ C_7 \\ C_8 \end{matrix} & \begin{bmatrix} 0 & 0.40 & 0.73 & 0.33 & 0.27 & 0.33 & 0.67 & 0.13 \\ 0.40 & 0 & 0.73 & 0.20 & 0.27 & 0.47 & 0.53 & 0.27 \\ 0.73 & 0.73 & 0 & 0.93 & 1 & 0.80 & 0.60 & 0.87 \\ 0.33 & 0.20 & 0.93 & 0 & 0.07 & 0.27 & 0.47 & 0.20 \\ 0.27 & 0.27 & 1 & 0.07 & 0 & 0.20 & 0.40 & 0.13 \\ 0.33 & 0.47 & 0.80 & 0.27 & 0.20 & 0 & 0.33 & 0.20 \\ 0.67 & 0.53 & 0.60 & 0.47 & 0.40 & 0.33 & 0 & 0.53 \\ 0.13 & 0.27 & 0.87 & 0.20 & 0.13 & 0.20 & 0.53 & 0 \end{bmatrix} \end{matrix}$$

The element  $K_{jj'}^\mu$  of matrix  $\mathbf{K}^\mu$  expresses the *degree of agreement* between criteria  $C_j = GSP_j$  and  $C_{j'} = GSP_{j'}$ , whereas the element  $K_{jj'}^\nu$  of matrix  $\mathbf{K}^\nu$  expresses the *degree of disagreement* between  $C_j = GSP_j$  and  $C_{j'} = GSP_{j'}$ . Based on these results, one sees that ACO algorithm performs similarly for  $GSP_2$ ,  $GSP_4$ ,  $GSP_5$  and  $GSP_8$  because they are all in high agreement. Indeed  $\mu_{jj'}$  values for  $j, j' \in \{2, 4, 5, 8\}$  are quite high (greater than 70%). They are GPS networks with different numbers of sessions, but may have a similar structure, therefore, the value of agreement is high. For other networks, we can conclude that they have very different structure. What is worth noting is that there appears also a strong agreement of GSP1 with GSP8 because  $\mu_{18} = 0.87$ . But because GSP8 is also in strong agreement with GSP2, GSP4, GSP5 and with GSP1 it is logically expected that GSP1 should be also in agreement with GSP2, GSP4, GSP5, which is unfortunately not the case based on this classical ICRA. This example points out some inconsistency of ICRA result because of the too crude method of estimation of the degree of agreement and disagreement between criteria based on IFS.

Now if we consider the same example with the same score matrix  $\mathbf{S}$  (built from Table I), we obtain the following IC Belief matrices<sup>10</sup>

$$\mathbf{K}(\theta) = \begin{matrix} & C_1 & C_2 & C_3 & C_4 & C_5 & C_6 & C_7 & C_8 \\ \begin{matrix} C_1 \\ C_2 \\ C_3 \\ C_4 \\ C_5 \\ C_6 \\ C_7 \\ C_8 \end{matrix} & \begin{bmatrix} 0.9098 & 0.6732 & 0.1791 & 0.5968 & 0.6106 & 0.5620 & 0.1659 & 0.7789 \\ 0.6732 & 0.9546 & 0.0364 & 0.8983 & 0.8783 & 0.8341 & 0.5532 & 0.7016 \\ 0.1791 & 0.0364 & 0.8722 & 0.0172 & 0.0154 & 0.0178 & 0.0366 & 0.1137 \\ 0.5968 & 0.8983 & 0.0172 & 0.9552 & 0.9146 & 0.9163 & 0.7395 & 0.6092 \\ 0.6106 & 0.8783 & 0.0154 & 0.9146 & 0.8917 & 0.8778 & 0.6922 & 0.6315 \\ 0.5620 & 0.8341 & 0.0178 & 0.9163 & 0.8778 & 0.9060 & 0.7630 & 0.6441 \\ 0.1659 & 0.5532 & 0.0366 & 0.7395 & 0.6922 & 0.7630 & 0.8587 & 0.2484 \\ 0.7789 & 0.7016 & 0.1137 & 0.6092 & 0.6315 & 0.6441 & 0.2484 & 0.8508 \end{bmatrix} \end{matrix}$$

$$\mathbf{K}(\bar{\theta}) = \begin{matrix} & C_1 & C_2 & C_3 & C_4 & C_5 & C_6 & C_7 & C_8 \\ \begin{matrix} C_1 \\ C_2 \\ C_3 \\ C_4 \\ C_5 \\ C_6 \\ C_7 \\ C_8 \end{matrix} & \begin{bmatrix} 0.0207 & 0.1941 & 0.5385 & 0.2578 & 0.1757 & 0.2117 & 0.5335 & 0.0399 \\ 0.1941 & 0.0166 & 0.8323 & 0.0486 & 0.0298 & 0.0513 & 0.1808 & 0.0682 \\ 0.5385 & 0.8323 & 0.0117 & 0.9002 & 0.8754 & 0.8548 & 0.7062 & 0.5486 \\ 0.2578 & 0.0486 & 0.9002 & 0.0187 & 0.0216 & 0.0204 & 0.0606 & 0.1193 \\ 0.1757 & 0.0298 & 0.8754 & 0.0216 & 0.0170 & 0.0201 & 0.0558 & 0.0832 \\ 0.2117 & 0.0513 & 0.8548 & 0.0204 & 0.0201 & 0.0154 & 0.0390 & 0.0726 \\ 0.5335 & 0.1808 & 0.7062 & 0.0606 & 0.0558 & 0.0390 & 0.0110 & 0.3495 \\ 0.0399 & 0.0682 & 0.5486 & 0.1193 & 0.0832 & 0.0726 & 0.3495 & 0.0100 \end{bmatrix} \end{matrix}$$

From ICBM  $\mathbf{K}(\theta)$  and  $\mathbf{K}(\bar{\theta})$  we compute the matrix  $\mathbf{D}(\theta)$  of distance of  $m_{jj'}(\cdot)$  to the full agreement state with BBA

<sup>9</sup>For presentation convenience and due to typesetting column width, we decompose et present the IC matrix  $\mathbf{K} = [K_{jj'} = (K_{jj'}^\mu, K_{jj'}^\nu)]$  into two distinct matrices  $\mathbf{K}^\mu = [K_{jj'}^\mu]$  and  $\mathbf{K}^\nu = [K_{jj'}^\nu]$ .

<sup>10</sup>For presentation convenience, the ICBM  $\mathbf{K} = [K_{jj'} = (m_{jj'}(\theta), m_{jj'}(\bar{\theta}), m_{jj'}(\theta \cup \bar{\theta}))]$  is decomposed into three matrices  $\mathbf{K}(\theta) = [K_{jj'}^\theta = m_{jj'}(\theta)]$ ,  $\mathbf{K}(\bar{\theta}) = [K_{jj'}^{\bar{\theta}} = m_{jj'}(\bar{\theta})]$  and  $\mathbf{K}(\theta \cup \bar{\theta}) = [K_{jj'}^{\theta \cup \bar{\theta}} = 1 - m_{jj'}(\theta) - m_{jj'}(\bar{\theta})]$ .

$m_F(\theta) = 1$  based on  $d_{BI}(\cdot)$  distance. We get the following distances to full agreement

$$\mathbf{D}(\theta) = [D_{jj'} = d_{BI}(m_{jj'}, m_T)]$$

	$C_1$	$C_2$	$C_3$	$C_4$	$C_5$	$C_6$	$C_7$	$C_8$
$C_1$	0.0590	0.2633	0.6845	0.3331	0.2892	0.3314	0.6893	0.1406
$C_2$	0.2633	0.0321	0.8987	<b>0.0767</b>	<b>0.0803</b>	0.1135	0.3230	0.1950
$C_3$	0.6845	0.8987	0.0774	0.9418	0.9306	0.9192	0.8381	0.7241
$C_4$	0.3331	<b>0.0767</b>	0.9418	0.0326	<b>0.0566</b>	0.0552	0.1706	0.2668
$C_5$	0.2892	<b>0.0803</b>	0.9306	<b>0.0566</b>	0.0679	0.0770	0.1958	0.2404
$C_6$	0.3314	0.1135	0.9192	0.0552	0.0770	0.0592	0.1494	0.2293
$C_7$	0.6893	0.3230	0.8381	0.1706	0.1958	0.1494	0.0849	0.5626
$C_8$	0.1406	0.1950	0.7241	0.2668	0.2404	0.2293	0.5626	0.0892

The element  $D_{jj'}$  represents the agreement distance between  $C_j$  and  $C_{j'}$ , the lower the better. From the values of elements of  $\mathbf{D}(\theta)$  matrix one sees clearly that ACO performs similarly for GSP2, GSP4 and GSP5 because distances  $D_{24}$ ,  $D_{25}$ , and  $D_{45}$  are very small. Also we see that GSP6 is also in good agreement with GSP4 and GSP5 but is relatively less in agreement with GSP2 because  $D_{26} = 0.1135$ . As we see there is no inconsistency in this new BF-ICrA method with respect to what provides classical ICrA because with BF-ICrA we have a much better and precise estimation of degrees of agreement and disagreement between criteria for making the analysis thanks to a proper belief functions modeling.

## VII. CONCLUSION

The GPS surveying problem and a new InterCriteria Analysis based on belief functions were addressed in this paper to overcome the potential inconsistencies of the results generated by the classical ICrA method. This technique proposes a more precise and refined method for estimating the degree of agreement and disagreement between criteria which use the whole information available in the data. Instances containing from 38 to 443 sessions have been solved using MMAS algorithm and we did compare the performance of ACO algorithms applied to eight GPS networks. Our results shows that ACO can provide fast near-optimal solution for observing GPS networks, and could help to improve the services based on GPS networks. From this new Inter-Criteria Analysis we are able to identify some relations and dependences between the considered eight GSPs and MMAS algorithm performance.

## ACKNOWLEDGEMENTS

**Abstract**—In this paper we propose a new Belief Function-based Inter-Criteria Analysis (BF-ICrA) for the assessment of the degree of redundancy of criteria involved in a multicriteria decision making (MCDM) problem. This BF-ICrA method allows to simplify the original MCDM problem by withdrawing all redundant criteria and thus diminish the complexity of MCDM problem. This is of prime importance for solving large MCDM problems whose solution requires the fusion of many belief functions. We provide simple examples to show how this new BF-ICrA works.

**Keywords:** Inter-Criteria Analysis, ICrA-BF, MultiCriteria Decision Making, MCDM, belief functions, information fusion.

## I. INTRODUCTION

In a Multi-Criteria Decision-Making (MCDM) problem we consider a set of alternatives (or objects)  $\mathbf{A} \triangleq \{A_1, A_2, \dots, A_M\}$  ( $M > 2$ ), and a set of criteria  $\mathbf{C} \triangleq \{C_1, C_2, \dots, C_N\}$  ( $N \geq 1$ ). We search for the best alternative  $A^*$  given the available information expressed by a  $M \times N$  score matrix (also called benefit or payoff matrix)  $\mathbf{S} \triangleq [S_{ij} = C_j(A_i)]$ , and (eventually) the importance factor  $w_j \in [0, 1]$  of each criterion  $C_j$  with  $\sum_{j=1}^N w_j = 1$ . The set of normalized weighting factors is denoted by  $\mathbf{w} \triangleq \{w_1, w_2, \dots, w_N\}$ . Depending on the context of the MCDM problem, the score  $S_{ij}$  of each alternative  $A_i$  with respect to each criteria  $C_j$  can be interpreted either as a cost (i.e. an expense), or as a reward (i.e. a benefit). By convention and without loss of generality<sup>1</sup> we will always interpret the score as a reward having monotonically increasing preference. Thus, the best alternative  $A_j^*$  for a given criteria  $C_j$  will be the one providing the highest reward/benefit.

The MCDM problem is not easy to solve because the scores are usually expressed in different (physical) units and different scales. This necessitates a choice of score/data normalization yielding rank reversal problems [1], [2]. Usually there is no same best alternative choice  $A^*$  for all criteria, so a compromise must be established to provide a reasonable

and acceptable solution of the MCDM problem for decision-making support.

Many MCDM methods exist, see references in [3]. Most popular methods are AHP<sup>2</sup> [4], ELECTRE<sup>3</sup> [5], TOPSIS<sup>4</sup> [6], [7]. In 2016 and 2017, we did develop BF-TOPSIS methods [3], [8] based on Belief Functions (BF) to improve the original TOPSIS approach to avoid data normalization and to deal also with imprecise score values as well. It appears however that the complexity of these new BF-TOPSIS methods can become a bottleneck for their use in large MCDM problems because of the fusion step of basic belief assignments required for the implementation of the BF-TOPSIS. That is why a simplification of the MCDM problem (if possible) is very welcome in order to save computational time and resources. This is the motivation of the present work.

For this aim we propose a new Inter-Criteria Analysis (ICrA) based on belief functions for identifying and estimating the possible degree of agreement (i.e. redundancy) between some criteria driven from the data (score values). This permits to remove all redundant criteria of the original MCDM problem and thus solving a simplified (almost) equivalent MCDM problem faster and at lower computational cost. ICrA has been developed originally by Atanassov et al. [9]–[11] based on Intuitionistic Fuzzy Sets [12], and it has been applied in different fields like medicine [13]–[15], optimization [16]–[20], workforce planning [21], competitiveness analysis [22], radar detection [23], ranking [24]–[27], etc. In this paper we improve ICrA approach thanks to belief functions introduced by Shafer in [28] from original Dempster's works [29]. We will refer it as BF-ICrA method in the sequel.

After a short presentation of basics of belief functions in section II, we present Atanassov's ICrA method in section III and discuss its limitations. In Section IV we present the new BF-ICrA approach based on a new construction of Basic Belief Assignment (BBA) matrix from the score matrix and a new establishment of Inter-Criteria belief matrix. In section

<sup>2</sup>Analytic Hierarchy Process

<sup>3</sup>ELimination Et Choix Taduisant la REalité

<sup>4</sup>Technique for Order Preference by Similarity to Ideal Solution

<sup>1</sup>because it suffices to multiply the scores values by  $-1$  to reverse the preference ordering.

V a method of simplification of MCDM using BF-ICrA is proposed. Examples are given in VI with concluding remarks in Section VII.

## II. BASICS OF THE THEORY OF BELIEF FUNCTIONS

To follow classical notations of the theory of belief functions, also called Dempster-Shafer Theory (DST) [28], we assume that the answer (i.e. the solution, or the decision to take) of the problem under concern belongs to a known finite discrete frame of discernment (FoD)  $\Theta = \{\theta_1, \theta_2, \dots, \theta_n\}$ , with  $n > 1$ , and where all elements of  $\Theta$  are exclusive. The set of all subsets of  $\Theta$  (including empty set  $\emptyset$  and  $\Theta$ ) is the power-set of  $\Theta$  denoted by  $2^\Theta$ . A BBA (or mass function) associated with a given source of evidence is defined [28] as the mapping  $m(\cdot) : 2^\Theta \rightarrow [0, 1]$  satisfying  $m(\emptyset) = 0$  and  $\sum_{A \in 2^\Theta} m(A) = 1$ . The quantity  $m(A)$  is called the mass of  $A$  committed by the source of evidence. Belief and plausibility functions are usually interpreted respectively as lower and upper bounds of unknown (possibly subjective) probability measure [29]. They are defined by<sup>5</sup>

$$\text{Bel}(A) \triangleq \sum_{B \subseteq A, B \in 2^\Theta} m(B), \quad \text{and} \quad \text{Pl}(A) \triangleq 1 - \text{Bel}(\bar{A}). \quad (1)$$

If  $m(A) > 0$ ,  $A$  is called a focal element of  $m(\cdot)$ . When all focal elements are singletons then  $m(\cdot)$  is called a *Bayesian BBA* [28] and its corresponding  $\text{Bel}(\cdot)$  function is homogeneous to a probability measure. The vacuous BBA, or VBBA for short, representing a totally ignorant source is defined as  $m_v(\Theta) = 1$ . The main challenge of the decision-maker consists to combine efficiently the possible multiple BBAs  $m_s(\cdot)$  given by  $s > 1$  distinct sources of evidence to obtain a global (combined) BBA, and to make a final decision from it. Historically the combination of BBAs is accomplished by Dempster's rule proposed by Shafer in DST. Because Dempster's rule presents several serious problems (insensitivity to the level of conflict between sources in some cases, inconsistency with bounds of conditional probabilities when used for belief conditioning, dictatorial behavior, counter-intuitive results), many fusion rules have been proposed in the literature as alternative to Dempster's rule, see [30], Vol. 2 for a detailed list of fusion rules. We will not detail here all the possible combination rules but just mention that the Proportional Conflict Redistribution rule no. 6 (PCR6) proposed by Martin and Osswald in [30] (Vol. 3) is one of the most serious alternative rule for BBA combination available so far.

## III. ATANASSOV'S INTER-CRITERIA ANALYSIS (ICrA)

Atanassov's Inter-Criteria Analysis (ICrA) approach is based on a  $M \times N$  score matrix<sup>6</sup>  $\mathbf{S} \triangleq [S_{ij} = C_j(A_i), i = 1, \dots, M, j = 1, \dots, N]$ , and intuitionistic fuzzy pairs [12] including two membership functions  $\mu(\cdot)$  and  $\nu(\cdot)$ . Mathematically, an intuitionistic fuzzy set (IFS)  $A$  is denoted by  $A \triangleq \{(x, \mu_A(x), \nu_A(x)) | x \in E\}$ , where  $E$  is the set of possible values of  $x$ ,  $\mu_A(x) \in [0, 1]$  defines the membership of

$x$  to the set  $A$ , and  $\nu_A(x) \in [0, 1]$  defines the non-membership of  $x$  to the set  $A$ , with the restriction  $0 \leq \mu_A(x) + \nu_A(x) \leq 1$ . The ICrA method consists to build an  $N \times N$  Inter-Criteria (IC) matrix from the score matrix  $\mathbf{S}$ . The elements of the IC matrix consist of all intuitionistic fuzzy pairs  $(\mu_{jj'}, \nu_{jj'})$  whose components express respectively the degree of agreement and the degree of disagreement between criteria  $C_j$  and  $C_{j'}$  for  $j, j' \in \{1, 2, \dots, N\}$ . For a given column  $j$  (i.e. criterion  $C_j$ ), it is always possible to compare with  $>$ ,  $<$  and  $=$  operators all the scores  $S_{ij}$  for  $i = 1, 2, \dots, M$  because the scores of each column are expressed in same unit. The construction of IC matrix can be used to search relations between the criteria because the method compares homogeneous data relatively to a same column. In [32] Atanassov prescribes to normalize the score matrix before applying ICrA as follows

$$S_{ij}^{\text{norm}} = (S_{ij} - S_j^{\text{min}}) / (S_j^{\text{max}} - S_j^{\text{min}}), \quad (2)$$

if one wants to apply it in the dual manner for the search of InterObjects analysis (IOBa).

Because we focus on ICrA only, we don't need to apply a score matrix normalization because each column of the score matrix represents the values of a same criterion for different alternatives, and the criterion values are expressed with the same unit (e.g.  $m$ ,  $m^2$ ,  $\text{sec}$ ,  $Kg$ , or  $\text{€}$ , etc).

### A. Construction of Inter-Criteria matrix

The construction of the  $N \times N$  IC matrix, denoted<sup>7</sup>  $\mathbf{K}$ , is based on the pairwise comparisons between every two criteria along all evaluated alternatives. Let  $K_{jj'}^\mu$  be the number of cases in which the inequalities  $S_{ij} > S_{i'j}$  and  $S_{ij'} > S_{i'j'}$  hold simultaneously, and let  $K_{jj'}^\nu$  be the number of cases in which the inequalities  $S_{ij} > S_{i'j}$  and  $S_{ij'} < S_{i'j'}$  hold simultaneously. Because the total number of comparisons between the alternatives is  $M(M-1)/2$  then one always has necessarily

$$0 \leq K_{jj'}^\mu + K_{jj'}^\nu \leq \frac{M(M-1)}{2}, \quad (3)$$

or equivalently after the division by  $\frac{M(M-1)}{2} > 0$

$$0 \leq \frac{2K_{jj'}^\mu}{M(M-1)} + \frac{2K_{jj'}^\nu}{M(M-1)} \leq 1. \quad (4)$$

This inequality permits to define the elements of  $N \times N$  IC matrix  $\mathbf{K} = [K_{jj'}]$  as intuitionistic fuzzy (IF) pairs  $K_{jj'} = (\mu_{jj'}, \nu_{jj'})$  where

$$\mu_{jj'} \triangleq \frac{2K_{jj'}^\mu}{M(M-1)}, \quad \text{and} \quad \nu_{jj'} \triangleq \frac{2K_{jj'}^\nu}{M(M-1)}. \quad (5)$$

$\mu_{jj'}$  measures the degree of agreement between criteria  $C_j$  and  $C_{j'}$ , and  $\nu_{jj'}$  measures their degree of disagreement. By construction the IC matrix  $\mathbf{K}$  is always a symmetric matrix.

<sup>5</sup>where the symbol  $\triangleq$  means *equal by definition*.

<sup>6</sup>called index matrix by Atanassov in [31].

<sup>7</sup>We use  $\mathbf{K}$  because it corresponds to the first letter of word Kriterium, meaning criteria in German. The letter  $C$  is being already in use.

The computation of  $K_{jj'}^\mu$  and  $K_{jj'}^\nu$  can be done explicitly thanks to Atanassov's formulas [32]

$$K_{jj'}^\mu = \sum_{i=1}^{M-1} \sum_{i'=i+1}^M [sgn(S_{ij} - S_{i'j})sgn(S_{ij'} - S_{i'j'}) + sgn(S_{i'j} - S_{ij})sgn(S_{i'j'} - S_{ij'})], \quad (6)$$

and

$$K_{jj'}^\nu = \sum_{i=1}^{M-1} \sum_{i'=i+1}^M [sgn(S_{ij} - S_{i'j})sgn(S_{i'j'} - S_{ij'}) + sgn(S_{i'j} - S_{ij})sgn(S_{ij'} - S_{i'j'})], \quad (7)$$

where the signum function  $sgn(\cdot)$  used by Atanassov is defined as follows

$$sgn(x) = \begin{cases} 1, & \text{if } x > 0, \\ 0, & \text{if } x \leq 0. \end{cases} \quad (8)$$

Actually the values of  $K_{jj'}^\mu$  and  $K_{jj'}^\nu$  depend on the choice of  $sgn(x)$  function<sup>8</sup>. That is why in [21], [33], the authors propose different algorithms implemented under Java in an ICRA software yielding different  $K_{jj'}^\mu$  and  $K_{jj'}^\nu$  values for making the analysis and to reduce the dimension (complexity) of the original MCDM problem.

### B. Inter-criteria analysis

Once the Inter-Criteria matrix  $\mathbf{K} = [K_{jj'}]$  of intuitionistic fuzzy pairs is calculated one needs to analyze it to decide which criteria  $C_j$  and  $C_{j'}$  are in strong agreement (or positive consonance) reflecting the correlation between  $C_j$  and  $C_{j'}$ , in strong disagreement (or negative consonance) reflecting non correlation between  $C_j$  and  $C_{j'}$ , or in dissonance reflecting the uncertainty situation where nothing can be said about the non correlation or the correlation between  $C_j$  and  $C_{j'}$ . If one wants to identify the set of criteria  $C_{j'}$  for  $j' \neq j$  that are strongly correlated with  $C_j$  then we can sort  $\mu_{jj'}$  values in descending order to identify those in strong positive consonance with  $C_j$ . In [25], [26], the authors propose a qualitative scale to refine the levels of consonance and dissonance and for helping the decision making procedure. A dual approach based on  $\nu_{jj'}$  values can be made to determine the set of criteria that are not correlated with  $C_j$ . An other approach [10], [27] proposes to define two thresholds  $\alpha, \beta \in [0; 1]$  for the positive and negative consonance respectively against which the components  $\mu_{jj'}$  and  $\nu_{jj'}$  of  $K_{jj'} = (\mu_{jj'}, \nu_{jj'})$  will be compared. The correlations between the criteria  $C_j$  and  $C_{j'}$  are called "positive consonance", "negative consonance" or "dissonance" depending on their  $\mu_{jj'}$  and  $\nu_{jj'}$  values with respect to chosen thresholds  $\alpha$  and  $\beta$ , see [22] for details. More precisely,  $C_j$  and  $C_{j'}$  are in

- $(\alpha, \beta)$  positive consonance (i.e. correlated):  
If  $\mu_{jj'} > \alpha$  and  $\nu_{jj'} < \beta$ .
- $(\alpha, \beta)$  negative consonance (i.e. no correlated):

<sup>8</sup>for instance if we use  $sgn(x) = 1$  if  $x \geq 0$  and  $sgn(x) = 0$  if  $x < 0$ , we will obtain, in general, other  $K_{jj'}^\mu$  and  $K_{jj'}^\nu$  values.

If  $\mu_{jj'} < \beta$  and  $\nu_{jj'} > \alpha$ .

- $(\alpha, \beta)$  dissonance (i.e. full uncertainty): Otherwise.

At the beginning of ICRA development it was not very clear how these intuitionistic fuzzy (IF) pairs  $(\mu_{jj'}, \nu_{jj'})$  had to be used and that is why Atanassova [34], [35] proposed to handle both components of the IF pair. For this, she interpreted pairs  $(\mu_{jj'}, \nu_{jj'})$  as points located in the elementary  $TFU$  triangle, where the point  $T$  of coordinate  $(1, 0)$  represents the maximal positive consonance (i.e. the true consonance), the point  $F$  with coordinate  $(0, 1)$  represents the maximal negative consonance (i.e. the falsity), and the point  $U$  with coordinates  $(0, 0)$  represents the maximal dissonance (i.e. the uncertainty). From this interpretation it becomes easy to identify the top of consonant IF pairs  $(\mu_{jj'}, \nu_{jj'})$  that fall in bottom right corner of  $(TFU)$  triangle limited by vertical line from  $x$ -axis  $x = \alpha$ , and horizontal line from  $y$ -axis  $y = \beta$ . The set of consonant IF pairs are then ranked according to their Euclidean distance  $d_{C_j C_{j'}}^T$  with respect to  $T$  point of coordinate  $(1, 0)$  defined by

$$d_{C_j C_{j'}}^T = d((1, 0), (\mu_{jj'}, \nu_{jj'})) = \sqrt{(1 - \mu_{jj'})^2 + \nu_{jj'}^2}. \quad (9)$$

In the MCDM context only the criteria that are negatively consonant (or uncorrelated) must be kept for solving MCDM and saving computational resources because they have no (or only very low) dependency with each other, so that each uncorrelated criterion provides useful information. The set of criteria that are positively consonant (if any), called the consonant set, indicates somehow a redundancy of information between the criteria belonging to it in term of decisional behavior. Therefore all these positively consonant criteria must be represented by only one representative criterion that will be kept in the MCDM analysis to simplify MCDM problem. Also all the criteria that are deemed strongly dissonant (if any) could be taken out of the original MCDM problem because they only introduce uncertainty in the decision-making.

### C. General comments on ICRA

Although appealing at the first glance, the classical ICRA approach induces the following comments:

- 1) The IF values  $\mu_{jj'}$  and  $\nu_{jj'}$  can be easily interpreted in the belief function framework. Indeed, the belief and plausibility of (positive) consonance between criteria  $C_j$  and  $C_{j'}$  can be directly linked to the values  $\mu_{jj'}$  and  $\nu_{jj'}$  by taking  $Bel_{jj'}(\theta) = \mu_{jj'}$  and  $Pl_{jj'}(\theta) = 1 - \nu_{jj'}$ . Moreover  $U_{jj'}(\theta) = Pl_{jj'}(\theta) - Bel_{jj'}(\theta) = 1 - \nu_{jj'} - \mu_{jj'}$  represents the dissonance (the uncertainty about the correlation) of the criteria  $C_j$  and  $C_{j'}$ . Here the proposition  $\theta$  means: the criteria  $C_j$  and  $C_{j'}$  are totally positively consonant (i.e. totally correlated) and the frame of discernment is defined as  $\Theta \triangleq \{\theta, \bar{\theta}\}$ , where  $\bar{\theta}$  means: the criteria  $C_j$  and  $C_{j'}$  are totally negatively

consonant (uncorrelated). From this, one can define any BBA  $m_{jj'}(\theta)$ ,  $m_{jj'}(\bar{\theta})$  and  $m_{jj'}(\theta \cup \bar{\theta})$  of  $2^\Theta$  by

$$m_{jj'}(\theta) = \mu_{jj'}, \quad (10)$$

$$m_{jj'}(\bar{\theta}) = \nu_{jj'}, \quad (11)$$

$$m_{jj'}(\theta \cup \bar{\theta}) = 1 - \mu_{jj'} - \nu_{jj'}. \quad (12)$$

- 2) The construction of  $\mu_{jj'}$  and  $\nu_{jj'}$  proposed in the classical ICRA is disputable because it is only based on counting the valid " $>$ " or " $<$ " inequalities but it doesn't exploit how bigger and how smaller the scores values are in each comparison done in the construction of the Inter-Criteria Matrix  $\mathbf{K}$ . Therefore the construction of  $\mu_{jj'}$  and  $\nu_{jj'}$  is actually only a very crude method to estimate IF pairs.
- 3) The construction of the Inter-Criteria Matrix  $\mathbf{K}$  is in fact not unique as reported in [33]. This will yield different results in general.
- 4) The exploitation of the ICRA method depends on the choice of  $\alpha$  and  $\beta$  thresholds that will impact the final result.
- 5) The classical ICRA method cannot deal directly with imprecise or missing score values.

#### IV. A NEW ICRA METHOD BASED ON BELIEF FUNCTIONS

In this paper we propose a new ICRA method, called BF-ICRA for short, based on belief functions that circumvents most of the aforementioned drawbacks of classical ICRA. Here we show how to get more precisely the Inter-Criteria Belief Matrix and how to exploit it for MCDM simplification.

##### A. Construction of BBA matrix from the score matrix

From any non-zero score matrix  $\mathbf{S} = [S_{ij}]$ , we can construct the  $M \times N$  BBA matrix  $\mathbf{M} = [m_{ij}(\cdot)]$  as follows

$$m_{ij}(A_i) = Bel_{ij}(A_i), \quad (13)$$

$$m_{ij}(\bar{A}_i) = Bel_{ij}(\bar{A}_i) = 1 - Pl_{ij}(A_i), \quad (14)$$

$$m_{ij}(A_i \cup \bar{A}_i) = Pl_{ij}(A_i) - Bel_{ij}(A_i). \quad (15)$$

Assuming  $A_{\max}^j \neq 0$  and  $A_{\min}^j \neq 0$ , we take<sup>9</sup>

$$Bel_{ij}(A_i) \triangleq Sup_j(A_i)/A_{\max}^j, \quad (16)$$

$$Bel_{ij}(\bar{A}_i) \triangleq Inf_j(A_i)/A_{\min}^j, \quad (17)$$

where  $A_{\max}^j \triangleq \max_i Sup_j(A_i)$  and  $A_{\min}^j \triangleq \min_i Inf_j(A_i)$  and with

$$Sup_j(A_i) \triangleq \sum_{k \in \{1, \dots, M\} | S_{kj} \leq S_{ij}} |S_{ij} - S_{kj}|, \quad (18)$$

$$Inf_j(A_i) \triangleq - \sum_{k \in \{1, \dots, M\} | S_{kj} \geq S_{ij}} |S_{ij} - S_{kj}|. \quad (19)$$

The entire justification of these formulas can be found in our previous works [3]. For example, consider the  $j$ -th column corresponding to a criterion  $C_j$  of a score matrix  $\mathbf{S} = [S_{ij}]$  with seven rows given by  $\mathbf{s}_j = [10, 20, -5, 0, 100, -11, 0]^T$ ,

where  $T$  denotes the transpose. Then based on above formula we get the BBA values listed in Table I.

For another criterion  $C_{j'}$  and the  $j'$ -th column of the score matrix we will obtain another set of BBA values  $m_{ij'}(\cdot)$ . Applying this method for each column of the score matrix we are able to compute the BBA matrix  $\mathbf{M} = [m_{ij}(\cdot)]$  whose each component is in fact a triplet  $(m_{ij}(A_i), m_{ij}(\bar{A}_i), m_{ij}(A_i \cup \bar{A}_i))$  of BBA values in  $[0, 1]$  such that  $m_{ij}(A_i) + m_{ij}(\bar{A}_i) + m_{ij}(A_i \cup \bar{A}_i) = 1$  for all  $i = 1, \dots, M$  and  $j = 1, \dots, N$ .

##### B. Construction of Inter-Criteria Matrix from BBA matrix

The next step of BF-ICRA approach is the construction of the  $N \times N$  Inter-Criteria Matrix  $\mathbf{K} = [K_{jj'}]$  from  $M \times N$  BBA matrix  $\mathbf{M} = [m_{ij}(\cdot)]$  where elements  $K_{jj'}$  corresponds to the BBA  $(m_{jj'}(\theta), m_{jj'}(\bar{\theta}), m_{jj'}(\theta \cup \bar{\theta}))$  about positive consonance  $\theta$ , negative consonance  $\bar{\theta}$  and uncertainty between criteria  $C_j$  and  $C_{j'}$  respectively. The principle of construction of the triplet  $K_{jj'} = (m_{jj'}(\theta), m_{jj'}(\bar{\theta}), m_{jj'}(\theta \cup \bar{\theta}))$  is based on two steps that will be detailed in the sequel:

- Step 1: For each alternative  $A_i$ , we first compute the BBA  $(m_{jj'}^i(\theta), m_{jj'}^i(\bar{\theta}), m_{jj'}^i(\theta \cup \bar{\theta}))$  for any two criteria  $j, j' \in \{1, 2, \dots, N\}$ .
- Step 2: The BBA  $(m_{jj'}(\theta), m_{jj'}(\bar{\theta}), m_{jj'}(\theta \cup \bar{\theta}))$  is then obtained by the combinations of the  $M$  BBA  $m_{jj'}^i(\cdot)$ .

##### Construction of BBA $m_{jj'}^i(\cdot)$

The mass of belief  $m_{jj'}^i(\theta)$  represents the degree of agreement between the BBA  $m_{ij}(\cdot)$  and  $m_{ij'}(\cdot)$  for the alternative  $A_i$ , and  $m_{jj'}^i(\bar{\theta})$  represents the degree of disagreement between  $m_{ij}(\cdot)$  and  $m_{ij'}(\cdot)$ . The mass  $m_{jj'}^i(\theta \cup \bar{\theta})$  is the degree of uncertainty about the agreement (or disagreement) between  $m_{ij}(\cdot)$  and  $m_{ij'}(\cdot)$  for the alternative  $A_i$ . The calculation of  $m_{jj'}^i(\theta)$  could be envisaged in several manners.

The first manner would consist to consider the degree of conflict [28]  $k_{jj'}^i \triangleq \sum_{X, Y \subseteq \Theta | X \cap Y = \emptyset} m_{ij}(X) m_{ij'}(Y)$  and consider the Bayesian BBA  $m_{jj'}^i(\theta) = 1 - k_{jj'}^i$ ,  $m_{jj'}^i(\bar{\theta}) = k_{jj'}^i$  and  $m_{jj'}^i(\theta \cup \bar{\theta}) = 0$ . Instead of using Shafer's conflict, the second manner would consist to use a normalized distance  $d_{jj'}^i = d(m_{ij}, m_{ij'})$  to measure the closeness between  $m_{ij}(\cdot)$  and  $m_{ij'}(\cdot)$ , and then consider the Bayesian BBA modeling defined by  $m_{jj'}^i(\theta) = 1 - d_{jj'}^i$ ,  $m_{jj'}^i(\bar{\theta}) = d_{jj'}^i$  and  $m_{jj'}^i(\theta \cup \bar{\theta}) = 0$ . These two manners however are not very satisfying because they always set to zero the degree of uncertainty between the

<sup>9</sup>If  $A_{\max}^j = 0$  then  $Bel_{ij}(A_i) = 0$ , and if  $A_{\min}^j = 0$  then  $Pl_{ij}(A_i) = 1$ .

Table I  
BBAS CONSTRUCTED FROM SCORE VALUES.

	$m_{ij}(A_i)$	$m_{ij}(\bar{A}_i)$	$m_{ij}(A_i \cup \bar{A}_i)$
$A_1$	0.0955	0.5236	0.3809
$A_2$	0.1809	0.4188	0.4003
$A_3$	0.0102	0.8115	0.1783
$A_4$	0.0273	0.6806	0.2921
$A_5$	1.0000	0	0
$A_6$	0	1.0000	0
$A_7$	0.0273	0.6806	0.2921

agreement and disagreement of the BBA, and the second manner depends also on the choice of the distance metric. So, we propose a more appealing third manner of the BBA modeling of  $m_{jj'}^i(\theta)$ ,  $m_{jj'}^i(\bar{\theta})$ , and  $m_{jj'}^i(\theta \cup \bar{\theta})$ . For this, we consider two sources of evidences (SoE) indexed by  $j$  and  $j'$  providing the BBA  $m_{ij}$  and  $m_{ij'}$  defined on the simple FoD  $\{A_i, \bar{A}_i\}$  and denoted  $m_{ij} = [m_{ij}(A_i), m_{ij}(\bar{A}_i), m_{ij}(A_i \cup \bar{A}_i)]$  and  $m_{ij'} = [m_{ij'}(A_i), m_{ij'}(\bar{A}_i), m_{ij'}(A_i \cup \bar{A}_i)]$ . We also denote  $\Theta = \{\theta, \bar{\theta}\}$  the FoD about the relative state of the two SoE, where  $\theta$  means that the two SoE agree,  $\bar{\theta}$  means that they disagree and  $\theta \cup \bar{\theta}$  means that we don't know. Then the BBA modeling is based on the important remarks

- Two SoE are in total agreement if both commit their maximum belief mass to the element  $A_i$  or to element  $\bar{A}_i$ . So they perfectly agree if  $m_{ij}(A_i) = m_{ij'}(A_i) = 1$ , or if  $m_{ij}(\bar{A}_i) = m_{ij'}(\bar{A}_i) = 1$ . Therefore the pure degree of agreement<sup>10</sup> between two sources is modeled by

$$m_{jj'}^i(\theta) = m_{ij}(A_i)m_{ij'}(A_i) + m_{ij}(\bar{A}_i)m_{ij'}(\bar{A}_i). \quad (20)$$

- Two SoE are in total disagreement if each one commits its maximum mass of belief to one element and the other to its opposite, that is if one has  $m_{ij}(A_i) = 1$  and  $m_{ij'}(\bar{A}_i) = 1$ , or if  $m_{ij}(\bar{A}_i) = 1$  and  $m_{ij'}(A_i) = 1$ . Hence the pure degree of disagreement<sup>11</sup> between two sources is modeled by

$$m_{jj'}^i(\bar{\theta}) = m_{ij}(A_i)m_{ij'}(\bar{A}_i) + m_{ij}(\bar{A}_i)m_{ij'}(A_i). \quad (21)$$

- All possible remaining products between components of  $m_{ij}$  and  $m_{ij'}$  reflect the part of uncertainty we have about the SoE (i.e. we don't know if they agree or disagree). Hence the degree of uncertainty between the two sources is modeled by

$$\begin{aligned} m_{jj'}^i(\theta \cup \bar{\theta}) &= m_{ij}(A_i)m_{ij'}(A_i \cup \bar{A}_i) + m_{ij}(\bar{A}_i)m_{ij'}(A_i \cup \bar{A}_i) \\ &+ m_{ij}(A_i \cup \bar{A}_i)m_{ij'}(A_i) + m_{ij}(A_i \cup \bar{A}_i)m_{ij'}(\bar{A}_i) \\ &+ m_{ij}(A_i \cup \bar{A}_i)m_{ij'}(A_i \cup \bar{A}_i). \end{aligned} \quad (22)$$

By construction  $m_{jj'}^i(\cdot) = m_{jj'}^i(\cdot)$ , hence this BBA modeling permits to build a set of  $M$  symmetrical Inter-Criteria Belief Matrices (ICBM)  $\mathbf{K}^i = [K_{jj'}^i]$  of dimension  $N \times N$  relative to each alternative  $A_i$  whose components  $K_{jj'}^i$  correspond to the triplet of BBA values  $m_{jj'}^i = (m_{jj'}^i(\theta), m_{jj'}^i(\bar{\theta}), m_{jj'}^i(\theta \cup \bar{\theta}))$  modeling the belief of agreement and of disagreement between  $C_j$  and  $C_{j'}$  based on  $A_i$ . One has also<sup>12</sup>  $m_{jj'}^i(\theta), m_{jj'}^i(\bar{\theta}), m_{jj'}^i(\theta \cup \bar{\theta}) \in [0, 1]$  and  $m_{jj'}^i(\theta) + m_{jj'}^i(\bar{\theta}) + m_{jj'}^i(\theta \cup \bar{\theta}) = 1$ . This BBA construction can be easily extended

for modeling the agreement, disagreement and uncertainty of  $n > 2$  criteria  $C_{j_1}, \dots, C_{j_n}$  altogether if needed by taking

$$\begin{aligned} m_{j_1 \dots j_n}^i(\theta) &= \prod_{k=1}^n m_{ij_k}(A_i) + \prod_{k=1}^n m_{ij_k}(\bar{A}_i), \\ m_{j_1 \dots j_n}^i(\bar{\theta}) &= \sum_{\substack{X_{j_1}, \dots, X_{j_n} \in \{A_i, \bar{A}_i\} \\ X_{j_1} \cap \dots \cap X_{j_n} = \emptyset}} \prod_{k=1}^n m_{ij_k}(X_{j_k}), \\ m_{j_1 \dots j_n}^i(\theta \cup \bar{\theta}) &= 1 - m_{j_1 \dots j_n}^i(\theta) - m_{j_1 \dots j_n}^i(\bar{\theta}). \end{aligned}$$

### Construction of BBA $m_{jj'}^i(\cdot)$

Once all the BBAs  $m_{jj'}^i(\cdot)$  ( $i = 1, \dots, M$ ) are calculated one combines them to get the component  $K_{jj'} = (m_{jj'}(\theta), m_{jj'}(\bar{\theta}), m_{jj'}(\theta \cup \bar{\theta}))$  of the Inter-Criteria Belief matrix (ICBM)  $\mathbf{K} = [K_{jj'}]$ . This fusion step can be done in many ways depending on the combination rule chosen by the user. If the number of alternatives  $M$  is not too large we recommend to combine the BBAs  $m_{jj'}^i(\cdot)$  with PCR6 fusion rule [30] (Vol. 3) because of known deficiencies of Dempster's rule. If  $M$  is too large to prevent PCR6 working on computer, we can just use the simple averaging rule of combination in these high dimensional MCDM problems.

### V. SIMPLIFICATION OF ORIGINAL MCDM

Once the global Inter-Criteria Belief Matrix  $\mathbf{K} = [K_{jj'} = (m_{jj'}(\theta), m_{jj'}(\bar{\theta}), m_{jj'}(\theta \cup \bar{\theta}))]$  is calculated, we need to identify and cluster the criteria that are in strong agreement, in strong disagreement, and those on which we are uncertain. For identifying the criteria that are in very strong agreement, we evaluate the distance of each component of  $K_{jj'}$  with the BBA representing the best agreement state and characterized by the specific BBA<sup>13</sup>  $m_T(\theta) = 1$ . From a similar approach we can also identify, if we want, the criteria that are in very strong disagreement using the distance of  $m_{jj'}(\cdot)$  with respect to the BBA representing the best disagreement state characterized by the specific BBA  $m_F(\bar{\theta}) = 1$ . As alternative of Jusselme's distance [37], we use the  $d_{BI}(\cdot, \cdot)$  distance based on belief interval [36] because it is a good method for measuring the distance  $d(m_1, m_2)$  between the two BBAs<sup>14</sup>  $m_1(\cdot)$  and  $m_2(\cdot)$  over the same FoD. It is defined by

$$d_{BI}(m_1, m_2) \triangleq \sqrt{N_c \cdot \sum_{X \in 2^{\Theta}} d_W^2(BI_1(X), BI_2(X))}, \quad (23)$$

where the *Belief-Intervals* are defined by  $BI_1(X) \triangleq [Bel_1(X), Pl_1(X)]$  and  $BI_2(X) \triangleq [Bel_2(X), Pl_2(X)]$  and computed from  $m_1(\cdot)$  and  $m_2(\cdot)$  thanks to formula (1).

<sup>10</sup>or positive consonance according Atanassov's terminology.

<sup>11</sup>or negative consonance according Atanassov's terminology.

<sup>12</sup>because  $(m_{ij}(A_i) + m_{ij}(\bar{A}_i) + m_{ij}(A_i \cup \bar{A}_i))(m_{ij'}(A_i) + m_{ij'}(\bar{A}_i) + m_{ij'}(A_i \cup \bar{A}_i)) = 1 \cdot 1 = 1$ .

<sup>13</sup>We use the index  $T$  in the notation  $m_T(\cdot)$  to refer that the agreement is true, and  $F$  in  $m_F(\cdot)$  to specify that the agreement is false.

<sup>14</sup>Here  $m_1(\cdot) = m_{jj'}(\cdot)$ , and  $m_2(\cdot) = m_T(\cdot)$  or  $m_2(\cdot) = m_F(\cdot)$

$d_W(BI_1(X), BI_2(X))$  is Wassertein's distance between intervals calculated by

$$d_W([a_1, b_1], [a_2, b_2]) = \sqrt{\left[\frac{a_1 + b_1}{2} - \frac{a_2 + b_2}{2}\right]^2 + \frac{1}{3}\left[\frac{b_1 - a_1}{2} - \frac{b_2 - a_2}{2}\right]^2},$$

and  $N_c = 1/2^{|\Theta|-1}$  is a factor to get  $d_{BI}(m_1, m_2) \in [0, 1]$ .

Because all criteria that are in strong agreement somehow contain redundant (correlated) information and behave similarly from decision-making standpoint, we propose to simplify the original MCDM problem by keeping in the MCDM only criteria that are non redundant. The remaining criteria can be eventually weighted by their degree of importance reflecting the number of different criteria that are in agreement through this BF-ICrA approach.

For instance, if one has a seven criteria MCDM problem and if criteria  $C_1, C_2$  and  $C_3$  are in strong agreement we will only select one remaining criterion among  $\{C_1, C_2, C_3\}$  and we give it a weight of  $w_1 + w_2 + w_3$ . Moreover if  $C_4$  and  $C_5$  are in strong agreement also we will only select one remaining criterion among  $\{C_4, C_5\}$  and we give it a weight of  $w_4 + w_5$ , and we will use the weight  $w_6$  for  $C_6$ , and  $w_7$  for  $C_7$ . Hence the original MCDM problem will reduce to a four simplified MCDM problem that can be solved using BF-TOPSIS method already presented in details in [3] and in [8], or with AHP [4] if one prefers, or with any other chosen method that the system-designer may prefer.

The strategy for selecting the most representative criterion among a set of redundant criteria is not unique and depends mainly on the cost necessary (i.e. human efforts, data mining, computational resources, etc) for getting the values of the score matrix of the problem under concern. The least costly criteria may be a good option of selection. In the next section we provide simple examples for BF-ICrA and, for simplicity, we will select the representative criterion as being the one with smallest index. So in the aforementioned example the simplified MCDM problem will reduce to a  $M \times 4$  MCDM problem involving only four criteria  $C_1, C_4, C_6$  and  $C_7$ .

The BF-ICrA method proposed in this work allows also, in principle, to make a refined analysis (if necessary) based on IC matrices  $\mathbf{K}_{jj'}^i$  about the origin of disagreement between criteria with respect to each alternative  $A_i$  in order to identify the potential inconsistencies in original MCDM problem. This aspect is not developed in this paper and has been left for future investigations. It is worth mentioning that the analysis of the number of redundant criteria versus time improvements that could be proposed as an effective measure of performance of this approach depends highly of the application under consideration and the difficulty (and cost) to get the value of each criteria. For convenience the Figure 1 shows the flow chart of BF-ICrA to help the reader to have a better understanding of this new proposed method.

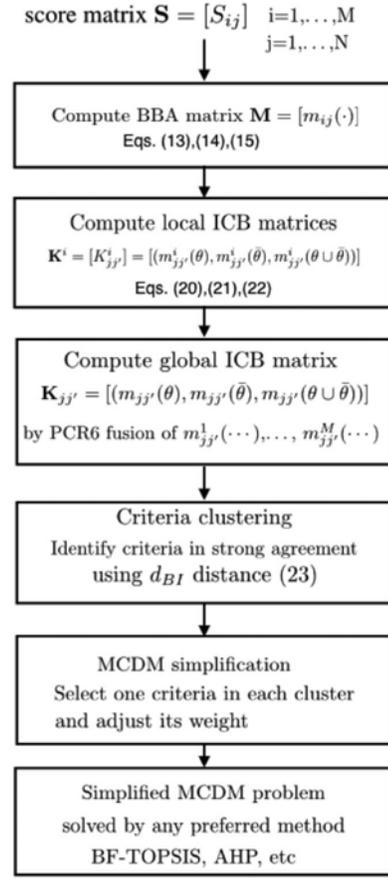

Figure 1. Flow chart of BF-ICrA method.

## VI. EXAMPLES

### A. Example 1 (Comparison of $\mathbf{K}$ matrices)

Here we compare the construction of the global IC matrix  $\mathbf{K}$  based on Atanassov ICrA and our new BF-ICrA approach. For this, we use the  $5 \times 4$  MCDM example given in [33] based on the following score matrix (called sample data matrix in [33]). Each row of  $\mathbf{S}$  corresponds to an alternative, and each column to a criterion. In [33], the authors use rows for criteria and columns for alternatives so they work with  $\mathbf{S}^T$ .

$$\mathbf{S} = [S_{ij}] = \begin{bmatrix} 6 & 7 & 4 & 4 \\ 5 & 7 & 3 & 5 \\ 3 & 8 & 5 & 6 \\ 7 & 1 & 9 & 7 \\ 6 & 3 & 1 & 8 \end{bmatrix}.$$

Based on Atanassov's ICrA method (using unbiased algorithm presented in details in [33]) we will get the following  $4 \times 4$  global Inter-Criteria  $\mathbf{K}^\mu$  and  $\mathbf{K}^\nu$  matrices

$$\mathbf{K}^\mu = [K_{jj'}^\mu] = \begin{bmatrix} 0.9 & 0 & 0.5 & 0.5 \\ 0 & 0.9 & 0.5 & 0.3 \\ 0.5 & 0.5 & 1 & 0.5 \\ 0.5 & 0.3 & 0.5 & 1 \end{bmatrix},$$

$$\mathbf{K}^\nu = [K_{jj'}^\nu] = \begin{bmatrix} 0 & 0.8 & 0.4 & 0.4 \\ 0.8 & 0 & 0.4 & 0.6 \\ 0.4 & 0.4 & 0 & 0.5 \\ 0.4 & 0.6 & 0.5 & 0 \end{bmatrix}.$$

Regrouping these two matrices into one matrix  $\mathbf{K} = [K_{jj'}]$  with components  $K_{jj'} = (K_{jj'}^\mu, K_{jj'}^\nu, 1 - K_{jj'}^\mu - K_{jj'}^\nu)$ , one gets the following global Inter-Criteria matrix  $\mathbf{K}$

$$\mathbf{K} = \begin{bmatrix} (0.9, 0, 0.1) & (0, 0.8, 0.2) & (0.5, 0.4, 0.1) & (0.5, 0.4, 0.1) \\ (0, 0.8, 0.2) & (0.9, 0, 0.1) & (0.5, 0.4, 0.1) & (0.3, 0.6, 0.1) \\ (0.5, 0.4, 0.1) & (0.5, 0.4, 0.1) & (1, 0, 0) & (0.5, 0.5, 0) \\ (0.5, 0.4, 0.1) & (0.3, 0.6, 0.1) & (0.5, 0.5, 0) & (1, 0, 0) \end{bmatrix}.$$

According to this  $\mathbf{K}$  matrix it appears intuitively that none of the criterion is in strong agreement with others. We observe that criteria  $C_1$  and  $C_2$  are in relatively strong disagreement because  $K_{12}^\nu = K_{21}^\nu = 0.8$  which is quite close to one. Criteria  $C_2$  and  $C_4$  are in relatively medium disagreement because  $K_{24}^\nu = K_{42}^\nu = 0.6$ . In this example no MCDM simplification is prescribed based on Atanassov's ICRA. To get a more precise evaluation of degree of agreement between criteria based on Atanassov's ICRA we apply formula (23) to get the  $\mathbf{D}_{BI}^\theta$  distance matrix from each component of  $\mathbf{K}$  to the total agreement state  $m_T = [m(\theta), m(\bar{\theta}), m(\theta \cup \bar{\theta})] = [1, 0, 0]$ . Hence we get

$$\mathbf{D}_{BI}^\theta = \begin{bmatrix} 0.0577 & \mathbf{0.9018} & 0.4509 & 0.4509 \\ \mathbf{0.9018} & 0.0577 & 0.4509 & 0.6506 \\ 0.4509 & 0.4509 & 0 & 0.5000 \\ 0.4509 & 0.6506 & 0.5000 & 0 \end{bmatrix}.$$

As we see from this  $\mathbf{D}_{BI}^\theta$  matrix, the distance of the inter-criteria BBA for  $C_1$  and  $C_2$  with respect to the total agreement state  $m_T(\theta) = 1$  is very large (i.e. 0.9018) which means that  $C_1$  and  $C_2$  strongly disagree in this example as we expect from a more intuitive reasoning based on  $K_{12}^\nu = 0.8$  value. Similar analyses can be done for all (non diagonal) elements of  $\mathbf{D}_{BI}^\theta$  to identify which criteria are in strong agreement, or not (if any).

Based on our new BF-ICRA method we first compute the  $5 \times 4$  BBA matrix  $\mathbf{M} = [m_{ij}(\cdot)]$  from the score matrix  $\mathbf{S}$  based on formulas (13)-(15). We get (all the values of results have been rounded at their second digit)

$$\mathbf{M} \approx \begin{bmatrix} (0.5, 0.08, 0.42) & (0.71, 0.05, 0.24) & (0.18, 0.35, 0.47) & (0, 1, 0) \\ (0.25, 0.33, 0.42) & (0.71, 0.05, 0.24) & (0.09, 0.53, 0.38) & (0.1, 0.6, 0.3) \\ (0, 1, 0) & (1, 0, 0) & (0.30, 0.24, 0.46) & (0.3, 0.3, 0.4) \\ (1, 0, 0) & (0, 1, 0) & (1, 0, 0) & (0.6, 0.1, 0.3) \\ (0.5, 0.09, 0.41) & (0.14, 0.62, 0.24) & (0, 1, 0) & (1, 0, 0) \end{bmatrix}.$$

The construction of Inter-Criteria Matrices  $\mathbf{K}^i = [K_{jj'}^i]$  (for  $i = 1, \dots, 5$ ) from the BBA matrix  $\mathbf{M}$  based on formulas (20)-

(22) yields the following five matrices

$$\mathbf{K}^1 \approx \begin{bmatrix} (0.26, 0.08, 0.66) & (0.36, 0.08, 0.56) & (0.12, 0.19, 0.69) & (0.08, 0.5, 0.42) \\ (0.36, 0.08, 0.56) & (0.51, 0.07, 0.42) & (0.14, 0.26, 0.6) & (0.05, 0.71, 0.24) \\ (0.12, 0.19, 0.69) & (0.14, 0.26, 0.6) & (0.15, 0.13, 0.72) & (0.35, 0.18, 0.47) \\ (0.08, 0.5, 0.42) & (0.05, 0.71, 0.24) & (0.35, 0.18, 0.47) & (1, 0, 0) \end{bmatrix}$$

$$\mathbf{K}^2 \approx \begin{bmatrix} (0.17, 0.17, 0.66) & (0.19, 0.25, 0.56) & (0.20, 0.16, 0.64) & (0.23, 0.18, 0.59) \\ (0.19, 0.25, 0.56) & (0.51, 0.07, 0.42) & (0.09, 0.38, 0.53) & (0.10, 0.43, 0.47) \\ (0.20, 0.16, 0.64) & (0.09, 0.38, 0.53) & (0.29, 0.09, 0.62) & (0.33, 0.10, 0.57) \\ (0.23, 0.18, 0.59) & (0.10, 0.43, 0.47) & (0.33, 0.10, 0.57) & (0.37, 0.12, 0.51) \end{bmatrix}$$

$$\mathbf{K}^3 \approx \begin{bmatrix} (1, 0, 0) & (0, 1, 0) & (0.24, 0.3, 0.46) & (0.3, 0.3, 0.4) \\ (0, 1, 0) & (1, 0, 0) & (0.30, 0.24, 0.46) & (0.3, 0.3, 0.4) \\ (0.24, 0.3, 0.46) & (0.30, 0.24, 0.46) & (0.15, 0.14, 0.71) & (0.16, 0.16, 0.68) \\ (0.3, 0.3, 0.4) & (0.3, 0.3, 0.4) & (0.16, 0.16, 0.68) & (0.18, 0.18, 0.64) \end{bmatrix}$$

$$\mathbf{K}^4 \approx \begin{bmatrix} (1, 0, 0) & (0, 1, 0) & (1, 0, 0) & (0.6, 0.1, 0.3) \\ (0, 1, 0) & (1, 0, 0) & (0, 1, 0) & (0.1, 0.6, 0.3) \\ (1, 0, 0) & (0, 1, 0) & (1, 0, 0) & (0.6, 0.1, 0.3) \\ (0.6, 0.1, 0.3) & (0.1, 0.6, 0.3) & (0.6, 0.1, 0.3) & (0.370, 0.12, 0.51) \end{bmatrix}$$

$$\mathbf{K}^5 \approx \begin{bmatrix} (0.26, 0.08, 0.66) & (0.12, 0.32, 0.56) & (0.08, 0.5, 0.42) & (0.5, 0.08, 0.42) \\ (0.12, 0.32, 0.56) & (0.40, 0.18, 0.42) & (0.62, 0.14, 0.24) & (0.14, 0.62, 0.24) \\ (0.08, 0.5, 0.42) & (0.62, 0.14, 0.24) & (1, 0, 0) & (0, 1, 0) \\ (0.5, 0.08, 0.42) & (0.14, 0.62, 0.24) & (0, 1, 0) & (1, 0, 0) \end{bmatrix}$$

The componentwise PCR6 fusion of all five  $\mathbf{K}^i$  matrices provides the following global Inter-Criteria matrix  $\mathbf{K}_{PCR6}$

$$\mathbf{K}_{PCR6} \approx \begin{bmatrix} (0.90, 0.02, 0.08) & (0.06, 0.83, 0.11) & (0.55, 0.15, 0.30) & (0.49, 0.25, 0.26) \\ (0.06, 0.83, 0.11) & (0.95, 0.01, 0.04) & (0.18, 0.58, 0.24) & (0.08, 0.80, 0.12) \\ (0.55, 0.15, 0.30) & (0.18, 0.58, 0.24) & (0.89, 0.02, 0.09) & (0.22, 0.48, 0.30) \\ (0.49, 0.25, 0.26) & (0.08, 0.80, 0.12) & (0.22, 0.48, 0.30) & (0.90, 0.02, 0.08) \end{bmatrix}$$

Applying formula (23) we get the following  $\mathbf{D}_{BI}^\theta$  distance matrix from each component of  $\mathbf{K}_{PCR6}$  to the total agreement state  $m_T = [m(\theta), m(\bar{\theta}), m(\theta \cup \bar{\theta})] = [1, 0, 0]$

$$\mathbf{D}_{BI}^\theta = \begin{bmatrix} 0.0601 & 0.8845 & 0.3124 & 0.3909 \\ 0.8845 & 0.0327 & 0.7037 & 0.8618 \\ 0.3124 & 0.7037 & 0.0668 & 0.6355 \\ 0.3909 & 0.8618 & 0.6355 & 0.0622 \end{bmatrix}. \quad (24)$$

We see that  $\mathbf{K}$  and  $\mathbf{K}_{PCR6}$  are different specially  $K_{23} = K_{32} = (0.5, 0.4, 0.1)$  with respect to  $K_{23}^{PCR6} = K_{32}^{PCR6} = (0.18, 0.58, 0.24)$ . Based on  $\mathbf{D}_{BI}^\theta$  matrix (24) it is obvious that no criteria strongly agree in this example so that no judicious MCDM simplification is recommended according to BF-ICRA.

### B. Example 2 (MCDM simplification)

Here we consider a more interesting example showing how an MCDM simplification is possible. We consider a  $6 \times 5$  MCDM problem with the following score matrix.

$$\mathbf{S} = [S_{ij}] = \begin{bmatrix} 7.5914 & 18.1828 & 18.3221 & 95.6739 & 4.5674 \\ 8.7753 & 20.5506 & 20.8240 & 48.0229 & -0.1977 \\ -1.3492 & 0.3017 & 0.7804 & 79.8283 & 2.9828 \\ 8.8739 & 20.7478 & 21.2302 & 13.3305 & -3.6669 \\ 5.2207 & 13.4413 & 13.5201 & 41.5979 & -0.8402 \\ -1.7320 & -0.4639 & 0.0213 & 91.4893 & 4.1489 \end{bmatrix}.$$

It is not very obvious to identify the closeness of these criteria (if any) to know if there is some underlying relationship between them. For the analysis, we apply the BF-ICRA approach proposed in this work. After applying all derivations (similarly to those presented in Example 1), we finally get the following  $\mathbf{D}_{BI}^\theta$  distance matrix from each component of  $\mathbf{K}_{PCR6}$  to the total agreement state  $m_T = [m(\theta), m(\bar{\theta}), m(\theta \cup \bar{\theta})] = [1, 0, 0]$

$$\mathbf{D}_{BI}^\theta = \begin{bmatrix} 0.0239 & \mathbf{0.0239} & \mathbf{0.0250} & 0.7512 & 0.7512 \\ \mathbf{0.0239} & 0.0239 & \mathbf{0.0250} & 0.7512 & 0.7512 \\ \mathbf{0.0250} & \mathbf{0.0250} & 0.0262 & 0.7595 & 0.7595 \\ 0.7512 & 0.7512 & 0.7595 & 0.0568 & \mathbf{0.0568} \\ 0.7512 & 0.7512 & 0.7595 & \mathbf{0.0568} & 0.0568 \end{bmatrix}.$$

From the analysis of upper off-diagonal components of  $\mathbf{D}_{BI}^\theta$  (put in boldface for convenience) it is clear that criteria  $C_1$ ,  $C_2$  and  $C_3$  are in almost total agreement because their distance is close to zero. Also we can observe from  $\mathbf{D}_{BI}^\theta$  that criteria  $C_4$  and  $C_5$  are also very close. So the original  $6 \times 5$  MCDM problem in this example can be simplified into a  $6 \times 2$  MCDM problem considering only the simplified score matrix involving only  $C_1$  and  $C_4$  because  $C_2$  and  $C_3$  behave similarly to  $C_1$  for decision-making, and  $C_5$  behaves similarly to  $C_4$ . Then the simplified MCDM will have to be solved by any preferred technique.

Does the BF-ICrA make sense in this example? The answer is positive because it suffices to remark that the columns of the score matrix are not totally independent because  $C_2(A_i) = 2 \cdot C_1(A_i) + 3$ ,  $C_3(A_i) = C_2(A_i) + \epsilon$  ( $\epsilon$  being a small contamination noise), and  $C_5(A_i) = 0.1 \cdot C_4(A_i) - 5$ . Hence the decision based either on  $C_1$ ,  $C_2$  or  $C_3$  will be very close, as well as the decision based on  $C_4$  or  $C_5$ . Therefore the result of BF-ICrA makes sense and the expected simplification of MCDM is well obtained from BF-ICrA. If we apply AHP, which is nothing but the weighted arithmetic average and we use the normalized score matrix based on (2), or BF-TOPSIS methods to solve original MCDM (assuming equal importance of criteria), or if we apply simplified MCDM based on BF-ICrA, we will get same preference order  $A_1 \succ A_2 \succ A_4 \succ A_5 \succ A_6 \succ A_3$ . So, the best decision to make is  $A_1$  in this example.

## VII. CONCLUSION

In this paper we have proposed a new method called BF-ICrA to simplify (when it is possible) Multi-Criteria Decision-Making problems based on inter-criteria analysis and belief functions. This method is in the spirit of Atanassov's method but proposes a better construction of Inter-Criteria Matrix that fully exploits all information of the score matrix, and the closeness measure of agreement between criteria based on belief interval distance. This BF-ICrA approach for simplifying MCDM could deal also with imprecise or missing score values using the technique presented in [8]. An application of BF-ICrA for GPS surveying problem is presented in [38], and applications of BF-ICrA for simplifying and solving real MCDM problems for the prevention of natural risks in mountains will be the object of forthcoming investigations.

**Abstract**—The decision-making trial and evaluation laboratory (DEMATEL) method employs expert assessments expressed by crisp values to construct a group initial direct-relation (IDR) matrix. However, it tends to be a low-precision expression, especially in complex practical problems. Although significant efforts have been made to improve the DEMATEL method, these improvements tend to neglect individual characteristics and group consensus, resulting in unconvincing decision results. This study provides a Dezert-Smarandache theory (DSmT)-based group DEMATEL method with reaching consensus. In order to reasonably determine the group IDR matrix, basic belief assignment (BBA) function is employed to extract expert assessments and the proportional conflict redistribution rule no.5 (PCR5) of DSmT is employed to make fusion to derive the temporary group IDR matrix. Moreover, the consensus measures at both expert level and pair-factors level are calculated to determine whether the acceptable consensus level has been reached or not. If the required consensus level is not reached, a feedback mechanism will be activated to help experts reach a consensus. A consensus group IDR matrix for the group DEMATEL can be obtained with the help of feedback mechanism, based on which an algorithm is summarized for the proposed method to identify major factors in a complex system. Finally, numerical comparison and discussion are introduced to verify the effectiveness and applicability of the proposed method and algorithm.

**Keywords:** DEMATEL, group decision making; Dezert-Smarandache theory (DSmT), consensus reaching, evidence distance, expert weight.

## I. INTRODUCTION

Between 1972 and 1976, the Science and Human Affairs Program of Battelle Memorial Institute of Geneva developed the decision-making trial and evaluation laboratory (DEMATEL) method. This method aimed to describe the basic concept of contextual relations and identify cause-effect chain factors for a complex decision problem in an understandable manner by addressing the influence relations among factors given by experts [1], [2]. It was considered to be a credible decision-making method.

The DEMATEL method has been extensively used to solve complex decision problems because of its simplicity and effectiveness, including problems pertaining to hospital service quality [3], decision making [4], sustainable supply chain

management [5], [6], etc. In special, in order to determine the weights of factors by considering their relations, the DEMATEL method is also extended into decision making fields, such as analytic hierarchy process (AHP) [7], [8], analytic network process (ANP) [9]–[14], and technique for order preference by similarity to ideal solution (TOPSIS) [15], [16]. In the DEMATEL method, the initial decision information is always subjectively given by experts in the form of crisp values and calculated to obtain an individual or group initial direct-relation (IDR) matrix by simple operations (e.g., weighted sum). However, such descriptions and operations are considered to hardly reflect the vagueness of the real world [17]. Therefore, scholars have carried out some research to improve the DEMATEL combined with fuzzy theory [18]. Several fuzzy DEMATEL methods have been introduced. For examples, Abdullah [19] introduced interval-valued intuitionistic fuzzy numbers to improve the judgement of DEMATEL in a group decision-making (GDM) environment. Addae [20] used a two-step fuzzy DEMATEL method to solve a practical problem. Asan [21] proposed a new interval-valued hesitant fuzzy approach to DEMATEL to explicitly deal with hesitation in expert assessments and offered a better representation of uncertainty, etc [22]–[25].

Obviously, all these extensions have made great contributions to the DEMATEL method, and its ability of dealing with complex problems can be strengthened to some extent. As currently defined, instead of one expert, a panel gives the assessments on the influence relations of factors, and multiple experts arrive at an acceptable result [26]. This process makes it necessary to extend the traditional DEMATEL method to a group DEMATEL method, which belongs to GDM problems. Although some literature considers the DEMATEL from the perspective of GDM, we believe that these group DEMATEL methods have a lot of room for further improvement in both expert assessment extraction and group IDR matrix construction.

Firstly, the expert assessment extraction of group DEMATEL method should be improved to obtain accurate decision information in accordance with experts' cognitive competence. As introduced earlier, DEMATEL is a GDM method totally

based on expert assessments to conduct later computation and analyzation. Considering the complexity of reality and individual characteristics of experts, there is no doubt that not every expert is proficient in all areas. In other words, experts may give incomplete or uncertain assessments to the influence relations among factors for a specific complex practical problem. However, all of the existing group DEMATEL methods default that each expert can give a definite assessment for every pair of factors by means of crisp values or fuzzy numbers, and neglect the problem that the assessments given by experts may be incomplete in practice. If experts who cannot give definite assessments with crisp values or fuzzy numbers are required to give the assessments in those forms, the final decision of DEMATEL resulted from the ineffective assessments may be erroneous. Therefore, understanding how to depict and fuse incomplete information from experts is of great importance to improve the properties of the group DEMATEL method. Fortunately, the basic belief assignment (BBA) function, as a key concept in the Dezert-Smarandache theory (DSMT) of evidence [27], can directly express the uncertainty by assigning probability to the subsets of a set composed of multiple objects rather than to each individual object [28]. The BBA functions generated from different evidence sources (experts) could be well fused by the proportional conflict redistribution rule no. 5 (PCR5). All these features exactly meet the requirements of the group DEMATEL method. Accordingly, DSMT is used to extract and fuse expert assessments to derive the group IDR matrix in this paper. Moreover, the differences in experts' knowledge backgrounds and cognitive abilities on a particular problem are reflected by expert weights [29]. Expert weights are reflected as discounting parameters to reflect one's relative importance in a group during fusion process. In this paper, expert weights are calculated based on similarity functions of expert assessments.

Secondly, the group IDR matrix construction of group DEMATEL method should be improved to obtain the acceptable decision results in accordance with experts' satisfaction. In the GDM, "group" refers to not only the number of experts merely, but also the experts who have common interests in reaching a consensus for the ultimate satisfactory results despite individual differences. This principle helps to reduce biased evaluations and inherent partiality in GDM processes [30]. Unfortunately, the group IDR matrix in the existing group DEMATEL methods is frequently constructed by making arithmetic average values for individual IDR matrices, while whether experts agree with the group results is scarcely concerned. The group IDR matrix plays a fundamental role in the entire DEMATEL processes and it has a significant influence on the effectiveness of final results. If strong inconsistency and conflict exist among experts, the group IDR matrix may not be able to precisely describe the real influence relations of factors. Therefore, it is particularly important to construct a group IDR matrix according to the consensus rules, that is, to construct a group consensus IDR matrix by reaching general or widespread agreement among the experts involved in the GDM processes [31]. Fortunately, Herrera-Viedma proposed

a rational consensus model in GDM composed of a selection process and a consensus-reaching process (CRP), which had become a hot issue in the recent GDM area. The CRP has been successfully introduced to make GDM with different situations, such as hesitant fuzzy preference relations, Delphi processes, multi-attribute large-scale GDM, sentiment analysis, and virtual reality industry [3]–[6], [32]. Traditionally, unanimous agreement of all experts in CRP is required. However, the desired result can hardly be achieved because of the diversity of opinions, knowledge, and experiences of experts. Therefore, the concept of "soft consensus" has been provided, in which, "soft" means better reflecting all possible levels of agreement by setting an acceptable consensus level (CL) threshold value (such as 0.8 rather than 1) and guiding the CRP until a high-level agreement is achieved among the individuals. Soft consensus can be reached through an iterative dynamic process with several collection and adjustment rounds [33], [34]. Hence, in this paper, we consider a soft CRP in the group IDR matrix construction, and transform the original static group DEMATEL problems into dynamic ones.

The motivation of this paper is to improve group DEMATEL method according to the following three aspects. Firstly, the BBA function is used to extract expert assessments to accurately express uncertainty and incompleteness, thus reducing the loss of accuracy. Secondly, the initial assessments are discounted with expert weights by using Shafer's discounting method. Moreover, the PCR5 of DSMT is used to fuse the discounted assessments to overcome the defects in the intuitional paradox of Dempster's combination rule. Thirdly, we apply a soft CRP to help reach an acceptable CL in the construction of group IDR matrix to ensure the consistency and satisfaction among experts. This paper is organized as follows. Section II briefly introduces the basic knowledge of DEMATEL and DSMT. In Section III, the DSMT-based group DEMATEL method with reaching consensus is proposed, and the corresponding algorithm is summarized. In Section IV, the numerical comparison and discussion are provided to demonstrate the performances of the proposed method and algorithm. In Section V, the conclusion is drawn and the future research directions are briefly discussed.

## II. PRELIMINARIES

In order to facilitate the later formulation, some basic concepts of DEMATEL and the Dezert-Smarandache theory (DSMT) are given in this section.

### A. DEMATEL method

The DEMATEL method is an effective way to analyze the influence relations among factors of a system. Through an analysis of the total influence relation of factors by the DEMATEL method, we can obtain a better understanding of structural relations and an ideal way to solve complicated system problems. Consider that a group of experts are invited to assess the influence relations for a set of factors  $F = \{f_1, \dots, f_L\}$  with a set of grade levels  $\{0, 1, 2\}$ , where the expert set is  $E = \{e_1, \dots, e_K\}$ , and the degree of influence to which he

or she believes factor  $f_i$  has an effect on factor  $f_j$  (denoted by  $f_i \rightarrow f_j$ ) is assessed by expert  $e_k$  and denoted as  $g_{ij}^k, \forall i, j, k$ . The meaning of each element in the set of grade levels is that 0 denotes “no influence”, 1 denotes a “low influence” and 2 denotes a “very high influence”. The central concepts in the DEMATEL are defined as follows.

**Definition 1** [35]. Suppose a pairwise comparison of influence degree from the  $i$ -th to the  $j$ -th factor given by the  $k$ -th expert  $e_k$  is denoted as  $g_{ij}^k$  with 0–2 grade levels, and the grade levels given by each expert form a  $L \times L$  non-negative answer matrix  $G^k = [g_{ij}^k]_{L \times L}$ ,  $k = 1, \dots, K$ . The group IDR matrix, which represents the initial direct relation between each pair of factors derived from experts, is obtained by calculating the average values of all experts’ answer matrices as  $G = [g_{ij}]_{L \times L}$ , where  $g_{ij} = \sum_{k=1}^K g_{ij}^k / K$ , for  $i, j = 1, \dots, L$ .

In Definition 1, the 0, 1, 2 grade levels mean “no influence”, “medium influence”, and “high influence”, respectively. Note that, the diagonal elements of each answer matrix  $G^k$  are all set to zero, which means that the factors do not influence themselves.

**Definition 2** [35]. The maximal row-wise and column-wise sum of matrix  $G$  is calculated by  $g' = \max(\max_{1 \leq i \leq L} \sum_{j=1}^L g_{ij}, \max_{1 \leq j \leq L} \sum_{i=1}^L g_{ij})$ ; then the normalized IDR matrix  $D = [d_{ij}]_{L \times L}$  can be computed according to (1).

$$D = G/g'. \quad (1)$$

**Definition 3** [35]. Suppose the direct and indirect relations among several factors are represented by the total relation matrix, and it is defined as in (2).

$$A = \lim_{N \rightarrow \infty} (D + D^2 + \dots + D^N) = D(I - D)^{-1}. \quad (2)$$

Some kinds of extensions are further discussed to strengthen the original DEMATEL. One kind of extensions is used to overcome the drawback that raising the normalized IDR matrix to the power of infinity may not converge to zero, and hence, the total relation matrix may not converge (see (2)). A very small positive number  $\mu$  (e.g.,  $\mu = 10^{-5}$ ) is introduced in the maximal row-wise and column-wise sum of matrix  $G$  as  $g'' = \max(\max_{1 \leq i \leq L} \sum_{j=1}^L g_{ij}, \mu + \max_{1 \leq j \leq L} \sum_{i=1}^L g_{ij})$ . Other steps remained unchanged as in the original DEMATEL. The revised DEMATEL guarantees that the normalized IDR matrix to infinite power will converge to zero and that the total relation matrix can be obtained smoothly [36].

**Definition 4** [35]. Suppose  $r$  and  $c$  represent the sum of rows and the sum of columns of the total relation matrix  $A$ . According to  $A = [a_{ij}]_{L \times L}$ ,  $r$  and  $c$  can be defined as follows:

$$\begin{aligned} r &= [r_i]_{L \times 1} = \left( \sum_{j=1}^L a_{ij} \right)_{L \times 1}, \\ c &= [c_i]_{1 \times L} = \left( \sum_{j=1}^L a_{ji} \right)_{1 \times L}. \end{aligned} \quad (3)$$

where  $r_i$  shows the total influence, both direct and indirect, given by the factor  $f_i$  to other factors;  $c_i$  shows the total influence, both direct and indirect, received by the factor  $f_i$  from other factors;  $r_i + c_i$  is defined as the prominence, showing the degree of the important role that the factor  $f_i$  plays in the complex system; and  $r_i - c_i$  shows the net influence that the factor  $f_i$  contributes to the complex system. Note that, if  $r_i - c_i$  is positive, the factor  $f_i$  is a net causer; if  $r_i - c_i$  is negative, the factor  $f_i$  is a net receiver.

### B. Dezert-Smarandache theory

DSMT, jointly proposed by Dezert and Smarandache [37], can be used to obtain more accurate fusion results of BBA functions especially in high conflicting information cases. It has a series of proportional conflict redistribution rules to make fusion for evidences [38], among which, PCR5 is the most widely used one with the advantages in dealing with conflict belief functions. For example, it provides the appropriate redistribution of conflict beliefs and can produce a reasonable fusion result even in highly conflicting cases. These attractive features motivate the use of DSMT in GDM problems, such as map reconstruction of robot [39], decision making support [40], [41], target type tracking [42], image processing [43], data classification [44]–[48], clustering [47], [49], [50], and so on.

In DSMT framework, the frame  $\Theta = \{\theta_1, \dots, \theta_Y\}$  is a finite set of  $Y$  exhaustive propositions that are not necessarily mutually exclusive. The hyper-power set  $D^\Theta$  is defined as the set of all composite propositions built from elements of  $\Theta$  with  $\cup$  and  $\cap$  operators, such that [51]:

- (i)  $\emptyset, \theta_1, \dots, \theta_Y \in D^\Theta$ ;
- (ii) if  $\theta_y, \theta_{y'} \in D^\Theta$ , then  $\theta_y \cup \theta_{y'} \in D^\Theta$  and  $\theta_y \cap \theta_{y'} \in D^\Theta$ ;
- (iii) No other elements belong to  $D^\Theta$ , except those obtained by using rules (i) or (ii).

**Definition 5** [37]. Suppose  $\Theta = \{\theta_1, \dots, \theta_Y\}$  is a set of exhaustive propositions; then the basic belief assignment is defined over the hyper-power set  $D^\Theta$ . If the mapping function  $m : D^\Theta \rightarrow [0, 1]$  could fulfill the following:

$$m(\emptyset) = 0, \quad \sum_{\theta \in D^\Theta} m(\theta) = 1, \quad (4)$$

then  $m(\cdot)$  is called the BBA function. If  $m(\theta) > 0$ ,  $\theta$  is called a focal element.

In DSMT framework, PCR5 for making fusion for two pieces of evidence is introduced as follows.

**Definition 6** [37]. Suppose the BBA functions of two pieces of evidence are  $m_1$  and  $m_2$  on  $D^\Theta$ ; then, PCR5 to fuse  $m_1$  and  $m_2$  can be defined as follows for all  $\theta \in D^\Theta$ :

$$m_{PCR5}(\theta) = \begin{cases} 0, & \text{if } \theta = \emptyset, \\ \sum_{\substack{\theta' \cap \theta'' = \theta \\ \theta', \theta'' \subseteq D^\Theta}} m_1(\theta') m_2(\theta'') \\ \quad + \sum_{\substack{\theta''' \in D^\Theta \\ \theta \cap \theta''' = \emptyset}} \left[ \frac{m_1(\theta)^2 m_2(\theta''')}{m_1(\theta)^2 + m_2(\theta''')} \right. \\ \quad \left. + \frac{m_2(\theta)^2 m_1(\theta''')}{m_2(\theta)^2 + m_1(\theta''')} \right], & \text{if } \theta \neq \emptyset. \end{cases} \quad (5)$$

### III. THE PROPOSED METHOD

In the proposed method, we construct the group IDR matrix in the DEMATEL by following two steps. Firstly, we develop an expert assessments extraction and fusion mechanism with DSMT to obtain a temporary group IDR matrix (see III-A). Secondly, we activate the soft CRP based on the current individual and group IDR matrices to reach a soft consensus among experts (see III-B).

#### A. Expert Assessment Extraction and Fusion

In traditional DEMATEL, experts are advised to give their assessments of the influence relations among factors by means of crisp values to construct the group IDR matrix  $G = [g_{ij}]_{L \times L}$  (see Definition 1), which is a rough extraction method with low precision. When restricted by expert experiences and knowledge, the assessments given by experts may be ignorant and partially credible. Taking the influence degree for  $f_i \rightarrow f_j$  and expert  $e_k$  as an example, the expert may well know this problem and he or she can give a definite result by using one of the given grade levels  $\{0, 1, 2\}$ . On the contrary, the expert may not know this problem at all, in which case he or she cannot give any assessment information about the influence degree. In most instances, the expert knows this problem to a certain extent and he or she may point out that the influence degree belongs to several grade levels but may not be sure which is the best one. Obviously, experts cannot give their assessments by means of crisp values in the latter two situations—that is, the original extraction method is not practical and does not consider experts' personality. Thus, we employed the BBA function to extract expert assessments in this paper as shown in Fig. 1.

As shown in Fig. 1, the expert assessment extraction and fusion mechanism includes three major steps. (1) Extracting expert assessments with BBA function; (2) Discounting these assessments with Shafer's discounting method; (3) Fusing the discounted assessments with PCR5. Next, we will give a detailed definition and explanation of the procedures involved in the above processes.

Let the frame of discernment be  $\Theta = \{\theta_1, \theta_2, \theta_3\} = \{0, 1, 2\}$ , which can be seen as the discernment frame of DSMT. Expert  $e_k$  is asked to assess the influence degree for  $f_i \rightarrow f_j$  and his/her assessment is allowed to be expressed by the BBA function as given in Definition 5 and shown in (6).

$$b_{ij}^k = \{(\theta, b_{ij}^k(\theta)) \mid \sum_{\theta \subseteq \Theta} b_{ij}^k(\theta) = 1; b_{ij}^k(\theta) \geq 0, \theta \subseteq \Theta, \forall i, j, k\}. \quad (6)$$

All of the BBA functions make up the individual IDR matrix for expert  $e_k$ , denoted as  $B^k = [b_{ij}^k]_{L \times L}$ , with  $i, j = 1, \dots, L$  and  $k = 1, \dots, K$ . Note that the basic beliefs in  $b_{ij}^k$  can be assigned not only to singleton grade levels but also to any subsets of  $\Theta$ , thereby it is allowed such an assessment (also called a piece of evidence) to be profiled by a BBA defined on the hyper-power set  $D^\Theta$ . It is capable of reflecting ignorance in expert assessments, and the basic beliefs in  $b_{ij}^k$

can be given to  $\Theta$  (global ignorance) or to  $\theta \subset \Theta$  (local ignorance) according to the unknown and partial assessments [52]. Expert assessments could be expressed precisely through BBA functions as discussed, laying a great foundation for later DEMATEL procedures.

**Example 1.** Assume expert  $e_1$  points out the influence degree for  $f_i \rightarrow f_j$  has 30% probabilities belonging to  $\theta_1$  and 70% probabilities belonging to  $\theta_2$ . Thus, his or her assessment is described as  $b_{ij}^1(\theta) = \{(\theta_1, 0.30), (\theta_2, 0.70)\}$ . Expert  $e_2$  points out the influence degree has 20% probabilities belonging to  $\theta_1$  and has 80% probabilities belonging to  $\theta_2 \cup \theta_3$  but is not sure which is the best one. Therefore, his or her assessment is described as  $b_{ij}^2(\theta) = \{(\theta_1, 0.20), (\theta_2 \cup \theta_3, 0.80)\}$ . Expert  $e_3$  points out the influence degree for  $f_i \rightarrow f_j$  has 100% probabilities belonging to  $\theta_2 \cap \theta_3$ . Thus, his or her assessment is described as  $b_{ij}^3(\theta) = \{(\theta_2 \cap \theta_3, 1.00)\}$ . Expert  $e_4$  cannot give any information about the influence degree. Therefore, his or her assessment is described as  $b_{ij}^4(\theta) = \{(\Theta, 1.00)\}$ .

Normally, expert weight is subjective and relative to reflect the importance of one's assessments in a group, and it is usually denoted by  $w$  in  $[0, 1]$ , with 0 and 1 respectively standing for not important at all and the most important [53], [54]. It is obvious to find that the expert weight can be determined by AHP [55], ANP [56] or Delphi [57], and it can also be determined subjectively according to the requirements of actual issues [58]. As discussed, expert weight is used to account for one's relative importance among all experts—that is, the closer one's assessments are to others' assessments, the more important the expert is likely to be [40]. Hence, in our opinion, expert weight could be calculated indirectly based on the similarity between one expert and other experts—that is, the higher the similarity of assessments between the expert and others, the larger the weight of the expert. Expert weight is directly proportional to the similarity between expert assessments and others' assessments. Thus, we use evidential distance to depict the similarity of expert assessments, based on which we could calculate expert weight in simple ways. The Euclidean evidential distance and Euclidean evidential similarity, which have little computation complexity and fast convergence speed, are defined as follows.

**Definition 7** [59]. Suppose  $m_1$  and  $m_2$  are two BBA functions for the same frame of discernment  $\Theta$ ,  $\theta_n$  is the  $n$ -th element of  $D^\Theta$ , and  $|D^\Theta|$  is the cardinality of  $D^\Theta$ . The distance between  $m_1$  and  $m_2$  is defined as follows.

$$Dist_E(m_1, m_2) = \frac{1}{\sqrt{2}} \sqrt{\sum_{n=1}^{|D^\Theta|} [m_1(\theta_n) - m_2(\theta_n)]^2}. \quad (7)$$

**Definition 8** [59]. Suppose  $m_1$  and  $m_2$  are two BBA functions for the same frame of discernment  $\Theta$ ,  $\theta_n$  is the  $n$ -th element of  $D^\Theta$ , and  $|D^\Theta|$  is the cardinality of  $D^\Theta$ . The Euclidean similarity function  $Sim_E(m_1, m_2)$  is defined based on the Euclidean evidential distance as follows.

$$Sim_E(m_1, m_2) = 1 - \frac{1}{\sqrt{2}} \sqrt{\sum_{n=1}^{|D^\Theta|} [m_1(\theta_n) - m_2(\theta_n)]^2}. \quad (8)$$

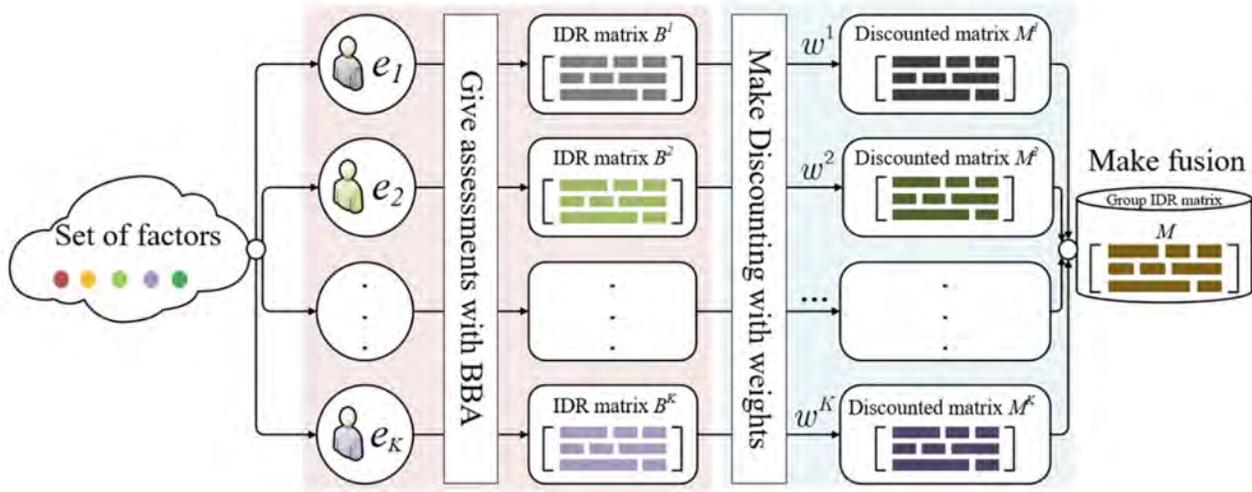

Figure 1. Expert assessments extraction and fusion mechanism.

**Example 2.** Assume two pieces of evidence,  $b_1 = \{(\theta_2, 1)\}$  and  $b_2 = \{(\theta_1, 0.4), (\theta_2, 0.6)\}$ , and that the distance between them could be computed by (7):  $Dist_E(m_1, m_2) = \frac{1}{\sqrt{2}}\sqrt{(0 - 0.4)^2 + (1 - 0.6)^2} = 0.4$ . The similarity between them is computed by (8):  $Sim_E(m_1, m_2) = 1 - 0.4 = 0.6$ .

On the basis of the previous definitions, the similarity between experts can be directly calculated. Thus, we define the following expert weight calculation method.

**Definition 9** [60]. Suppose the individual IDR matrix consisting of all influence relations among factors given by expert  $e_k$  is  $B^k = [b_{ij}^k]_{L \times L}$ , with  $i, j = 1, \dots, L$  and  $k = 1, \dots, K$ . The similarity between experts  $e_k$  and  $e_{k'}$  on each pair of factors  $f_i \rightarrow f_j$  is  $Sim_E(b_{ij}^k, b_{ij}^{k'})$ , and the similarity between any two experts is computed as  $s^{kk'} = \sum_{i,j=1, i \neq j}^L Sim_E(b_{ij}^k, b_{ij}^{k'}) / L^2$ , where  $L^2$  denotes the quantity of factor pairs, making up the similarity matrix as follows.

$$S = [s^{kk'}]_{K \times K} = \begin{bmatrix} 1 & \dots & s^{1k} & \dots & s^{1K} \\ \vdots & \ddots & \vdots & \ddots & \vdots \\ s^{k1} & \dots & 1 & \dots & s^{kK} \\ \vdots & \ddots & \vdots & \ddots & \vdots \\ s^{K1} & \dots & s^{Kk} & \dots & 1 \end{bmatrix}. \quad (9)$$

The support of  $e_k$  can be obtained by adding all of the elements in the similarity matrix  $S$  that are related to expert  $e_k$  except for self-similarity, i.e.,  $Sup(e_k) = \sum_{k'=1, k' \neq k}^K s^{kk'}$ ,  $k = 1, \dots, K$  where  $Sup(e_k)$  represents the support degree of expert  $e_k$  received from other experts. By normalizing them, we could obtain the expert credibility  $Crd(e_k)$  which is generally regarded as expert weight  $w^k$  as follows.

$$w^k = Crd(e_k) = Sup(e_k) / \sum_{k=1}^K Sup(e_k), \quad k = 1, \dots, K. \quad (10)$$

**Example 3.** Assume experts  $e_1, e_2, e_3$  give their assessments for the influence relations among factor set  $F = \{F_1, F_2, F_3\}$ , respectively, as follows:

$$B^1 = \begin{bmatrix} \{(\theta_1, 1)\} & \{(\theta_2, 1)\} & \{(\theta_3, 1)\} \\ \{(\theta_2, 0.7), (\theta_3, 0.3)\} & \{(\theta_1, 1)\} & \{(\theta_1, 0.4), (\theta_3, 0.6)\} \\ \{(\theta_1, 1)\} & \{(\theta_2, 1)\} & \{(\theta_1, 1)\} \end{bmatrix},$$

$$B^2 = \begin{bmatrix} \{(\theta_1, 1)\} & \{(\theta_2, 1)\} & \{(\theta_3, 1)\} \\ \{(\theta_1, 0.8), (\theta_2, 0.2)\} & \{(\theta_1, 1)\} & \{(\theta_1, 1)\} \\ \{(\theta_1, 1)\} & \{(\theta_1, 0.5), (\theta_2, 0.5)\} & \{(\theta_1, 1)\} \end{bmatrix},$$

$$B^3 = \begin{bmatrix} \{(\theta_1, 1)\} & \{(\theta_2, 1)\} & \{(\theta_1, 0.2), (\theta_2 \cup \theta_3, 0.8)\} \\ \{(\theta_2 \cup \theta_3, 1)\} & \{(\theta_1, 1)\} & \{(\theta_1, 1)\} \\ \{(\theta_1, 1)\} & \{(\theta_1, 1)\} & \{(\theta_1, 1)\} \end{bmatrix}.$$

The similarity matrix can be calculated by Definition 9 as follows:

$$S = \begin{bmatrix} 1.00 & 0.47 & 0.29 \\ 0.47 & 1.00 & 0.41 \\ 0.29 & 0.41 & 1.00 \end{bmatrix}.$$

We calculate the support degree of experts as  $Sup(e_1) = 0.47 + 0.29 = 0.76$ ,  $Sup(e_2) = 0.47 + 0.41 = 0.88$ ,  $Sup(e_3) = 0.29 + 0.41 = 0.70$ . Then we compute the expert weight as  $w^1 = Crd(e_1) = 0.76 / (0.76 + 0.88 + 0.70) \approx \{(\theta_1, P_{ij}^1), (\theta_2, P_{ij}^2), (\theta_3, P_{ij}^3)\}$ ,  $w^2 = 0.87 / 2.34 \approx 0.37$ ,  $w^3 = 0.70 / 2.34 \approx 0.30$ .

As mentioned above, expert weight should be considered through Shafer's discounting method, which multiplies the masses of focal elements by the expert weight and transfers all of the remaining discounted mass to the full ignorance  $\Theta$ . Mathematically, Shafer's discounting method can be given as in Definition 10.

**Definition 10** [61]. Suppose the BBA function is  $b$  as in (4), and  $w$  is a parameter to discount the evidence,  $0 \leq w \leq 1$ . Then, Shafer’s discounting method is defined as follows:

$$m(\theta) = \begin{cases} 0, & \theta = \emptyset, \\ w \cdot b(\theta), \theta \subseteq \Theta & \theta \neq \emptyset, \\ w \cdot b(\theta) + 1 - w, & \theta = \Theta. \end{cases} \quad (11)$$

If the sum of weights is equal to 1, then the discounting parameter is usually derived by standardizing the weights as  $\bar{w}^k = w^k / \max(w^k | k = 1, \dots, K)$ . The discounted expert assessments could be described as follows.

$$m_{ij}^k = \{(\theta, m_{ij}^k(\theta)) | \sum_{\theta \subseteq \Theta} m_{ij}^k(\theta) = 1; m_{ij}^k(\theta) \geq 0, \theta \subseteq \Theta, \forall i, j, k\}. \quad (12)$$

The discounted individual IDR matrix is denoted as  $M^k = [m_{ij}^k]_{L \times L}$ , with  $i, j = 1, \dots, L$  and  $k = 1, \dots, K$ .

**Example 4.** Assume expert weight is  $W = \{w_1 = 0.40, w_2 = 0.20, w_3 = 0.20, w_4 = 0.20\}$ . The assessments given by four experts are the same as in Example 1. The discounting parameters for the four experts can be standardized as  $\bar{w}^1 = w_1 / \max(w_1, \dots, w_4) = 0.40/0.40 = 1.00$ , and similarly we get  $\bar{w}^2 = \bar{w}^3 = \bar{w}^4 = 0.20/0.40 = 0.50$ . Taking them into (11), the discounted assessments are as follows:  $m_{ij}^1(\theta) = \{(\theta_1, 0.30), (\hat{a}\theta_2, 0.70)\}$ ,  $m_{ij}^2(\theta) = \{(\theta_1, 0.10), (\theta_2 \cup \theta_3, 0.70), (\Theta, 0.50)\}$ ,  $m_{ij}^3(\theta) = \{(\theta_2 \cap \theta_3, 0.50), (\Theta, 0.50)\}$ , and  $m_{ij}^4(\theta) = \{(\Theta, 1.00)\}$ .

The DSMT framework with PCR5 rule can be used to make fusion for individual discounted assessments as in (12) and the fusion result can be described as follows:

$$m_{ij} = \{(\theta, m_{ij}(\theta)) | \sum_{\theta \subseteq \Theta} m_{ij}(\theta) = 1; m_{ij}(\theta) \geq 0, \theta \subseteq \Theta, \forall i, j\}. \quad (13)$$

**Example 5.** Assume two pieces of evidence are:  $m_{ij}^1(\theta) = \{(\theta_1, 0.20), (\theta_2, 0.30), (\Theta, 0.50)\}$ , and  $m_{ij}^2(\theta) = \{(\theta_2, 0.70), (\Theta, 0.30)\}$ . Taking them into (5), the fusion results are obtained as  $m_{ij}(\theta) = \{(\theta_1, 0.09), (\theta_2, 0.76), (\Theta, 0.15)\}$ .

**B. The Soft CRP for Group DEMATEL**

Soft CRP can be designed with the aim of supporting experts until a group consensus is reached by following several discussion and adjustment rounds. As discussed in Section I, situations in which all of the experts agree with each other unanimously are rare or not desirable in the decision making process. Since the “unanimous consensus” of conflict tolerance, which has the ability to satisfy all pairs of BBA functions, rarely exists, the choice of a “soft consensus” is largely subjective and application oriented [62]. That is, setting an acceptable CL threshold value (suppose that the value is 0.8 there) to guide the whole process to reach group consensus. Basically, this process relies on making assumptions about experts’ willingness to change their opinion or preferences

[63], [64]. Initially, consensus measures are computed based on individual and group IDR matrices to determine whether an acceptable CL has been reached or not. If so ( $CL \geq 0.8$ ), the soft CRP is finished and a consensus group IDR matrix can be obtained. Otherwise ( $CL < 0.8$ ), the feedback mechanism will be activated, and the experts who are not contributing to the consensus are identified and the advice about how to alter their assessments is generated [65].

This consensus measure can indicate the current consensus situation throughout the soft CRP. According to the characteristics of group DEMATEL, the consensus measure is categorized into two levels, i.e., pair-factors level and expert level. The pair-factors level is the most basic level and reflects the original conflict degree. At this level, experts make some adjustments to increase consistency among the group. The expert level is the highest level, which reflects the conflict degree between a specific expert and the group as a whole for the collected results on all pairs of factors [66]. We employ these two levels of consensus measures to identify inconsistencies between experts and group.

The calculation methods for consensus measures can be derived based on the similarities between these assessments. At the pair-factors level, the consensus measure values can be calculated based on the Euclidean similarity function as in Definition 11. At the expert level, the consensus measure values can be calculated by adding the consensus measure values on all of pair-factors for an expert as in Definition 12. Obviously, the order for calculating the two levels of consensus measure is pair-factors level at first and then expert level. When determining the inconsistency assessments that need to be modified, the order is the highest level at first and then the most basic level. Experts only adjust the conflicting assessments based on the recommendations at the pair-factors level.

**Definition 11.** In the  $t$ -th round, suppose the assessments of the pair of factors  $f_i \rightarrow f_j$  given/calculated by expert  $e_k$  and group are  $b_{ij}^{k,t}$  and  $m_{ij}^t$ . Then, the consensus measure values can be calculated by the Euclidean similarity function as follows.

$$c_{ij}^{k,t} = 1 - \frac{1}{\sqrt{2}} \sqrt{\sum_{n=1}^{|D^\Theta|} [b_{ij}^{k,t}(\theta_n) - m_{ij}^t(\theta_n)]^2}. \quad (14)$$

**Definition 12.** In the  $t$ -th round, suppose the consensus measure value of expert  $e_k$  for  $f_i \rightarrow f_j$  at pair-factors level is  $c_{ij}^{k,t}$ ,  $\forall i, j, k$ , then the consensus measure value of expert  $e_k$  at expert level in this round can be calculated as follows.

$$c^{k,t} = \sum_{i,j=1, i \neq j}^L c_{ij}^{k,t} / L^2, \quad (15)$$

where  $L^2$  denotes the quantity of factor pairs.

The closer the value  $c^{k,t}$  is to 0, the greater the conflict degree; the closer the value is to 1, the smaller the conflict. Obviously,  $c^{k,t} = 0$  indicates complete conflict between expert  $e_k$  and group, and  $c^{k,t} = 1$  indicates no conflict between them.

If each expert's consensus measure  $c^{k,t}$  is larger than the acceptable CL threshold value, indicating that existing conflict degree can be accepted by all experts and group consensus is reached, then the soft CRP is finished and the current collected group IDR matrix  $M^t = [m_{ij}^t]_{L \times L}$  is taken as a consensus result. Otherwise, if one's consensus measure  $c^{k,t}$  is lower than the acceptable CL threshold value, indicating that strong conflict degree among experts, then the feedback mechanism is carried out to help the inconsistent experts adjust their assessments to enhance group consensus, and a new round ( $t + 1$ ) of group IDR matrix construction should be initiated.

Note that, expert weights may be not fixed during several of the rounds for the reason that expert assessments may be changed in the context of not reaching the acceptable CL. Thus, in each new round, we need to recalculate expert weights based on the latest assessments. In order to prevent the collective assessments from failing to converge after several discussion rounds, we incorporate a maximum number of rounds ( $t_{MAX}$ ) in the soft CRP to develop. It can be ensured that the feedback mechanism will not be carried out when and the current collected group IDR matrix will be taken as the final result even if the acceptable CL has not been reached yet.

Suppose the acceptable CL threshold values at expert level and pair-factors level are  $\varepsilon_e$  and  $\varepsilon_f$ . Then the processes of feedback mechanism can be divided into the following two steps.

- Step 1: Experts whose consensus measure values at expert level are lower than the threshold value  $\varepsilon_e$  in the  $t$ -th round are identified as follows.

$$\tilde{E}_t = \{k | c^{k,t} \leq \varepsilon_e\}. \quad (16)$$

- Step 2: For the identified experts in step 1, their assessments for such pairs of factors that the consensus measure values are lower than the threshold value are identified as follows.

$$\tilde{F}_t = \{k, i \rightarrow j | c_{ij}^{k,t} \leq \varepsilon_f \wedge k \in \tilde{E}_t\}. \quad (17)$$

When  $\tilde{E}_t$  and  $\tilde{F}_t$  have been identified, personal advices for experts will be generated to reduce the conflict caused by the moderator. Since pair-factors level is the most basic level and contains the original assessments of experts, only the experts whose consensus measure values  $c^{k,t}$  are lower than the threshold value  $\varepsilon_e$  may obtain the adjusted advices. After the identified experts all finish their adjustments, a new round of group IDR matrix construction will be carried out to determine the consensus situation. It is obvious to find that the above procedure is very similar to the Delphi method.

### C. DSMT-Based Group DEMATEL Method and Algorithm

The construction of a group IDR matrix includes two main processes. The first is collection process, which focuses on expert assessment extraction and fusion; and the second is soft consensus reaching process, which aims at reaching an acceptable CL among experts. After the above two processes,

the final group IDR matrix  $M$  can be constructed. Obviously,  $M$  is different from the original IDR matrix  $G$  as given in Definition 1 for two reasons. (1)  $M$  is a consensus group IDR matrix that satisfies all experts, while  $G$  does not consider consensus and satisfaction of experts. (2)  $M$  is made up of BBA functions that is capable of reflecting local or global ignorance in experts' mind, while  $G$  is made up of crisp values. Note that, the IDR matrix included in the DEMATEL is required to be exact influence degrees rather than BBA functions. Therefore, we apply the generalized pignistic probability as in Definition 13, which is an extension of the original pignistic probability [67], to reassign the local and global ignorance in the BBA functions to singleton grade levels. Then, we calculate the expected value to derive the exact influence degrees.

**Definition 13** [68]. Suppose the frame of discernment in the DSMT framework is  $\Theta = \{\theta_1, \dots, \theta_Y\}$ , then the generalized pignistic probability for all  $A \in D^\Theta$  can be calculated by (18).

$$P(A) = \sum_{X \in D^\Theta} \frac{|X \cap A|}{|X|} m(X). \quad (18)$$

where  $|X|$  denotes the cardinal of proposition  $X$ .

Taking  $m_{ij}$  in the final group IDR matrix  $M$  into (18), the transformation results can be obtained and recorded as  $\{(\theta_1, P_{ij}^1), \dots, (\theta_Y, P_{ij}^Y)\}$ , where  $P_{ij}^y$  denotes the probability of influence degree  $\theta_y$ ,  $y = 1, \dots, Y$ . The subscript  $Y$  is equal to 3 for the reason that the frame of discernment is defined as  $\Theta = \{\theta_1, \theta_2, \theta_3\} = \{0, 1, 2\}$  in this paper. Which influence grade level or influence degree is attached to the relationship of  $f_i \rightarrow f_j$ ? We follow two kinds of principles to solve this problem: (1) Highest probability principle. The grade level with the highest probability  $\tilde{g}_{ij} = \theta_*$  is chosen as the final influence grade level, where  $\{\theta_* | P_{ij}^* = \max(P_{ij}^1, \dots, P_{ij}^Y)\}$ ; (2) Expected value principle. The expected value  $\tilde{g}_{ij} = \sum_{y=1}^Y \theta_y \times P_{ij}^y$ ,  $\forall i, j$  is calculated as the final influence degree. According to the real situation, we obtain the final influence degree for  $f_i \rightarrow f_j$  by using one of the two principles, and then the final group IDR matrix  $\tilde{G} = [\tilde{g}_{ij}]_{L \times L}$  can be constructed.

The process of DSMT-based group DEMATEL is illustrated as in Fig. 2. As shown in Fig.2, the complete steps of DSMT-based group DEMATEL can be summarized as follows.

- Step 1: *Define group DEMATEL problem and soft CRP parameters.* Suppose the set of factors is  $F = \{f_1, \dots, f_L\}$ , the set of experts is  $E = \{e_1, \dots, e_K\}$ , the set of grade levels is  $\Theta = \{0, 1, 2\}$ , and the threshold value to filter out major factors is  $\eta$ . Then, the acceptable CL threshold values at expert level and pair-factors level are  $\varepsilon_e$  and  $\varepsilon_f$ , the round counter is  $t$  ( $t$  is set to one at first), and the maximum number of rounds is  $t_{MAX}$ . A moderator is invited to participate in the group decision making process and responsible for managing the whole process such as consensus measure value calculation, inconsistent expert identification, the maximum number of round judgement.
- Step 2: *Expert assessments extraction and fusion.* Experts are advised to indicate the influence degree to which he or

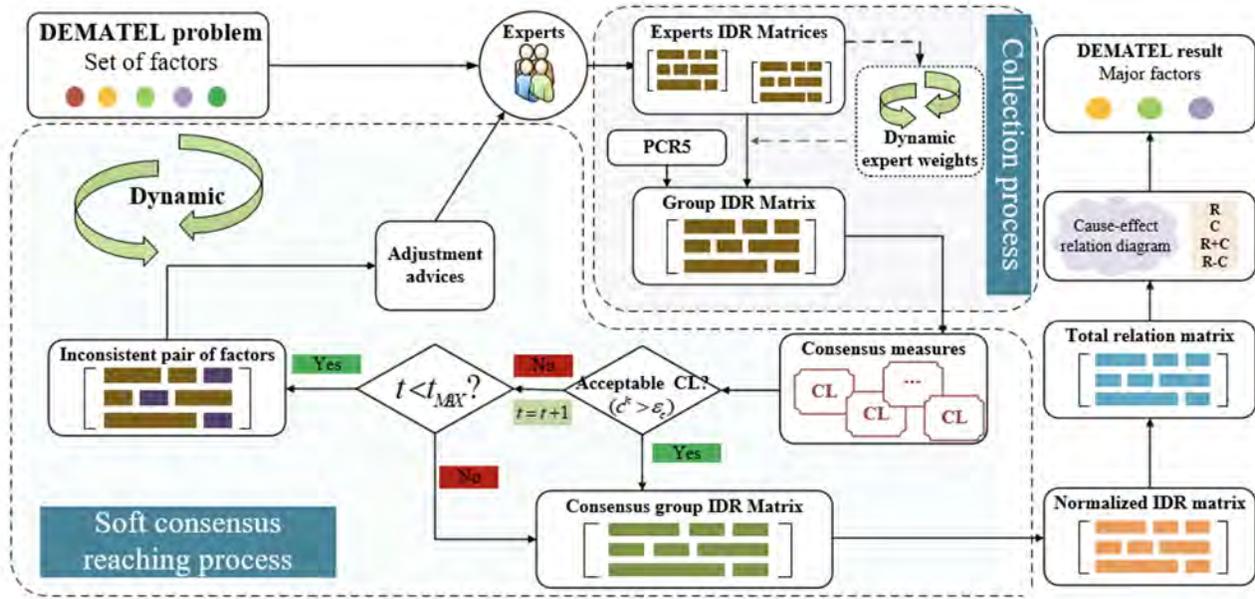

Figure 2. The process of proposed method.

she believes factor  $f_i$  has an effect on factor  $f_j$  (denoted by  $f_i \rightarrow f_j$ ) under the framework of DSMT. The BBA functions assessed for each pair of factors  $f_i \rightarrow f_j$  by expert  $e_k$  are described as  $b_{ij}^k$  (as in (6)), and make up an individual IDR matrix  $B^k = [b_{ij}^k]_{L \times L}$ . On the basis of expert assessments, expert weights  $W = [w^1, \dots, w^K]$  are calculated by Definition 8. Initial assessments  $b_{ij}^k$  are discounted by Shafer's discounting method with expert weight as in Definition 10 to obtain the discounted assessments  $m_{ij}^k$ . Then PCR5 is applied to fuse those BBA functions to obtain group assessments  $m_{ij}$ , making up group IDR matrix  $M = [m_{ij}]_{L \times L}$ .

- Step 3: *Soft consensus reaching process*. The moderator calculates the consensus measure values  $c_{ij}^{k,t}$  and  $c_{ij}$  by means of expert and group IDR matrices to identify whether an acceptable CL is reached in the current round. If so, the soft CRP is finished and a consensus group IDR matrix  $M$  has been obtained. Generalized pignistic probability is introduced to deal with global ignorance and local ignorance as in (18) and the influence degree for  $f_i \rightarrow f_j$  ( $\forall i, j$ ) is determined by one of the two principles as mentioned above to construct  $\tilde{G} = [\tilde{g}_{ij}]_{L \times L}$ , and proceeding to step 4. Otherwise, let  $t = t + 1$  and carry out the feedback mechanism. The moderator identifies the experts who differed strongly from the group by (16) and provides advices for them by (17). Then, return to step 2 and follow the same two processes. Note that the moderator also should detect whether the maximum number of rounds (means by  $t = t_{MAX}$ ) has been reached before carrying out the feedback mechanism. If so, the mechanism will be ceased, taking the current group IDR matrix  $M$  as the final result and applying the generalized

pignistic probability to obtain  $\tilde{G} = [\tilde{g}_{ij}]_{L \times L}$ . Then proceed to step 4.

- Step 4: *Calculate the normalized IDR matrix*. To guarantee that the normalized IDR matrix to infinite power will converge to zero and that the total relation matrix can be smoothly obtained,  $\tilde{g}_{ij}'' = \max(\max_{1 \leq i \leq L} \sum_{j=1}^L \tilde{g}_{ij}, \mu + \max_{1 \leq j \leq L} \sum_{i=1}^L \tilde{g}_{ij})$  is introduced as shown in (1) to calculate the normalized IDR matrix  $D = [d_{ij}]_{L \times L}$ , where  $d_{ij} = \tilde{g}_{ij} / \tilde{q}_{ij}'', \forall i, j$ .
- Step 5: *Compute total relation matrix*. The total relation matrix is calculated by  $A = D(I - D)^{-1}$ . The influencing degree of  $f_i$  is computed by  $r_i = \sum_{j=1}^L a_{ij}$ , the influenced degree of  $f_i$  is computed by  $c_i = \sum_{j=1}^L a_{ji}$ , the prominence degree of  $f_i$  is computed by  $r_i + c_i$ , and the net influence degree of  $f_i$  is computed by  $r_i - c_i$ .
- Step 6: *Obtain the major factors with the threshold value*. To simplify the complexity of a system to a manageable level, negligible factors should be filtered out. Only those factors whose prominence degrees are greater than the threshold value ( $r_i + c_i \geq \eta$ ) should be chosen and considered in the complex system. Generally, the cause-effect relation diagram can be made for the major factors based on their prominence degrees and net influence degrees.

Through the analysis of total relation of the factors by DEMATEL, a better understanding of the structural relation and an ideal way to solve complicate system problems can be obtained. The algorithm can be summarized to help moderator manage the whole processes.

---

**Algorithm 1** The algorithm for DSMT-based group DEMATEL method with reaching consensus

---

**Inputs:** Set of factors  $F = \{f_1, \dots, f_L\}$ , set of grade levels  $\Theta = \{\theta_1, \theta_2, \theta_3\}$ , set of experts  $E = \{e_1, \dots, e_K\}$ , DEMATEL threshold value  $\eta$ , threshold values at expert level and pair-factors level  $\varepsilon_e$  and  $\varepsilon_f$ , round counter  $t$ , accepted maximum number of rounds  $t_{MAX}$ .

**Outputs:** Set of major factors  $\hat{F} = \{f_1, \dots, f_L\}$ .

**Begin**

$t=1$ ,  $\tilde{F}_i = \{k, i \rightarrow j \mid \forall k, \forall i, \forall j\}$ ,  $b_{ij}^{k,0} = \{(\theta_1, 1)\}$  for  $\forall i, j, k$

**Step 1: Collection process**

For  $i=1$  to  $L$

  For  $j=1$  to  $L$

    If  $i \neq j$

      For  $k=1$  to  $K$

        If  $\{k, i \rightarrow j\} \in \tilde{F}_i$  Then

          Give/modify the influence degree  $b_{ij}^{k,t}$  by expert  $e_k$

        Else

$b_{ij}^{k,t} = b_{ij}^{k,t-1}$

        EndIf

      EndFor

      Calculate expert weight  $W_i = \{w^{k,j} \mid k=1, \dots, K\}$  by Eqs.(8)-(10)

      Calculate  $m_{ij}^{k,t}$  in Eq.(12) by discounting  $b_{ij}^{k,t}$  with  $w^{k,j}$

      Make fusion to get  $m_{ij}^t = m_{ij}^{1,t} \oplus \dots \oplus m_{ij}^{K,t}$  with Eq.(5)

    Else

      Let  $m_{ij}^t = \{(\theta_1, 1)\}$

    EndIf

  EndFor

EndFor

Get temporary group IDR matrix in the  $t$ th round  $M^t = [m_{ij}^t]_{L \times L}$

**Step 2: Soft consensus reaching process**

For  $i=1$  to  $L$

  For  $j=1$  to  $L$

    Calculate consensus measure value at pair-factors level by  $c_{ij}^{k,t} = 1 - \sqrt{\sum_{n=1}^{|\Theta|} [b_{ij}^{k,t}(\theta_n) - m_{ij}^t(\theta_n)]^2} / \sqrt{2}$

  EndFor

EndFor

Calculate consensus measure value at expert level by  $c^{k,j} = \sum_{i=1}^L c_{ij}^{k,t} / L^2$

Derive inconsistent expert set by Eq.(16) and derive  $\tilde{E}_i = \{k \mid c^{k,i} < \varepsilon_e\}$

Derive inconsistent pair of factors set by Eq.(17) and derive  $\tilde{F}_i = \{k, i \rightarrow j \mid c_{ij}^{k,t} < \varepsilon_f \wedge k \in \tilde{E}_i\}$

If  $\tilde{F}_i \neq \emptyset$  and  $t \leq t_{MAX}$  Then

  For each  $\{k, i \rightarrow j\} \in \tilde{F}_i$

    Give the advices that expert  $e_k$  is suggested to make corrections for  $b_{ij}^{k,t}$

  EndFor

  Let  $t=t+1$

  Return to Step 1

Else

  Get final BBA-formed group IDR matrix  $M^t = [m_{ij}^t]_{L \times L}$

  Turn to Step 3

EndIf

**Step 3: Group DEMATEL process**

For  $i=1$  to  $L$

  For  $j=1$  to  $L$

    Take  $m_{ij}^t$  into Eq.(18) and get its generalized pignistic probability  $\{(\theta_1, P_{ij}^1), (\theta_2, P_{ij}^2), (\theta_3, P_{ij}^3)\}$

    Use the highest probability or the expected value principle to obtain the final influence degree  $\tilde{g}_{ij}$

  EndFor

EndFor

Construct final group IDR matrix  $\tilde{G} = [\tilde{g}_{ij}]_{L \times L}$

Calculate normalized IDR matrix by  $D = \tilde{G} / \max(\max_{1 \leq i \leq L} \sum_{j=1}^L \tilde{g}_{ij}, \mu + \max_{1 \leq j \leq L} \sum_{i=1}^L \tilde{g}_{ij})$

Calculate total-relation matrix by  $A = (a_{ij})_{L \times L} = D(I - D)^{-1}$

Initialize set of major factors by  $\hat{F} = \emptyset$

For  $i=1$  to  $L$

  Calculate the important degree of  $f_i$  by  $r_i + c_i = \sum_{j=1}^L a_{ij} + \sum_{j=1}^L a_{ji}$

  If  $r_i + c_i \geq \eta$

    Add  $f_i$  into the set of major factors by  $\hat{F} = \hat{F} \cup f_i$

  EndIf

EndFor

**End**

---

IV. NUMERICAL COMPARISON AND DISCUSSION

In this section, we apply the proposed method and the fuzzy DEMATEL method to conduct a numerical simulation case, in which the key factors will be selected by two methods respectively. Afterwards, the results are compared and discussed.

A. The Proposed Method

- Step 1: Define DEMATEL problem and soft CRP parameters.

Similar to the examples in the literatures about DSmt [69], here the group IDR matrix construction of the given example works on the classical power set  $2^\Theta$ , not on the hyper-power set  $D\Theta$ . In the numerical simulation case, suppose the set of factors is  $F = \{f_1, f_2, f_3, f_4, f_5\}$ , the set of experts is  $E = \{f_1, e_2, e_3, e_4, e_5\}$ , the set of grade levels is  $\Theta = \{\theta_1, \theta_2, \theta_3\} = \{0, 1, 2\}$ , the threshold value is  $\eta = 0.35$ , and the acceptable CL threshold values at expert level is  $\varepsilon_e = 0.55$ , and at pair-factors level is  $\varepsilon_f = 0.50$ , the round counter is  $t$ , and the maximum number of rounds is  $t_{MAX} = 5$ .

- Step 2: Expert assessments extraction and fusion.

Experts are advised to indicate the influence degree to which he or she believes factor  $f_i$  has an effect on factor  $f_j$  (denoted by  $f_i \rightarrow f_j$ ) under the framework of DSmt. As an example, the BBA functions on each pair of factors  $f_i \rightarrow f_j$  from expert  $e_k$  are shown in Table I. Due to limited space, other experts' assessments are not given in this paper.

On the basis of the experts' assessments, we calculate the similarity matrix by the Euclidean similarity function as given in Definition 8 and shown in (19).

$$S = \begin{bmatrix} 1.00 & 0.20 & 0.16 & 0.13 & 0.18 \\ 0.20 & 1.00 & 0.15 & 0.17 & 0.19 \\ 0.16 & 0.15 & 1.00 & 0.14 & 0.18 \\ 0.13 & 0.17 & 0.14 & 1.00 & 0.18 \\ 0.18 & 0.19 & 0.18 & 0.18 & 1.00 \end{bmatrix}. \quad (19)$$

Hence,  $Sup(e_1)^1 = 0.20 + 0.16 + 0.13 + 0.18 = 0.68$ ,  $Sup(e_2)^1 = 0.72$ ,  $Sup(e_3)^1 = 0.64$ ,  $Sup(e_4)^1 = 0.62$ , and  $Sup(e_5)^1 = 0.73$ ; the expert weight is computed as  $w^{1,1} = Sup(e_1)^1 / \sum_{k=1}^5 Sup(e_k)^1 = 0.68/3.40 = 0.20$ ,  $w^{2,1} = 0.21$ ,  $w^{3,1} = 0.19$ ,  $w^{4,1} = 0.18$ , and  $w^{5,1} = 0.22$ ; the discounting parameters are derived by  $\bar{w}^{1,1} = w^{1,1} / \max\{w^{k,1} | k = 1, \dots, 5\} = 0.20/0.22 = 0.93$ ,  $\bar{w}^{2,1} = 0.98$ ,  $\bar{w}^{3,1} = 0.87$ ,  $\bar{w}^{4,1} = 0.82$ , and  $\bar{w}^{5,1} = 1.00$ .

Taking  $b_{ij}^{k,1}$  and  $\bar{w}^{k,1}$  into Shafer's discounting method (as in (11)), we derive the discounted assessments  $m_{ij}^{k,1}$ ,  $i, j = 1, \dots, 5$ , and  $k = 1, 2, 3, 4, 5$ . With the help of the MATLAB code for PCR5, we fuse the BBA functions and derive a holism result for the influence degrees between any two factors, as shown in Table II.

- Step 3: Soft consensus reaching process.

The moderator calculates the consensus measure values  $c_{ik}^{k,1}$  and  $c^{k,1}$  by means of  $b_{ik}^{k,1}$  and  $m_{ik}^1$  to identify whether an acceptable CL has been reached. Taking expert and fusion assessment BBA functions into (13) and (14), we calculate the consensus measure values at two levels, as shown in Tables III and IV. The bold values of data in Table III indicate the pair of factors that do not reach the set consensus level. The bold values of data in Table IV indicate the experts that do not reach the set consensus level. According to the selected threshold value  $\varepsilon_e = 0.55$  and (16), we find that the acceptable CL is not reached in this round for  $\tilde{F}_t \neq \emptyset$ . Then, the moderator lets  $t = 1 + 1 = 2$ , which is lower than  $t_{MAX}$ , and carries out the feedback mechanism. The order from expert level to pair-factors level should be followed to determine the inconsistent experts and the pairs of factors that need to be modified (for those values less than  $\varepsilon_f = 0.50$ ). Tables III and IV show that expert  $e_3$  greatly differs from the group results on the pairs of factors  $f_1 \rightarrow f_4$ ,  $f_2 \rightarrow f_4$ , and  $f_4 \rightarrow f_5$ , and  $e_4$  greatly differs from the group results on the pairs of factors  $f_1 \rightarrow f_2$ ,  $f_2 \rightarrow f_3$ ,  $f_2 \rightarrow f_4$ , and  $f_4 \rightarrow f_5$  (see those underlined data in Tables III and IV). Experts  $e_3$  and  $e_4$  need to modify those assessments on the mentioned pairs of factors. V and VI.

Because some of the expert assessments are changed. In the second round, expert weights are recalculated to be  $w^{1,2} = 0.19$ ,  $w^{2,2} = 0.20$ ,  $w^{3,2} = 0.20$ ,  $w^{4,2} = 0.21$ , and  $w^{5,2} = 0.21$ , and the corresponding discounting parameters are standardized as  $\bar{w}^{1,2} = 0.89$ ,  $\bar{w}^{2,2} = 0.93$ ,  $\bar{w}^{3,2} = 0.96$ ,  $\bar{w}^{4,2} = 1.00$ , and  $\bar{w}^{5,2} = 1.00$ . Taking  $b_{ik}^{k,2}$  and  $\bar{w}^{k,2}$  into (11), we obtain the discounted assessments  $m_{ij}^{k,2}$ , ( $\forall i, j$ ) and fuse these results by PCR5 to construct the group IDR matrix in the second round. The moderator calculates the new consensus measure values at two levels. Fusion results and consensus measures at expert level in the second round are shown in Tables VII and VIII.

As shown in Table VIII, the acceptable CL has been reached in the second round, which means that the current group IDR matrix is a consensus result and can be applied to the group DEMATEL method. Then we derive pignistic probability transformation for each element in final BBA-formed group IDR matrix  $M^2 = [m_{ij}^2]_{5 \times 5}$ . Take the pair of factors  $f_1 \rightarrow f_2$  as an example,  $m_{12}(\theta_1) = m(\theta_1) + \frac{1}{2}m(\theta_1 \cup \theta_2) + \frac{1}{2}m(\theta_1 \cup \theta_3) + \frac{1}{3}m(\theta_1 \cup \theta_2 \cup \theta_3) = 0.12$ ,  $m_{12}(\theta_2) = 0.12$ ,  $m_{12}(\theta_3) = 0.76$ , and  $\tilde{g}_{12} = 0 \times 0.12 + 1 \times 0.12 + 2 \times 0.76 = 1.64$ . After pignistic probability transformation, the final group IDR matrix is constructed as in (20).

$$\tilde{G} = \begin{bmatrix} 0.00 & 1.64 & 0.99 & 1.22 & 1.13 \\ 0.00 & 0.00 & 1.33 & 1.53 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.67 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 1.76 \\ 0.00 & 1.12 & 1.25 & 0.00 & 0.00 \end{bmatrix}. \quad (20)$$

- Step 4: Calculate the normalized IDR matrix.

Let consider  $\mu = 0.00001$ . We obtain

$$\tilde{g}_{ij}'' = \max(\max_{1 \leq i \leq L} \sum_{j=1}^L \tilde{g}_{ij}, \mu + \max_{1 \leq j \leq L} \sum_{i=1}^L \tilde{g}_{ij}) \approx 4.98,$$

and the normalized IDR matrix can be calculated by (1). The result is shown as in (21).

$$D = \begin{bmatrix} 0.00 & 0.33 & 0.20 & 0.24 & 0.23 \\ 0.00 & 0.00 & 0.27 & 0.31 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.13 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.35 \\ 0.00 & 0.22 & 0.25 & 0.00 & 0.00 \end{bmatrix}. \quad (21)$$

- Step 5: Compute the total relation matrix.

The total relation matrix can be calculated by (2). The result is shown as

$$A = \begin{bmatrix} 0.00 & 0.14 & 0.08 & 0.10 & 0.09 \\ 0.00 & 0.00 & 0.08 & 0.11 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.02 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.13 \\ 0.00 & 0.05 & 0.08 & 0.00 & 0.00 \end{bmatrix}. \quad (22)$$

According to  $A = [a_{ij}]_{5 \times 5}$  and (3), we derive the following parameters: the total influence  $r_i = \sum_{j=1}^5 a_{ij}$  given by the factor  $f_i$  to other factors, the total influence  $c_i = \sum_{j=1}^5 a_{ji}$  received by the factor  $f_i$  from other factors, the degree of the important role  $r_i + c_i$ , and the net influence  $r_i - c_i$ . These parameters are listed in Table IX. Additionally, we construct the cause-effect relation diagram of factors with the horizontal axis  $r + c$  and the vertical axis  $r - c$ , as shown in Fig. 3. According to Definition 4 and Fig. 3,  $f_1$  is known as net causer,

Table IX  
THE ATTRIBUTE PARAMETERS OF FACTORS.

	$r$	$c$	$r + c$	$r - c$
$f_1$	0.41	0.00	0.41	0.41
$f_2$	0.19	0.19	0.38	0.00
$f_3$	0.02	0.24	0.26	-0.22
$f_4$	0.13	0.23	0.36	-0.10
$f_5$	0.13	0.22	0.35	-0.09

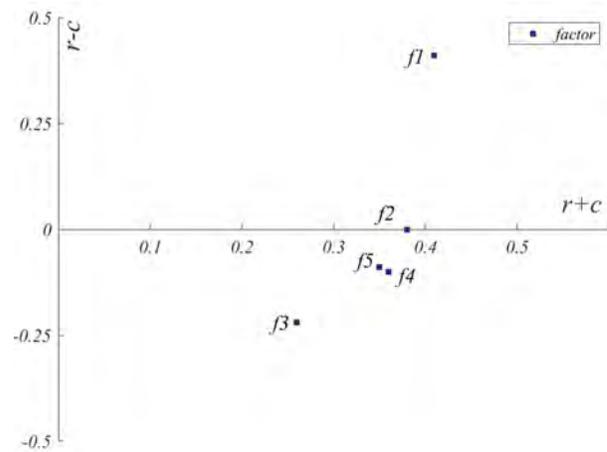

Figure 3. The cause-effect relation diagram derived by the proposed method.

whereas  $f_3$ ,  $f_4$  and  $f_5$  are net receivers. Because  $r - c = 0$  for  $f_2$ ,  $f_2$  is neither net causer, or net receiver.

- Step 6: Obtain major factors with the threshold value. Because of the threshold value  $\eta = 0.35$ , we select the factors whose degrees of the important role are greater than the threshold ( $r_i + c_i \geq \eta$ ) as major factors. As a result, the major factors in the complex system are  $\hat{F} = \{f_1, f_2, f_4, f_5\}$ .

We find that the Algorithm 1 can be programmed easily. Thus, the proposed method in this study is valid and applicable for solving group DEMATEL problems.

### B. The Fuzzy DEMATEL Method

The fuzzy DEMATEL method proposed by Wu and Lee [18] is a vital and significant improvement of DEMATEL. Since the fuzzy DEMATEL method is not only a major extension of DEMATEL but also extracts information with fuzzy linguistic terms, here we employ it to make a comparison with the proposed method. To ensure the results of two kinds of methods can be compared with each other, the set of factors  $F = \{f_1, f_2, f_3, f_4, f_5\}$ , the set of experts  $E = \{e_1, e_2, e_3, e_4, e_5\}$  and the threshold value is  $\eta = 0.35$  are all the same as in Subsection IV-A. Besides, the inputs of fuzzy DEMATEL method should be generated from the

initial assessments given by experts in the proposed method to ensure its comparability. According to the procedure of fuzzy DEMATEL method, its computation processes can be summarized as follows.

- Step 1: *Define DEMATEL problem and fuzzy linguistic scale.*

The DEMATEL problem is defined as the same as in Subsection IV-A and the fuzzy linguistic scale is defined as in Table X, where {No, L, H} are equal to  $\{\theta_1, \theta_2, \theta_3\}$  as defined in this paper.

Table X  
THE FUZZY LINGUISTIC SCALE.

Linguistic terms	Triangular fuzzy numbers
High influence (H)	(0.75,1.00,1.00)
Low influence (L)	(0.25,0.50,0.75)
No influence (No)	(0.00,0.00,0.25)

- Step 2: *Exact and fuse expert assessments..*

In order to ensure the comparability, the inputs of fuzzy DEMATEL method should be generated from the initial assessments given by experts in the proposed method. Because the assessments given by experts in Subsection 4.1 are in the form of BBA functions, how to make a transformation from the BBA functions to the inputs of fuzzy DEMATEL method is quite important. It is reasonable and logical to choose the grade level with the highest probability as expert assessments in the fuzzy DEMATEL method. Following this thought, the inputs of fuzzy DEMATEL method are transformed from the experts' assessments in Subsection IV-A. For example, the transformed assessments of expert are shown in Table XI. As introduced in fuzzy DEMATEL, the Converting

Table XI  
THE TRANSFORMED ASSESSMENTS OF EXPERT  $e_1$ .

	$f_1$	$f_2$	$f_3$	$f_4$	$f_5$
$f_1$	No	H	L	No	No
$f_2$	No	No	H	H	No
$f_3$	No	No	No	L	No
$f_4$	No	No	No	No	H
$f_5$	No	No	L	No	No

Fuzzy data into Crisp Scores (CFCS) defuzzification method is applied to aggregate these assessments by five experts. Due to limited space, the detailed CFCS steps can be referred to [18] and are not repeated here. The IDR matrix  $G' = [g'_{ij}]_{5 \times 5}$  is produced as in (23).

$$G' = \begin{bmatrix} 0.04 & 0.19 & 0.87 & 0.19 & 0.50 \\ 0.19 & 0.04 & 0.96 & 0.96 & 0.04 \\ 0.04 & 0.04 & 0.04 & 0.41 & 0.19 \\ 0.04 & 0.04 & 0.04 & 0.04 & 0.87 \\ 0.04 & 0.50 & 0.59 & 0.04 & 0.04 \end{bmatrix}. \quad (23)$$

- Step 3: *Calculate the normalized IDR matrix.*

The normalizing method for IDR matrix in fuzzy DEMATEL is the same as in traditional DEMATEL. The

normalized IDR matrix is calculated by taking (23) into (1) and it is shown as in (24).

$$D' = \begin{bmatrix} 0.02 & 0.08 & 0.35 & 0.08 & 0.20 \\ 0.08 & 0.02 & 0.38 & 0.38 & 0.02 \\ 0.02 & 0.02 & 0.02 & 0.16 & 0.08 \\ 0.02 & 0.02 & 0.02 & 0.02 & 0.35 \\ 0.02 & 0.20 & 0.24 & 0.02 & 0.02 \end{bmatrix}. \quad (24)$$

- Step 4: *Compute the total relation matrix.*

The computing method for total-relation matrix in fuzzy DEMATEL is also the same as in traditional DEMATEL. The total-relation IDR matrix is calculated by taking (24) into (2) and it is shown as in (25).

$$A' = \begin{bmatrix} 0.02 & 0.01 & 0.18 & 0.02 & 0.07 \\ 0.01 & 0.02 & 0.21 & 0.20 & 0.00 \\ 0.00 & 0.00 & 0.02 & 0.03 & 0.01 \\ 0.00 & 0.00 & 0.00 & 0.02 & 0.14 \\ 0.00 & 0.05 & 0.09 & 0.00 & 0.02 \end{bmatrix}. \quad (25)$$

According to (3), we derive the following parameters as shown in Table XII and the cause-effect relation diagram as shown in Fig. 4. According to Definition 4 and Fig. 4, it is obvious to find that  $f_1$  and  $f_2$  are net causers, while  $f_3$ ,  $f_4$  and  $f_5$  are net receivers.

Table XII  
THE FACTORS' ATTRIBUTES PARAMETERS.

	$r'$	$c'$	$r' + c'$	$r' - c'$
$f_1$	0.30	0.03	0.33	0.27
$f_2$	0.44	0.08	0.52	0.36
$f_3$	0.07	0.50	0.57	-0.43
$f_4$	0.17	0.28	0.44	-0.11
$f_5$	0.16	0.25	0.41	-0.09

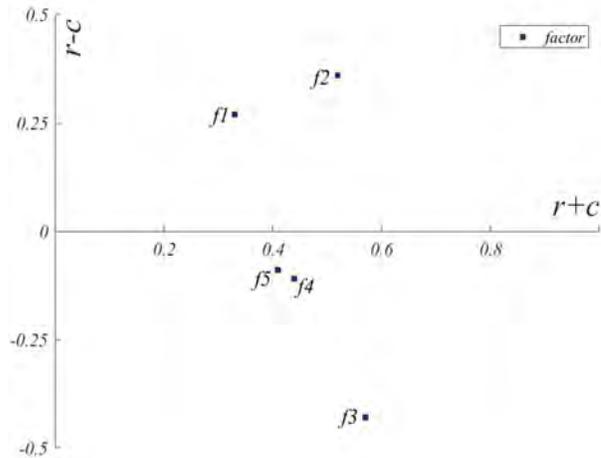

Figure 4. The cause-effect relation diagram derived by fuzzy DEMATEL method.

- Step 5: *Set a threshold value and obtain the major factors.* Because of the threshold value  $\eta = 0.35$ , only the factors with  $r' + c' \geq \eta$  should be chosen as the major factors. As a result, the major factors in the complex system are  $\tilde{F}' = \{f_2, f_3, f_4, f_5\}$ .

### C. Discussion

It is obvious to find that the major factors in the complex system determined by the proposed method are  $\hat{F} = \{f_1, f_2, f_4, f_5\}$ , while those determined by the fuzzy DEMATEL method are  $\hat{F}' = \{f_2, f_3, f_4, f_5\}$ . The results of two kinds of methods are different from each other. Which one is more reasonable? Now we make discussions from the following three aspects.

(1) Expert assessment extraction mechanism. The assessments of experts are used as the fundamental inputs of DEMATEL whether in the proposed method or in the fuzzy DEMATEL method. The proposed method allows experts to give assessments with BBA functions, while the fuzzy DEMATEL method employs the fuzzy linguistic scale to express their assessments. The local or global ignorance in experts' minds can be well reflected in the proposed method (e.g.,  $b_{12}^{1,1} = \{((\theta_1, \theta_2), 0.30), (\theta_3, 0.70)\}$ ), but it is unfortunate to find that such the ignorance cannot included in the fuzzy DEMATEL method (it seems that only the grade level/fuzzy linguistic scale with the highest probability may be allowed to express assessments, e.g.,  $b_{12}^{1,1} = \{L\} = \{\theta_3\}$ ). Consequently, it is believed that the proposed method is more feasible than the fuzzy DEMATEL method in the aspect of expert assessment extraction mechanism.

(2) The importance roles of experts. As discussed in subsection III-A, the importance roles of experts are reflected by expert weights that are calculated based on expert assessments information, hence, the weight parameters could effectively express the relative importance of experts in the group and they have a significant impact on the group DEMATEL decision results. If the importance roles of experts are neglected in the process of decision making, the decision results may lose effectiveness. The proposed method calculates expert weights based on expert assessments with the aid of evidence distance and employs Shafer's discounting method to modify the subjective assessments. Unfortunately, the importance roles of experts are unconsidered in the whole processes of fuzzy DEMATEL method. Consequently, it is believed that the proposed method is more accurate than the fuzzy DEMATEL method in the aspect of reflecting the importance roles of experts.

(3) Group consensus reaching. Group consensus reaching is a key problem in the GDM field. Only when the assessments given by experts reach an acceptable CL, the GDM results are seen to be valuable and credible. In other words, the GDM results that lack of consensus may be ineffective and have few reference value for decision-making. From subsection IV-B, we know that the fuzzy DEMATEL method is a static method without taking the group consensus reaching into consideration. In the proposed method, we apply the soft CRP into the construction of group IDR matrix to help the experts group reach a high CL, among which the feedback and modification mechanism are introduced. Consequently, it is believed that the proposed method is more reasonable than the fuzzy DEMATEL in the aspect of reaching group consensus.

### V. CONCLUSIONS

In the present study, the DSMT is used to extract and fuse expert assessments, and a soft CRP is introduced to construct the group IDR matrix for the DEMATEL. The DSMT-based group DEMATEL method and the corresponding algorithm are proposed. Moreover, a numerical comparison is performed to discuss the applicability of the proposed method and algorithm. The main contributions of the present study can be summarized into three aspects.

Firstly, an expert assessment extraction and fusion mechanism is established on the basis of DSMT. Expert assessments on the influence relations among factors are extracted by BBA functions, which can help experts to express uncertainty and incompleteness assessments. The PCR5 of DSMT, which can overcome the defects of intuitional paradox in Dempster's combination rule, is employed to make fusion for the individual BBA functions discounted by Shafer's discounting method. Secondly, expert weights are defined and introduced to reflect importance roles of experts in a group. Following the principle of pairwise comparisons, expert weights are calculated by the Euclidean similarity function to reflect experts' relative importance in the group. Expert weights are not fixed during the whole processes of group IDR matrix construction and they may vary dynamically with different expert assessments in each round. Shafer's discounting method is used to discount expert assessments in each round so as to reflect the importance roles of experts in the group dynamically. The above processes are beneficial to obtain an accurate group IDR matrix for the DEMATEL.

Thirdly, a soft CRP is established to construct the group IDR matrix with consensus and an algorithm is summarized for the group DSMT-based DEMATEL. The consensus measures at expert and pair-factors levels are defined to help establish the feedback/modification mechanism, based on which a soft CRP is established for the construction of consensus group IDR matrix, so that experts can reach a high CL. An algorithm for DSMT-based group DEMATEL method with reaching consensus is proposed to identify major factors in a complex system. The proposed algorithm can be programmed easily and is valid and applicable for solving group DEMATEL problems.

The proposed method forms an expert assessment extraction mechanism on the basis of the BBA function. However, the belief degrees or probabilities in BBA functions given by experts may hardly be assessed with exact values in more complex situations. Therefore, investigating how to deal with the group DEMATEL with the interval BBA function may be a good direction for future research.

**Abstract**—Belief function theory manages uncertain information and offers useful combination rules for multi-sensor fusion. However, when sensor readings are in conflict or even unreliable, the quality of the fusion result is significantly affected. Recently, many discounting approaches have been proposed to combine unreliable sensor readings. The discounting factors involved in these methods are often determined based on a single criterion which is not sufficient in general to obtain a precise assessment of the reliability degrees of the sources to combine. In this work, that is why we propose a novel discounting combination approach, in which the reliability factors are obtained by using the multi-criteria strategy. Our discounting combination method includes two main steps. The first step to assess the sensor's reliability is based on belief function-based technique for order preference by similarity to ideal solution (BF-TOPSIS). The second step is to discount and global combine all involved sensor readings according to their degree of reliability with proportional conflict redistribution no. 6 (PCR6) rule. Several simulations and comprehensive comparisons with classical approaches are given to show the efficiency of our proposed method.

**Keywords:** Belief function theory, multi-sensor fusion, conflict measure, multi-criteria, sensor reliability.

## I. INTRODUCTION

In order to achieve the accurate and complete description of an environment, multi-sensor fusion technology is applied to combine data from multi-sources. In view of their good applicability, multi-sensor systems play an essential role in real-world applications which include wireless sensor networks [1], [2], image processing [3], [4], target tracking [5], health-related areas [6], environmental monitoring [7] and so on [8], [9]. Nevertheless, depending on environmental and working conditions, like sensor failure, deterioration of energy supply, adverse weather conditions etc., the corresponding sensor readings can be incorrect, imprecise, conflicting or even unreliable so that it may yield a wrong decision. Thus, in order to avoid a degradation of the multi-sensor fusion system performances [10], the reliability degree of sensor reading needs to be estimated in the process of combination.

Before evaluating the reliability degrees of sensors, the imprecision or uncertain information of sensor readings should be mathematically described. Many methods can be used to handle uncertainty information, such as maximum entropy

[11], [12], Bayesian theory [13]–[15] and Belief Functions (BF) theory [16]–[18]. BF allows to model uncertainty and fuse sensors' measurements [19], and in this paper we focus our discussions on BF theory. Several classical combination rules are provided by BF theory to fuse the pieces of sensor readings. Among all available combination rules, Dempster's rule proposed by Shafer in [20] is the most well-known rule still used in many application even if it remains very controversial. Indeed, if there exists the high or even low conflict between sensor readings during the combination, a counter-intuitive result may occur. To circumvent the problem of Dempster's rule, usually the system designer discounts original sensor readings before applying the combination [21]–[24].

In the discounting approach, the primary challenge is to accurately estimate the reliability degrees of the sensors. Several researchers in [22], [23], [25] estimated the reliability degree of each sensor reading according to the single criterion. However, classical methods based on mono-criterion strategies are not good enough to assess the reliability factor. Recently, Frikha [26], [27] presented two multi-criteria strategies to compute the discounting factors. In [26], authors proposed a novel method to evaluate the degree of imprecision of sensor readings and conflict between pieces of evidence according to six criteria by using PROMETHEE II. Similarly, Frikha [27] suggested another way to estimate the reliability of the sensors based on Analytical Hierarchy Process (AHP). Based on Frikha's works, Sarabi-Jamab in [28] also followed the multi-criteria line and proposed a new selective multi-criteria method based on AHP. Different from the mentioned methods in [26] and [27], all involved criteria are further evaluated and the most discriminative criteria are selected. Some appealing findings have been revealed in [26], [27] and [28] when compared to those mono-criterion approaches currently available in the literature. However, all the multi-criteria methods used in the aforementioned references require a data normalization step, which affects the process of the precise evaluation how much better or worse to some extent a sensor is with respect to the others.

In this paper, a novel multi-criteria discounting combination method is proposed. The discounting factors associated with sensor readings are evaluated by using Belief Function based Technique for order preference by Similarity to Ideal Solution (BF-TOPSIS) [29]. We take two classes of criteria into account in the process of calculating the weights of sensor readings. The first class is the conflict between the sensors. The second class is the imprecision of the information provided by each sensor. Once all the weights are calculated, the involved sensor readings are discounted and global combined with Proportional Conflict Redistribution no. 6 (PCR6) rule. The main contributions of this paper are summarized as follows:

- A novel multi-criteria discounting combination approach is given. In our method, the recent proposed BF-TOPSIS is first applied to evaluate the reliability of the involved sensors. We also propose a new method to calculate weights of criteria involved in BF-TOPSIS. Moreover, the comprehensive comparisons between classical discounting combination methods are also illustrated in detail;
- The global fusion with PCR6 rule in Dezert-Smarandache Theory (DSMT) is applied for combining sensor readings. Unlike the conventional discounting combination approaches [26], [27] and [28], which combine all evidences with Dempster's rule, we herein use PCR6 to combine all discounted sensor readings. The advantage of this new approach is that it yields reasonable results particularly when the sensor readings are in high conflict.

This paper is organized as follows: we introduce the basic concepts of BF theory in section II. The Section III describes the discounting strategies in BF theory and the involved criteria applied in our proposed method. In section IV, our proposed discounting combination rule based on the BF-TOPSIS is described in detail. Then, the simulation results and discussions are given in section V. Finally, we conclude and give some perspectives in section VI.

## II. BASICS OF BELIEF FUNCTIONS

Belief function assigns mass of belief to the subsets of Frame of Discernment (FoD). In general, a mass function  $m(\cdot)$  is a mapping defined as follows [20] and for  $X \subseteq 2^\Theta$ :

$$m : 2^\Theta \rightarrow [0, 1], \sum_{X \subseteq 2^\Theta} m(X) = 1, \quad (1)$$

$$m(\emptyset) = 0, m(X) > 0. \quad (2)$$

where  $\Theta$  represents FoD which includes a set of  $p$  hypotheses.  $m(\cdot)$  is a mapping function and this function is also called Basic Belief Assignment (BBA). When  $m(X) > 0$ , the element  $X$  is called Focal Element (FE) of  $m$ . The set of focal elements of a BBA  $m(\cdot)$  is denoted  $F(m)$ .

In BF theory, the combination of two independent Body of Evidences (BoEs) by Dempster's rule is denoted  $m_1 \oplus m_2$ . For  $\forall X \subseteq 2^\Theta, X \neq \emptyset$ , the belief of  $X$  is given by [20]:

$$(m_1 \oplus m_2)(X) = \frac{1}{1-K} \cdot \sum_{Y, Z \subseteq 2^\Theta, Y \cap Z = X} m_1(Y)m_2(Z). \quad (3)$$

where  $K$  represents the degree of conflict between  $m_1$  and  $m_2$  as:

$$K = \sum_{Y, Z \subseteq 2^\Theta, Y \cap Z = \emptyset} m_1(Y)m_2(Z). \quad (4)$$

To palliate the drawbacks of Dempster's rule, Martin and Osswald [30] proposed a very interesting combination rule: PCR6. Due to its good performance, it is widely applied in recent applications. The combination of two BBAs  $m_1(\cdot)$  and  $m_2(\cdot)$  by the PCR6 rule is given as follows: for  $m_{PCR6}(\emptyset) = 0$  and  $\forall X \in 2^\Theta$

$$m_{PCR6}(X) = m_{12}(X) + \sum_{Y \in 2^\Theta \setminus \{X\}, X \cap Y = \emptyset} \left[ \frac{m_1(X)^2 m_2(Y)}{m_1(X) + m_2(Y)} + \frac{m_2(X)^2 m_1(Y)}{m_2(X) + m_1(Y)} \right]. \quad (5)$$

where  $m_{12}(X) = \sum_{Y, Z \subseteq 2^\Theta, Y \cap Z = X} m_1(Y)m_2(Z)$  is the conjunctive operator, and each element  $X$  and  $Y$  are expressed in their disjunctive normal form. If the denominator involved in the fraction is zero, then this fraction is discarded.

We recall that the PCR6 formula for the combination of two BBAs coincides with PCR5 formula originally developed by Smarandache and Dezert in [31]. The combination of more than two BBAs altogether with PCR5 and with PCR6 fusion rule provides in general different results. The choice of PCR6 with respect to PCR5 has been justified at first by Martin and Osswald in [30] from on a specific application, and then theoretically by Smarandache and Dezert in [32]. The general formula of PCR6 for combining more than two BBAs is given in details in [30] with examples.

To make a final decision in BF from a BBA  $m(\cdot)$ , Smets [20] suggests to transform  $m(\cdot)$  into pignistic probability by using function BetP in pignistic level. For  $\forall X \subseteq \Theta$ ,  $Bet P(\cdot)$  is defined as:

$$Bet P(X) = \sum_{Y \subseteq 2^\Theta} \frac{|X \cap Y|}{|Y|} \cdot m(Y). \quad (6)$$

where  $|Y|$  refers to the cardinality of a subset  $Y$ .

## III. DISCOUNTING PROCEDURE AND ASSESSMENT CRITERIA

### A. Discounting Procedure

The discounting operations are frequently conducted by using the discounting factor  $\omega$  with each sensor reading. Firstly introduced by Shafer [20], this factor  $\omega$  is evaluated and regarded as the reliability of the sensor reading. In this paper, the discounting factors are determined by multi-criteria strategy: BF-TOPSIS. In general, the parameter  $\omega$  varies in an interval:  $[0, 1]$ : that is to say, if the value of  $\omega$  is closer to 1, the greater the reliability of sensor reading is. The discounting steps are given as follows and for  $\forall X \in 2^\Theta \setminus \{\emptyset\}$ :

$$\begin{cases} m^\omega(X) = \omega \cdot m(X), \\ m^\omega(\emptyset) = \omega \cdot m(\emptyset) + (1 - \omega). \end{cases} \quad (7)$$

where  $X$  refers to the FE of  $m(\cdot)$  and  $\omega \in [0, 1]$ .

## B. Assessment Criteria

1) *Imprecision*: The degree of non-specificity of a sensor reading is also regarded as a degree of imprecision. With the belief function, the imperfection of BoE is mainly caused by two factors: the first one is contradiction (strife:  $C_1$ ) proposed by Vejnarová and Klir [33] and imprecision (non-specificity:  $C_2$ ) proposed by Dubois and Prade [34]. The measure of contradiction (i.e. the strife  $C_1$ ) is defined as:

$$\begin{aligned} C_1(m) &= St(m) \\ &= - \sum_{X \in F(m)} m(X) \log_2 \left( \sum_{Y \in F(m)} \frac{|X \cap Y|}{|X|} m(Y) \right), \end{aligned} \quad (8)$$

where  $|X \cap Y|$  and  $|X|$  refers to the cardinality of the subset  $|X \cap Y|$  and  $X$ .

Also, the measure of non-specificity  $C_2$  is defined as:

$$\begin{aligned} C_2(m) &= I(m) \\ &= \sum_{X \in F(m)} m(X) \cdot \log_2(|X|), \end{aligned} \quad (9)$$

where  $|X|$  refers to the cardinality of a subset  $X$ .

2) *Conflict Between the BoEs*: The second class of evaluation criteria relates to conflicting information, which is usually represented by  $m_{\oplus}(\emptyset)$  and distance measures. Two conflict measures are used in this paper: Shafer's weight of conflict ( $C_3$ ), and the interval distance between evidences ( $C_4$ ):

$$\begin{aligned} C_3(m) &= Conf(m) \\ &= \frac{1}{M} \sum_{i=1}^M [-\log_2(1 - K(m, m_i))], \end{aligned} \quad (10)$$

where  $K$  is the conflict between two BoEs  $m(\cdot)$  and  $m_i(\cdot)$  calculated by Eq.(4) and  $M$  is the number of sensor readings.

The criterion  $C_4$  is based on the interval distance  $d_{BI}$ , see [35], [36], that is:

$$\begin{aligned} C_4(m) &= d_{BI}^E(m) = \frac{1}{M} \sum_{i=1}^M d_{BI}(m, m_i) \\ &= \frac{1}{M} \sum_{i=1}^M \left[ \sqrt{n_c \cdot \sum_{X \in F(m)} [d^I(BI(X), BI_i(X))]^2} \right] \end{aligned} \quad (11)$$

where,  $n_c = 1/2^{(p-1)}$ ,  $M$  is the number of sensor readings, and  $p$  is the number of FEs in  $\Theta$ ,  $BI(X) \triangleq [Bel(X), Pl(X)]$ , and  $BI_i(X) \triangleq [Bel_i(X), Pl_i(X)]$ , and

$$\begin{aligned} d^I([a, b], [a', b']) &= \left[ \left[ \frac{a+b}{2} - \frac{a'+b'}{2} \right]^2 \right. \\ &\quad \left. + \frac{1}{3} \left[ \frac{b-a}{2} - \frac{b'-a'}{2} \right]^2 \right]^{\frac{1}{2}} \end{aligned}$$

## IV. NEW COMBINATION APPROACH BASED ON BF-TOPSIS

### A. Construction of Scoring Matrix

At first, there exists  $A_i$ ,  $i = 1, \dots, M$  sensors, and each sensor gives a corresponding reading  $m_i$ ,  $i = 1, \dots, \theta_p$  according to eq. (12)

$$\begin{matrix} & X_1 & X_2 & \dots & X_{2^{|\Theta|}} \\ \begin{matrix} A_1 \\ A_2 \\ \vdots \\ A_M \end{matrix} & \begin{bmatrix} m_1(X_1) & m_1(X_2) & \dots & m_1(X_{2^{|\Theta|}}) \\ m_2(X_1) & m_2(X_2) & \dots & m_2(X_{2^{|\Theta|}}) \\ \dots & \dots & \dots & \dots \\ m_M(X_1) & m_M(X_2) & \dots & m_M(X_{2^{|\Theta|}}) \end{bmatrix} \end{matrix} \quad (12)$$

where  $X \in 2^\Theta$ .

Then, one calculates the evaluation of all sensors from the perspective of imprecision ( $C_1$  and  $C_2$ ) and conflict ( $C_3$  and  $C_4$ ), and then constructs the following scoring matrix  $S$  defined by eq. (13)

$$\begin{matrix} & A_1 & A_2 & \dots & A_i & \dots & A_M \\ \begin{matrix} C_1 \\ C_2 \\ C_3 \\ C_4 \end{matrix} & \begin{bmatrix} S_1(A_1) & S_1(A_2) & \dots & S_1(A_i) & \dots & S_1(A_M) \\ S_2(A_1) & S_2(A_2) & \dots & S_2(A_i) & \dots & S_2(A_M) \\ S_3(A_1) & S_3(A_2) & \dots & S_3(A_i) & \dots & S_3(A_M) \\ S_4(A_1) & S_4(A_2) & \dots & S_4(A_i) & \dots & S_4(A_M) \end{bmatrix} \end{matrix} \quad (13)$$

Without loss of generality, we just use the general mathematical symbol  $C_j$ ,  $j = 1, \dots, N$  (in this paper,  $N = 4$ ) to represent one of the mentioned four criteria for convenience in the following sections. That is:  $j = 1$ ,  $C_1 \triangleq St(\cdot)$ ;  $j = 2$ ,  $C_2 \triangleq I(\cdot)$ ;  $j = 3$ ,  $C_3 \triangleq Conf(\cdot)$ ;  $j = 4$ ,  $C_4 \triangleq d_{BI}^E(\cdot)$ .

### B. Construction of BBAs for Multi-Criteria Decision Making (MCDM) Problems

In traditional mono-criterion problems, the weights of sensors  $A_i$ ,  $i = 1, \dots, M$  are calculated according to a single criterion. However, in MCDM problems, the direct weights associated with different criteria can be very different. Therefore, efficient fusion techniques must be developed in order to provide the global evaluating solution to solve the MCDM problem. For this aim, original BF-TOPSIS is used to Estimate the Ranking Vector (ERV) from all evidences that support or refute each sensor thanks to BBAs. First, the FoD is the set of sensors, that is  $A \triangleq \{A_1, A_2, \dots, A_M\}$ . The construction of BBAs is based on the method of construction presented in [29]

$$m_j(A_i) \triangleq Bel_j(A_i), \quad (14)$$

$$m_j(\bar{A}_i) \triangleq Bel_j(\bar{A}_i) = 1 - Pl_j(A_i), \quad (15)$$

$$m_j(A_i \cup \bar{A}_i) \triangleq Pl_j(A_i) - Bel_j(A_i), \quad (16)$$

where  $m_j(A_i)$  means the support belief in favor of  $A_i$  according to criterion  $C_j$ ,  $m_j(\bar{A}_i)$  means the support belief against  $A_i$  according to  $C_j$  and  $m_j(A_i \cup \bar{A}_i)$  means the uncertainty degree whether support or against  $A_i$  based on  $C_j$ .

$Bel_j(A_i)$ ,  $Pl_j(A_i)$  and  $Bel_j(\bar{A}_i)$  in Eqs.(15) and (16) are defined as follows:

$$\begin{aligned} Sup_j(A_i) &\triangleq \sum_{k \in \{1, \dots, M\} | S_j(A_k) \leq S_j(A_i)} |S_j(A_i) - S_j(A_k)|, \end{aligned} \quad (17)$$

$$\begin{aligned} Bel_j(A_i) &\triangleq \frac{Sup_j(A_i)}{A_{\max}^{j-Sup}} \\ &= \frac{Sup_j(A_i)}{\max(Sup_j(A_1), Sup_j(A_2), \dots, Sup_j(A_M))}, \end{aligned} \quad (18)$$

$$Inf_j(A_i) \triangleq - \sum_{k \in \{1, \dots, M\} | S_j(A_k) > S_j(A_i)} |S_j(A_i) - S_j(A_k)| \quad (19)$$

$$\begin{aligned} Bel_j(\bar{A}_i) &\triangleq \frac{Inf_j(A_i)}{A_{\min}^{j-Inf}} \\ &= \frac{Inf_j(A_i)}{\min(Inf_j(A_1), Inf_j(A_2), \dots, Inf_j(A_M))}. \end{aligned} \quad (20)$$

and

$$Pl_j(A_i) \triangleq 1 - Bel_j(\bar{A}_i). \quad (21)$$

### C. Calculation of Criteria Weights

In original BF-TOPSIS [29], the weights of criteria are often chosen subjectively which limits the applications of this new multi-criteria strategy in practice. In this paper, we automatically determine the importance of each criterion from the scoring matrix without manual intervention.

1) *Normalized Scoring Matrix According to the Max-Min Scaling*: Here, we first transform all values of  $S_j(A_j)$  in S (Eq.(13)) into the same measurement scale based on Max-Min scaling.

*Definition 1*: The normalized scoring matrix is defined by

$$S'_j(A_i) = \frac{S_j(A_i) - A_{\min}^{j-S}}{A_{\max}^{j-S} - A_{\min}^{j-S}}, \quad (22)$$

where  $i \in \{1, \dots, M\}$ ,  $j \in \{1, \dots, N\}$  and  $A_{\max}^{j-S}$  and  $A_{\min}^{j-S}$  refer to the maximum value and minimum value in  $[S_j(A_1), S_j(A_2), \dots, S_j(A_M)]$ .

The aim of this Max-Min scaling is to transform the original scoring linearly so that all the values of elements in scoring matrix are within the interval  $[0, 1]$ .

2) *Pairwise Comparison Matrix for All Criteria*: Based on Eq.(22), we can calculate the pairwise comparison results for all criteria according to the following definition:

*Definition 2*: The pairwise comparison matrix is defined by

$$pc_{h'h} = \frac{\sum_{i=1}^M \exp(S'_{h'}(A_i))}{\sum_{i=1}^M \exp(S'_h(A_i))}, \quad (23)$$

where  $h' \in \{1, \dots, N\}$ , and  $h \in \{1, \dots, N\}$ . In this paper, the value of parameter N is 4, which represents the number of the involved criteria.

Obviously, Eq.(23) is consistent because all pairs of criteria satisfy  $pc_{h'l} \times pc_{lh} = pc_{h'h}$ .

*Proof*:

$$\begin{aligned} pc_{h'l} \times pc_{lh} &= \frac{\sum_{i=1}^M \exp(S'_{h'}(A_i))}{\sum_{i=1}^M \exp(S'_l(A_i))} \times \frac{\sum_{i=1}^M \exp(S'_l(A_i))}{\sum_{i=1}^M \exp(S'_h(A_i))} \\ &= \frac{\sum_{i=1}^M \exp(S'_{h'}(A_i))}{\sum_{i=1}^M \exp(S'_h(A_i))} = pc_{h'h}. \end{aligned}$$

*End Proof*.

3) *Weights Determination for All Criteria*: Next, we can calculate the weight of each criterion  $v(C_j)$  based on the following expressions:

$$v(C_j) = \frac{\sum_{h=1}^N pc'_{jh}}{M}, \quad (24)$$

$$pc'_{jh} = \frac{pc_{jh}}{\sum_{l=1}^N pc_{lh}}, \quad (25)$$

where  $j = 1, \dots, N$  and  $N = 4$  in this paper;  $M$  is the number of sensor readings.

### D. Steps of BF-TOPSIS Algorithm

- *Step 1*: From the scoring matrix  $S$ , compute BBAs  $m_j(A_i)$ ,  $m_j(\bar{A}_i)$  and  $m_j(A_i \cup \bar{A}_i)$  using Eqs. (15)–(16), and then construct  $vec_j(A_i) \triangleq [m_j(A_i), m_j(\bar{A}_i), m_j(A_i \cup \bar{A}_i)]$  for each sensor  $A_i$  according to the criterion  $C_j$ ;
- *Step 2*: For each sensor  $A_i$ , also construct the best ideal BBA  $vec_j^{best}(A_i) \triangleq [m_j^{best}(A_i), 0, 0] \triangleq [1, 0, 0]$  and the worst ideal BBA  $vec_j^{worst}(A_i) \triangleq [0, m_j^{worst}(\bar{A}_i), 0] \triangleq [0, 1, 0]$ ; Then compute the belief interval distance [35], [36]  $d_{BI}(vec_j(A_i), vec_j^{best}(A_i))$  and  $d_{BI}(vec_j(A_i), vec_j^{worst}(A_i))$ ;
- *Step 3*: Compute the weighted average of distance  $d_{BI}(vec_j(A_i), vec_j^{best}(A_i))$  and distance  $d_{BI}(vec_j(A_i), vec_j^{worst}(A_i))$  with the relative importance weighting factor  $v(C_j)$  of each criterion  $C_j$ , that is

$$dis^{best}(A_i) \triangleq \sum_{j=1}^N v(C_j) \cdot d_{BI}(vec_j(A_i), vec_j^{best}(A_i)), \quad (26)$$

$$dis^{worst}(A_i) \triangleq \sum_{j=1}^N v(C_j) \cdot d_{BI}(vec_j(A_i), vec_j^{worst}(A_i)), \quad (27)$$

where  $vec_j(A_i) \triangleq [m_j(A_i), m_j(\bar{A}_i), m_j(A_i \cup \bar{A}_i)]$ ,  $vec_j^{best}(A_i) \triangleq [1, 0, 0]$  and  $vec_j^{worst}(A_i) \triangleq [0, 1, 0]$ .

- *Step 4*: The final weights  $\omega$  of the sensor  $A_i$  with respect to ideal best solution  $A^{best}$  is then defined by

$$\omega(A_i) \triangleq \frac{dis^{worst}(A_i)}{dis^{worst}(A_i) + dis^{best}(A_i)} \quad (28)$$

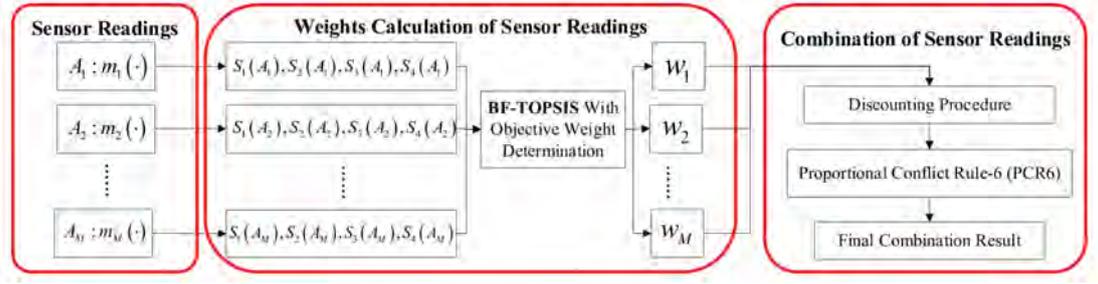

Figure 1. The framework of our proposed multi-criteria discounting combination method.

### E. Discounting sensor readings and PCR6 combination

- All the weights of the involved sensors are constructing a weight vector, which is denoted as  $Weight = \{\omega(A_1), \omega(A_2), \dots, \omega(A_M)\}$  based on Eq.(28) and then discount all involved BBAs with Eq.(7).
- PCR6 Combination Rule: According to the sensor reading of  $A_i, i \in \{1, \dots, M\}$  and PCR6 combination rule, we can globally combine all the involved sensor readings with their corresponding weights:  $m_{fusion} = PCR6(m_1^{\omega(A_1)}(\cdot), m_1^{\omega(A_2)}(\cdot), \dots, m_1^{\omega(A_M)}(\cdot))$ .

### F. A Proposed Combination Method and Fusion Process

Because the unreliable sensors often provide conflicting and imprecision information which may lead to counter-intuitive results in traditional combination methods, the novel multi-criteria discounting combination method is used. Here, we would like to emphasize that the involved criteria mentioned in this paper can be modified to any criteria according to the actual demand in the process of the objective weight estimation.

The process of our multi-criteria discounting combination method is illustrated in Fig.1 and in order to help the readers to reproduce this new combination method proposed in this paper, pseudo code is given in Algorithm 1.

## V. NUMERICAL SIMULATIONS AND DISCUSSIONS

In this part, we make comprehensive comparisons between the proposed combination procedure and other classical combination rules. Also, several tests and comparative analysis are illustrated in details. Independent random runs of Monte Carlo simulations are generated to observe the appealing behaviors of the proposed approach. All simulations results were obtained with MATLAB R2018a running with a hardware of Intel Core i7-5600U CPU at 2.60GHz and with 8G RAM.

### A. Target Recognition Context

In this case, six sensors give their corresponding readings which consider the class of the same target in Table I. The common FoD of these sensors is  $\Theta = \{\theta_1 \triangleq \text{target 1}, \theta_2 \triangleq \text{target 2}, \theta_3 \triangleq \text{target 3}\}$ . Among the given BBAs in Table I, we can notice that four of these sensors (1, 2, 4 and 5) give the maximum belief to  $\theta_1$ . On the contrary, sensor 3 assigns most

Table I  
SENSOR'S CORRESPONDING BBAs  $m_i(\cdot)$ .

	$m_1$	$m_2$	$m_3$	$m_4$	$m_5$	$m_6$
$\theta_1$	0.75	0.4	0	0.35	0.5	0.05
$\theta_2$	0.1	0.2	0.9	0.15	0.1	0.1
$\theta_3$	0.05	0.1	0.1	0.25	0	0
$\{\theta_1, \theta_2\}$	0	0.3	0	0.2	0	0.3
$\{\theta_1, \theta_3\}$	0	0	0	0	0	0.2
$\{\theta_2, \theta_3\}$	0	0	0	0	0.15	0.1
$\{\theta_1, \theta_2, \theta_3\}$	0.1	0	0	0.05	0.25	0.25

of its belief to  $\theta_2$ . Accordingly, sensor 3 is highly conflicting with the mentioned four sensors (1, 2, 4 and 5).

According to Eq.(13), we can evaluate each sensor reading  $m_i$  by calculating  $S_j(m_i)$ , for all  $i = 1, \dots, 6$  and  $j = 1, \dots, 4$ . All results of  $S_j(m_i)$  are listed in the scoring matrix (Table II).

Table II  
SCORING MATRIX  $S_j(m_i)$ .

$S_j(m_i)$	$m_1$	$m_2$	$m_3$	$m_4$	$m_5$	$m_6$
$St(\cdot)$	0.6771	0.9591	0.4690	1.1508	0.6959	0.4721
$I(\cdot)$	0.1585	0.3000	0	0.2792	0.5462	0.9962
$Conf(\cdot)$	0.8813	0.6374	1.2641	0.7562	0.5317	0.3225
$d_{BI}^E I(\cdot)$	0.3785	0.2586	0.6115	0.2682	0.2622	0.3127

As we can see in Table II, the sorted rankings with the involved criteria are quite different:

$$\begin{aligned}
 St(\cdot) &: m_3 \succ m_6 \succ m_1 \succ m_5 \succ m_2 \succ m_4, \\
 I(\cdot) &: m_3 \succ m_1 \succ m_4 \succ m_2 \succ m_5 \succ m_6, \\
 Conf(\cdot) &: m_6 \succ m_5 \succ m_2 \succ m_4 \succ m_1 \succ m_3, \\
 d_{BI}^E I(\cdot) &: m_2 \succ m_5 \succ m_4 \succ m_6 \succ m_1 \succ m_3.
 \end{aligned}$$

This phenomenon indicates that it is not appropriate to evaluate the involved BBAs based on single criterion and a robust multi-criteria strategy is necessary. For this, we first calculate the positive and negative evidence supports of all sensor readings which are illustrated in Table III and Table IV.

Table III  
EVIDENTIAL SUPPORTS  $Sup_j(m_i)$ .

$Sup_j(m_i)$	$St(\cdot)$	$I(\cdot)$	$Conf(\cdot)$	$d_{BI}^E I(\cdot)$
$m_1$	0.7746	1.4877	0.3828	0.2330
$m_2$	0.1917	0.9425	0.9893	0.5404
$m_3$	1.6101	2.2802	0	0
$m_4$	0	1.0047	0.6330	0.4980
$m_5$	0.7180	0.4500	1.4123	0.5221
$m_6$	1.5944	0	2.4581	0.3646

In Table III  $Sup_j(m_i)$  is called the positive support of  $m_i$  according to criterion  $C_j$ . Because the four involved criteria we mentioned before are such that the smaller the value, the better the BoE. Thus, if the value of the BoE  $m_i$  in Table II is small according to  $C_j$  (such as  $m_3$  in  $St(\cdot)$ ), the support value  $Sup_1(m_3)$  will be the largest according to  $St(\cdot)$  in Table III.

Table IV  
EVIDENTIAL SUPPORTS  $Inf_j(m_i)$ .

$Inf_j(m_i)$	$St(\cdot)$	$I(\cdot)$	$Conf(\cdot)$	$d_{BI}^E I(\cdot)$
$m_1$	-0.4131	-0.1585	-1.2774	-0.4123
$m_2$	-1.5223	-0.4623	-0.4206	0
$m_3$	0	0	-3.1914	-1.5773
$m_4$	-2.4897	-0.4000	-0.7769	-0.0157
$m_5$	-0.4696	-1.4472	-0.2092	0.0036
$m_6$	-0.0031	-3.6972	0	-0.1492

According to Eq.(15)-Eq.(16), the specific supporting BBAs  $m_s(\cdot)$  of all involved sensors are given in Fig. 2.

In Fig. 2 (a) and (b), we can find that  $m_3$  (orange plot) receives the fully support belief (because  $m_s(m_3) = 1$ ) from the perspective of the imprecision criteria ( $St(\cdot)$  and  $I(\cdot)$ ). This is because  $m_3$  is the only Bayesian BBAs. On the contrary, since  $m_3$  is highly conflicting with other BBAs, the support against  $m_3$  in Fig. 2 (c) and (d) is largest (because  $m_s(\bar{m}_3) = 1$ ) according to the conflict measures ( $Conf(\cdot)$  and  $d_{BI}^E I(\cdot)$ ). The supporting degrees of  $m_3$  under different criteria are totally inconsistent, which directly indicates that it is difficult to evaluate the reliability of sensor readings comprehensively depending on a single criterion. In our proposed discounting combination method, the reliability factors are given by multi-criteria based on BF-TOPSIS.

According to Eqs. (22)–(25), the corresponding weights of all involved criteria are:

$$\begin{aligned}
 v(St) &= 0.2581, \\
 v(I) &= 0.1519, \\
 v(Conf) &= 0.2581, \\
 v(d_{BI}^E I) &= 0.1519.
 \end{aligned}$$

Then, all weights of the involved six sensor readings are given in Table V based on Eq. (28).

Table V  
WEIGHTS OF ALL SENSOR READINGS  $\omega(m_i)$ .

	$dis^{best}(m_i)$	$dis^{worst}(m_i)$	$\omega(m_i)$
$m_1$	2.8450	3.8938	0.5778
$m_2$	2.6323	4.0353	<b>0.6838</b>
$m_3$	2.8284	2.8284	0.5000
$m_4$	3.1726	3.3888	0.5165
$m_5$	2.2802	4.2988	0.6534
$m_6$	1.8371	3.9732	0.6052

As we can see in Table V,  $m_2$  receives the highest degree of reliability and the highly conflicting BBA  $m_3$  gets the lowest reliability degree. It is worth mentioning that the four weighting values of the involved criteria are automatically calculated based on the input sensor readings. To make a direct comparison between manual adjustment of criteria weights (subjective) and objective weighting used in BF-TOPSIS, we first set the weights of  $St(\cdot)$  and  $I(\cdot)$  to 1 and set the weights of  $Conf(\cdot)$  and  $d_{BI}^E I(\cdot)$  to 0 and we can observe that in this case the weight of  $m_3$  increases to 1 in Fig.3 (a) and

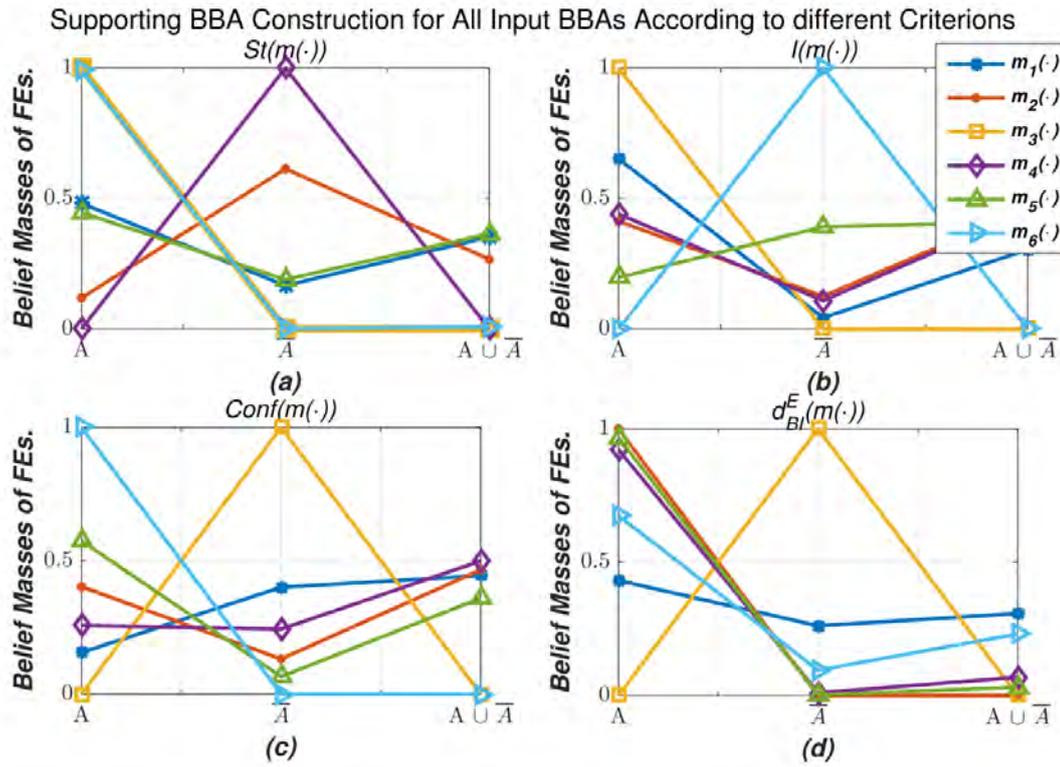

Figure 2. Construction of BBAs based on four distinct criteria. (a) FEs in supporting BBA. (b) FEs in supporting BBA. (c) FEs in supporting BBA. (d) FEs in supporting BBA.

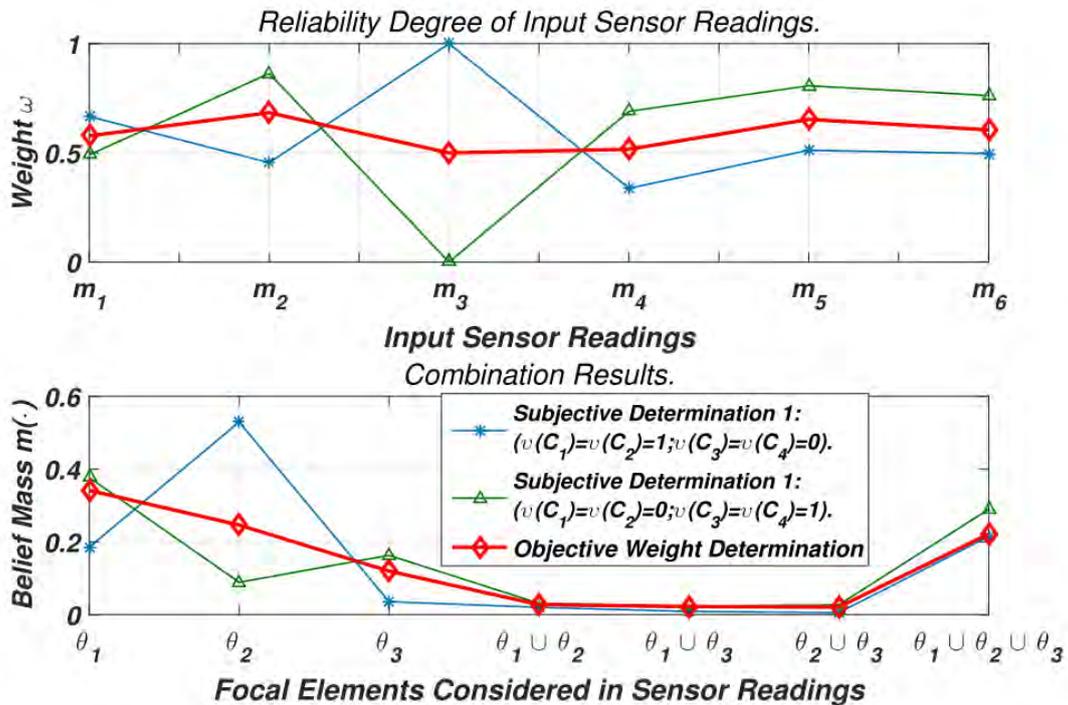

Figure 3. Comparison of subjective and objective weights of criteria for BF-TOPSIS.

accordingly, the mass of  $\theta_2$  becomes the largest in Fig.3 (b). When we modify subjectively the corresponding weights of different criteria, the corresponding weights of all BoEs and the masses of all FEs will also change. Thus, the more criteria are considered, the more weights need to be set, which makes subjective determination of criteria weighting factors more difficult in BF-TOPSIS. In this new method, we do not set the weights of all involved criteria in advance and we can see in Fig.3 (a) that the weight of  $m_3$  is calculated appropriately (red plot) and the final decision is  $\theta_1$ . Based on the obtained weights calculated by this new method, we can use PCR6 rule to fuse all discounted sensor readings. Fig. 3 (b) illustrates the corresponding belief mass of the considered FE.

### B. Fusion of High Conflicting Sensor Readings

Here we show that our multi-criteria discounting combination method can fuse high conflicting sensor readings and give reasonable belief mass distribution. We herein consider two independent BBAs  $m_1$  and  $m_2$  which are defined over the identical FoD  $\Theta = \{\theta_1, \theta_2, \theta_3\}$ . And we also assume that these two BBAs are in highly conflict which are given as follows:

$$\begin{cases} m_1(\{\theta_1\}) = 0.99, m_1(\{\theta_3\}) = 0.01, \\ m_2(\{\theta_2\}) = 0.9, m_2(\{\theta_3\}) = 0.1. \end{cases} \quad (29)$$

In order to be able to see whether our approach can handle highly conflicting problems and how it differs from other classical approaches, we summarize the combination results in Table VI.

We can note that the Dempster's rule directly leads to counter-intuitive results because  $\theta_3$  receives the total mass of belief by using this classical rule. Martin's approach and Jiang's approach assign most values of belief to FE  $\{\theta_1, \theta_2, \theta_3\}$  and after probabilistic transformation ( $BetP(\cdot)$ ), these two methods can give the final decision:  $\theta_1$ . Frikha's approaches in [26], [27] and our approach can directly draw the conclusion that  $\theta_1$  is the final decision based on the principle of maximum probability. In addition, we also give a comparison of the computational time of each mentioned approach. Because the multi-criteria methods need to process more fusion steps, it takes more time than the classical method (Dempster's rule, Martin's method and Jiang's method). However, in this paper, those methods with lower computational complexity (such as Dempster's rule) are not the optimal choice because the criterion for judging the pros and cons of the fusion algorithms here is to give reasonable and correct decision results in face of highly conflicting fusion problems.

### C. Combination of Conflict and Imperfect BBAs

Assume that three sensors 1, 2 and 3 providing three BBAs  $m_1, m_2$  and  $m_3$  defined over the same FoD  $\Theta = \{\theta_1, \theta_2, \theta_3\}$  in Table VII.

As we can see, the most supported element is  $\theta_1$  by sensor 1. Contrary to sensor 1, it is  $\theta_2$  in sensors 2 and 3.

From Table VIII, we can find that the weight of sensor 1 is the lowest ( $\omega(m_1) = 0.3109$  and  $\omega(m_2) = 0.6834$ ,  $\omega(m_3) = 0.6578$ ) which means that  $m_1(\cdot)$  is the most imprecision and

also in conflict with  $m_2$  and  $m_3$ . This result is in some degree consistent with Frinkha's method [26], which also agrees that sensor  $m_1$  is much more less important than  $m_2$  and  $m_3$ . So, based on the results of the obtained weights in Table VIII, we can say that sensor 1 should not play an important rule in the combination result which means that  $m_1$  needs to be discounted.

From the given three BBAs, we can find that  $m_1$  gives the most mass of belief to FE  $\theta_1$ . At the same time,  $m_2$  and  $m_3$  considerably support  $\theta_2$ . However,  $m_2$  and  $m_3$  are not in conflict with  $m_1$  because these two BBAs also assign appropriate masses to  $\theta_1$ . When we combine these three BBAs with Dempster's rule, Jiang's approach or Martin's approach, we can see that the final combination results of these methods are almost the same in Table IX (the final decision is  $\theta_1$ ). This is because that only one conflict criterion is applied for weight calculation in Martin's method or Jiang's method. As we can see in Table VIII, conflict measure could not capture the difference between  $m_1$  and  $m_2, m_3$  which leads to almost same weights of these three BBAs. However, in our proposed method based on BF-TOPSIS, multi-criteria (imprecision and conflict measure) are both cooperated into the weight calculation which can give more comprehensive evaluations. In Table VIII,  $m_1$  receive the lowest weight compared to  $m_2$  and  $m_3$  which means that  $m_2$  and  $m_3$  have the most important effect on the final combination result. In Table IX, we can see that our proposed method supports  $\theta_2$  as the final decision and this conclusion is consistent with the other multi-criteria approaches (PROMETHEE II and AHP).

### D. Random Runs Generated by Monte Carlo Simulations

In this part, we make 50 Monte Carlo simulations and in each simulation, we generate 25 random BBAs over the identical FoD  $\Theta = \{\theta_1, \theta_2, \theta_3\}$ . The first six sensors are in favour of  $\{\theta_1\}$ , the next eight ones are in favour of  $\{\theta_3\}$ , whereas the last eleven sensors are again in favour of  $\{\theta_1\}$ . A mass function focused on  $\{\theta_1\}$  has four focal elements:  $\{\theta_1\}, \{\theta_2\}, \{\theta_3\}$  and  $\{\theta_1, \theta_2\}$  with  $m(\{\theta_1\}) = 0.45 + x$ ;  $m(\{\theta_2\}) = 0.15 - y$ ;  $m(\{\theta_3\}) = 0.15 - x$ ; and  $m(\{\theta_1, \theta_2\}) = 0.25 + y$ . The values  $x$  and  $y$  are randomly generated in the intervals of [0.01, 0.15] and [0.01, 0.10] according the uniform distribution, respectively. Besides, the average values of the weights  $\omega$  of the involved sensors and the pignistic probability  $BetP(\theta)$  are generated in the 50 Monte Carlo simulations.

Due to the fact that the weight of one BoE is independent of the other BoEs according to the class of imperfection criteria, in this case, the evolution of the weight of each sensor when we sequentially add BBAs is definitely affected by conflict criteria.

Figures 4–6 indicate the average of reliability degrees for each group of BoEs (first six BoEs, next eight BoEs, the last 11 BoEs). In each step, one BoE is added, and the discounting factors are calculated for all BoEs. The discounting factors are obtained by averaging the 50 Monte-Carlo simulations. In Fig.4, we can observe that the weights of sensors (1-6) decrease as soon as the next eight BoEs are added. This

Frikhas's approach [27]	0.3938	0.4923	0.0039	0.1090	0	0	0	$\theta_2$	75.563ms
<b>Our proposed method</b>	<b>0.2285</b>	<b>0.3090</b>	<b>0.0081</b>	<b>0.2060</b>	<b>0.0012</b>	<b>0.0012</b>	<b>0.2460</b>	$\theta_2$	73.832ms

phenomenon is mainly due to that these eight sensors (sensor 7-14) are in conflict with the initial sensor readings. In Fig.5, at the beginning stage, there are no BoEs which are in conflict with the first six sensors, the weights of sensors 7-14 are relatively low. After that, their corresponding reliability degrees tend to increase because of the increment of those sensors which support  $\theta_3$ . Finally, these weights of the 7-14 sensors decrease because the remaining BoEs (Sensors 17-25) support  $\theta_1$ . It can be seen that the proposed method in this paper can give the corresponding weights of each sensor reading effectively when conflicts occur. This feature is extremely important in complex dynamic fusion problems.

We also show the evolution of  $BetP(\theta_i)$  for all  $i = 1, 2, 3$  using our proposed approach and other mentioned methods (especially the two multi-criteria methods) in Figures 7–9. As shown in Fig. 7, at the beginning, our method supports:  $\theta_1$ , then, with the increment of the number of conflicting BoEs,

our approach reacts slowly. However, when receiving many conflicting BoEs which support:  $\theta_3$ , the value of  $BetP(\theta_1)$  can decrease rapidly and then the mass of belief of  $\theta_3$  increases when the second group is added in Fig. 9. Besides, we can notice that the related reaction of our method when the second groups of BoEs are added in Fig. 8. Compared to our proposed method, the value of  $BetP(\theta_3)$  obtained by Dempster's rule in Fig. 9 is always zero which proves that Dempster's rule cannot be applied to fuse efficiently highly conflicting BoEs; The changing trends of the mentioned multi-criteria methods (Frikha's two methods in [26] and [27]) can prove that they can deal with the conflicting fusion problem to a certain extent, but it is not sensitive enough compared with our proposed method in this paper. For example, in Fig. 9, with the increment of the number of BoEs supporting  $\theta_3$ ,  $BetP(\theta_3)$  obtained by our method is much larger than the values of  $BetP(\theta_3)$  derived from these two methods [26] and [27];

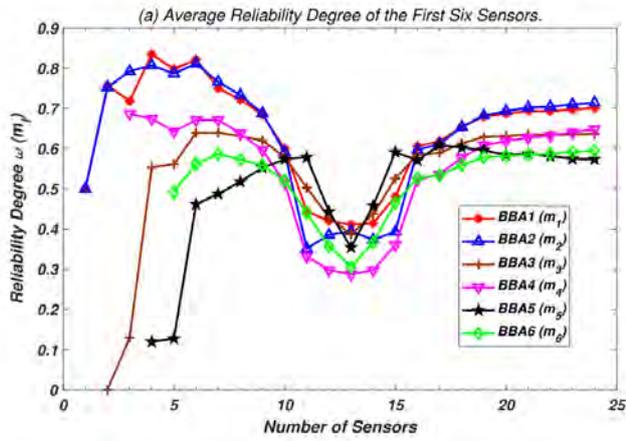

Figure 4. Evolution of the average reliability degrees (sensor 1–sensor 6).

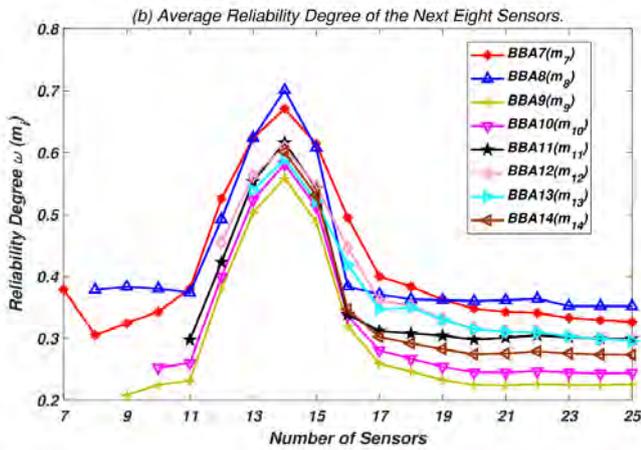

Figure 5. Evolution of the average reliability degrees (sensor 7–sensor 14).

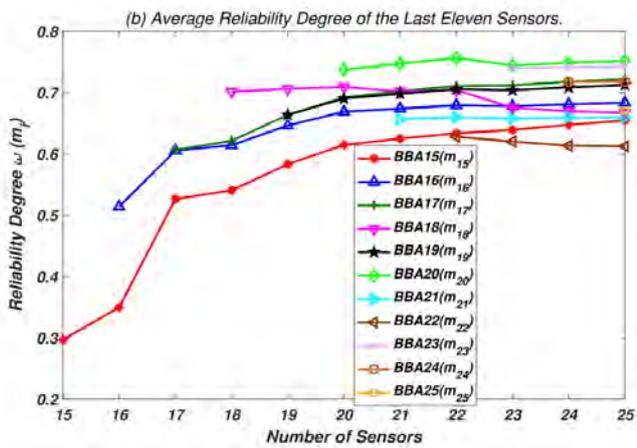

Figure 6. Evolution of the average reliability degrees (sensor 15–sensor 25).

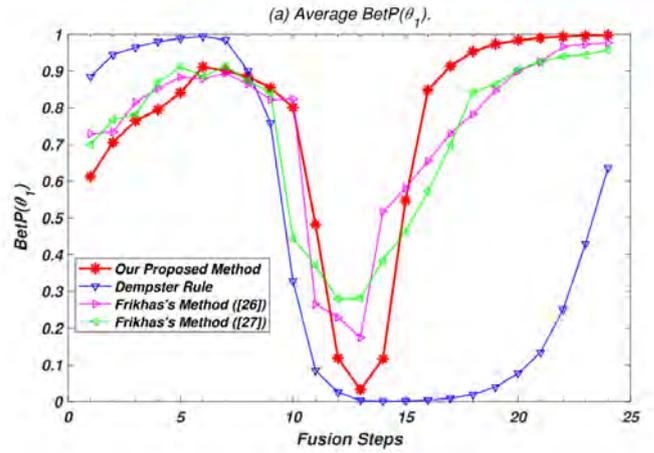

Figure 7.  $BetP(\theta_1)$  using the different methods.

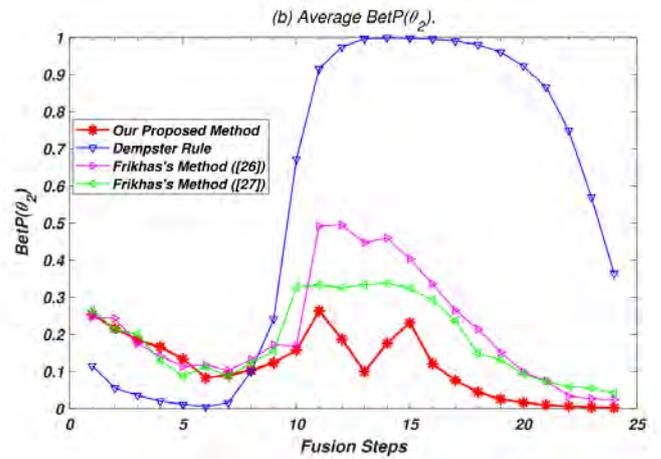

Figure 8.  $BetP(\theta_2)$  using the different methods.

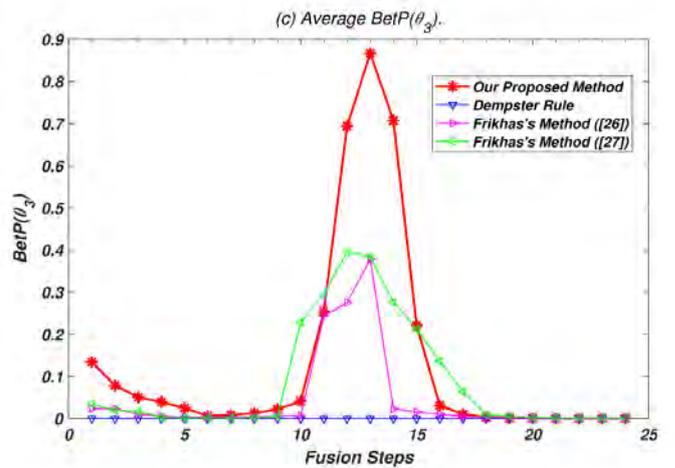

Figure 9.  $BetP(\theta_3)$  using the different methods.

As shown in Fig. 7, the convergence speed of  $BetP(\theta_1)$  in our method is also significantly faster (when the BBAs increase from 15th to 25th fusion step). It can be seen from the Monte Carlo simulations that the proposed method can adapt to the dynamic changes of the environment and give the correct decisions.

## VI. CONCLUSION

In this work, a novel multi-criteria discounting combination rule has been proposed and presented. The BF-TOPSIS approach with an original objective criteria weighting method has been used to evaluate the reliability of the involved sensor readings. The procedure of assessing the reliability degree is based on two categories of criteria. The first class is the degree of imprecision (contradiction and imprecision) and the second class is the conflict degree between sensor readings (conflict and interval distance). After discounting the original sensor reading, all involved BBAs are combined with PCR6 fusion rule for decision-making support.

In order to prove the efficiency of our proposed approach, several simulations have been provided to illustrate the applicability and efficiency of our method. Also, meaningful comparisons were made with other classical approaches. Our results and the analysis of the performance obtained show that our approach is effective in dealing with conflict issues because of multi-criteria strategy adopted. Consequently, this approach can help to reduce counter-intuitive behaviors and biased readings.

In future work, we will focus on the impact of each criterion in the combination results and more criteria will be taken into account. Also, more investigations will be done to explore the difference of performances between global fusion with PCR6 in this paper and sequential fusion with PCR6. We plan to analyze the performance of this new approach for real-world sceneries using real data sets.

**Abstract**—Image registration is a crucial and fundamental problem in image processing and computer vision, which aims to align two or more images of the same scene acquired from different views or at different times. In image registration, since different keypoints (e.g., corners) or similarity measures might lead to different registration results, the selection of keypoint detection algorithms or similarity measures would bring uncertainty. These different keypoint detectors or similarity measures have their own pros and cons and can be jointly used to expect a better registration result. In this paper, the uncertainty caused by the selection of keypoint detector or similarity measure is addressed using the theory of belief functions, and image information at different levels are jointly used to achieve a more accurate image registration. Experimental results and related analyses show that our proposed algorithm can achieve more precise image registration results compared to several prevailing algorithms.

**Keywords:** image registration, evidential reasoning, belief functions, uncertainty.

## I. INTRODUCTION

Image registration is a fundamental problem encountered in image processing, e.g., image fusion [1] and image change detection [2]. It refers to the alignment of two or more images of the same scene taken at different time, from different sensors, or from different viewpoints. Image registration plays an increasingly important role in applications of surveillance [3], remote-sensing [4] and medical imaging [5].

For a collection of images to be registered, one is chosen as the reference image and the others are selected as sensed images. Image registration align each sensed image to the reference image by finding the correspondence between all pixels in the image pair and estimating the spatial transformation from the sensed image to the reference image. In this paper, we just consider the image registration between two images, i.e., there is only one sensed image together with a given reference image.

Current image registration techniques that based on image domain can be generally divided into two categories [6]: the sparse methods and dense methods. There are also some methods based on transform domain, like Fourier-Mellin transformation method [7]. The transform domain based methods are often used for image registration with similarity transformation

model. In this paper, we focus on the image domain based methods.

The sparse methods [8] extracts and matches salient features from the reference image and sensed image and then estimates the spatial transformation between the two images based on these matched features. Line features (e.g., edges) and point features (corners, line intersections and gravities of regions) all can be used for image registration. Corner features are the mostly used features and can be manually selected or automatically detected by Harris [9], FAST (Features from Accelerated Segment Test) [10], SIFT (Scale-Invariant Feature Transform) [11], SURF (Speeded-Up Robust Features) [12], DAISY [13], ORB (Oriented FAST and Rotated BRIEF) [14], KAZE [15], etc.

In contrast to the sparse methods, the dense methods [16] do not detect features from the image pair but search the optimal spatial transformation directly that can best match all the pixels in the image pair. Similarity (resp. dissimilarity) measures are defined to quantify the independency (resp. dependency) between the pair of images. Various similarity and dissimilarity measures have been proposed [17] such as RMSE (Root-Mean-Squared Error), PSNR (Peak Signal to Noise Ratio), Spearman's Rho [18], NCC (Normalized Cross-correlation Coefficient) and MI (Mutual Information). It should be noted that dense methods based on RMSE or PSNR cannot handle the cases with illumination variation since these two similarity/dissimilarity measures are very sensitive to illumination changes.

Both the sparse methods and dense methods involve uncertainty problems. For the sparse methods, keypoints obtained from different keypoint detectors describe different corner features of the image. Therefore, image registrations based on different keypoint detectors would obtain different spatial transformations. For the dense methods, different similarity (dissimilarity) measures quantify the difference between the pair of images from different aspects so that image registrations based on different similarity (dissimilarity) measures would obtain different spatial transformations. These different spatial transformations obtained have their own pros and cons, and the selection of the spatial transformation (the selection of

the feature detector or similarity measure indeed) would bring uncertainty.

To deal with the uncertainty caused by the particular selection of feature detector or similarity (dissimilarity) measure, one feasible way is to combine these registration transformations obtained from different feature detection methods or similarity measures to obtain a better registration result. The belief functions introduced in Dempster–Shafer Theory (DST) [19] of evidence offer a powerful theoretical tool for uncertainty modeling and reasoning; therefore, we propose a fusion based image registration method using belief functions. In this paper, the spatial transformations obtained from different feature detection algorithms or similarity measures compose the frame of discernment (FOD) and their uncertainties are modeled using belief functions. In uncertainty modeling, image information at different levels, i.e., image’s intensities, edges and phase angles, are jointly used to evaluate the beliefs about image transformations. Then, these uncertainties are further handled through the evidence combination of the above multiple information. The final registration result is obtained according to the combined evidence.

This paper is an extension of our previous work in [20] where the basic idea is briefly presented. The main added values with respect to [20] are as follows. First, the transformation model between the reference image and sensed image is more comprehensive. We use similarity transformation model in [20] but use projective transformation model in this paper, which is more general since all similarity transformations are examples of projective transformations. Second, the keypoints used in the sparse approach in [20] are manually selected. To reduce the subjective influence to the registration result, in this paper, the keypoints are generated from detection algorithms. Accordingly, feature matching and mismatching removal are added after the keypoint detection. Third, when modeling uncertainties, one more information source, i.e., image’s phase angle information, is considered in this work. Fourth, more experiments and analyses are provided for performance evaluation and analysis.

The rest of this paper is organized as follows. The basics of image registration are introduced in Section II. The basics of evidence theory are introduced in Section III. The proposed image registration method is introduced in Section IV with emphasis of uncertainty modeling and handling. Evaluation method is introduced in Section V. Experiment results of the proposed method and other registration methods are presented and compared in Section VI. Concluding remarks are given in Section VII.

## II. BASICS OF IMAGE REGISTRATION

For two (or more) images of the same scene taken at different time, from different sensors, or from different viewpoints, one is chosen as the reference image ( $R$ ) and the other one is chosen as the sensed image ( $S$ ). In this paper, we focus on the projective transformation model between the reference image and sensed image, which is a commonly used model in image registration [16]. Denote pixel coordinates in the

reference image  $R$  as  $(v, w)$  and their mapping counterparts in the sensed image  $S$  as  $(g, h)$ . The projective transformation from  $R$  to  $S$  can be expressed based on the homogeneous coordinates (Homogeneous coordinates can easily express the translation transformation as matrix multiplications while Cartesian coordinates cannot) as

$$[g \ h \ 1] = [v \ w \ 1]T = [v \ w \ 1] \begin{bmatrix} t_{11} & t_{12} & t_{13} \\ t_{21} & t_{22} & t_{23} \\ t_{31} & t_{32} & t_{33} \end{bmatrix} \quad (1)$$

The similarity transformation and affine transformation are important specializations of the projective transformation, as illustrated in Table I.

Table I  
PROJECTIVE TRANSFORMATION AND ITS TWO SPECIALIZATIONS.

Similarity	Affine	Projective
$\begin{bmatrix} s \cos \theta & s \sin \theta & 0 \\ -s \sin \theta & s \cos \theta & 0 \\ t_{31} & t_{32} & 1 \end{bmatrix}$	$\begin{bmatrix} t_{11} & t_{12} & 0 \\ t_{21} & t_{22} & 0 \\ t_{31} & t_{32} & 1 \end{bmatrix}$	$\begin{bmatrix} t_{11} & t_{12} & t_{13} \\ t_{21} & t_{22} & t_{23} \\ t_{31} & t_{32} & t_{33} \end{bmatrix}$
		

The purpose of image registration is to estimate the transformation  $T$  to align the sensed image  $S$  with the reference image  $R$  by

$$[v' \ w' \ 1] = [g \ h \ 1]T^{-1}, \quad (2)$$

where  $(v', w')$  and  $(g, h)$  denote pixel coordinates in registered sensed image  $S'$  and sensed image  $S$ , respectively. Current image registration techniques can be divided into two categories [6] in general, including the sparse method and dense method. Basics of these two methods are introduced below.

### A. Sparse Image Registration and Its Uncertainty

The feature detection and feature matching are two critical steps in the sparse methods. The flow chart of the sparse approach is illustrated in Figure 1, where each functional block is detailed in the sequel.

1) *Feature Detection*: Corner features are the mostly used features in image registration due to their invariance to imaging geometry [6]. Some early keypoint detectors, like Harris and FAST, are very sensitive to image scale changes so that have poor performance when the sensed images have different scales with the reference image. The most well-known SIFT detector shows good robustness to illumination, orientation and scale changes. Most scale invariant detectors, like SIFT, SURF, ORB and BRISK, detect and describe features at different scale levels by building or approximating the Gaussian scale space of the image. In a different way, KAZE detects features in a nonlinear scale space built using

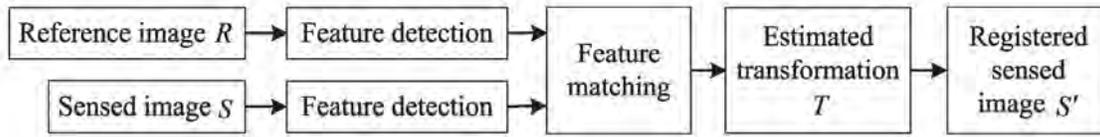

Figure 1. Flow chart of sparse approach.

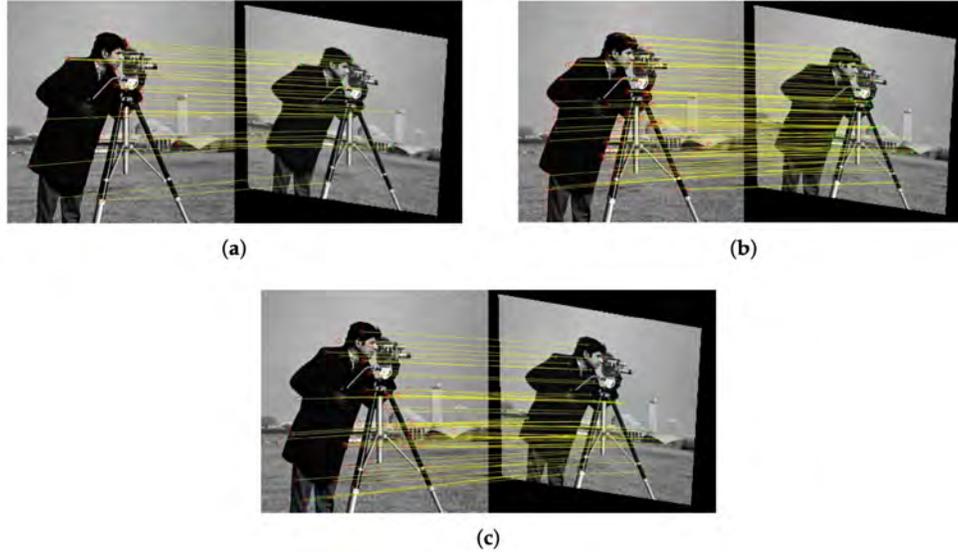

Figure 2. Different keypoint pairs detected by different keypoint detectors. (a) BRISK, (b) KAZE, (c) SURF.

efficient additive operator splitting techniques and variable conductance diffusion.

2) *Feature Matching*: To align the sensed image and the reference image, the detected keypoints in the two images are matched first by comparing their local feature characterized by descriptors. Generally, if the two keypoints' descriptors are similar, the two keypoints are likely to be a matched pair. Given a keypoint  $t$  in the reference image, there might be a set of candidates in the sensed image having similar descriptor with  $t$ . Among these candidates,  $t$ 's real counterpart should have the closest distance with  $t$ , and at the same time its distance should be much closer than other candidates' distances.

The accuracy of the keypoints' matching affects the accuracy of the transformation's estimation. The mismatched keypoint pairs should be further removed before estimating the transformation. RANSAC (RANdom SAMple Consensus) [21] and MSAC (M-estimator SAMple and Consensus) [22] are often used to deal with this problem. A recent RANRESAC (RANdom RESAMple Consensus) [23] algorithm has been proposed to remove mismatched keypoint pairs for noisy image registration. Besides the accuracy of the keypoints' matching, the distribution of matched pairs over the image space is another key factor to obtain a high-quality estimation of transformation.

3) *Transformation Estimation*: With all the matched keypoint pairs, the transformation matrix  $T$  can be estimated using Eq. (1). Since  $T$  has eight degrees of freedom, four point correspondences (with no three collinear) are needed to obtain the unique solution of  $T$  according to Cramer's rule.

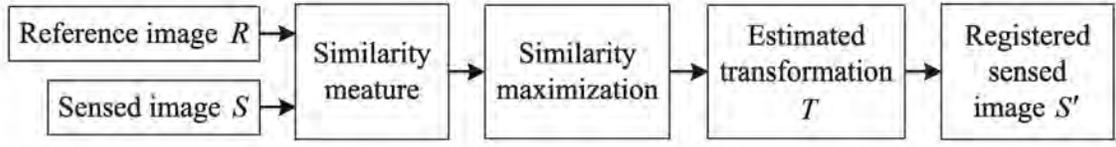

Normally, the amount of the matched keypoint pairs is more than four and  $T$  can be estimated using the least squares (LS) fitting technique [6] by searching the minimum sum of the Euclidean distances between all the matched keypoints:

$$\hat{T} = \arg \min \sum_i d(\text{cor}_i^R, \text{cor}_i^{S'}), \quad (3)$$

where  $\text{cor}_i^R = (v_i, w_i)$  represents the coordinate of the  $i$ -th matched keypoint in the reference image and  $\text{cor}_i^{S'} = (v'_i, w'_i)$  represents the coordinate of the  $i$ -th matched keypoint in the registered sensed image transformed from the sensed image using Eq. (2).

4) *Uncertainty Encountered in Sparse Approach*: Since different keypoint detection algorithms detect different kinds of corner features, the detected keypoints are usually different, as shown in Figure 2.

Image registrations based on different matched keypoint pairs would in general yield different spatial transformations to align two images. Different transformations obtained have their own pros and cons. Therefore, the selection of keypoint detection algorithms would bring uncertainty problem to the registration results.

### B. Dense Image Registration and Its Uncertainty

The dense image registration estimates the optimal transformation  $T$  by searching the largest similarity (or the smallest dissimilarity) between the reference image  $R$  and the registered sensed image  $S' = T(S)$ :

$$\hat{T} = \arg \min Sim(R, T(S)), \quad (4)$$

where  $Sim$  is a chosen similarity measure.

The flow chart of the dense approach is illustrated in Figure 3, where each functional block is detailed in the sequel.

1) *Similarity Measure*: Various similarity (or dissimilarity) measures have been proposed. Here we briefly introduce the commonly used MI, NCC and PSNR measures.

#### 1) MI (Mutual Information) measure:

The MI measure between images  $A$  and  $B$  is defined by

$$MI(A, B) = \sum_{a=0}^{255} \sum_{b=0}^{255} p_{AB}(a, b) \log \frac{p_{AB}(a, b)}{p_A(a)p_B(b)}, \quad (5)$$

where  $p_{AB}$  is the joint probability distribution function (PDF) of images  $A$  and  $B$ , and  $p_A$  and  $p_B$  are the marginal PDFs of  $A$  and  $B$ , respectively.  $MI(A, B)$  is larger when  $A$  and  $B$  are more similar.

#### 2) NCC (Normalized Cross-Correlation) measure:

For given images  $A$  and  $B$  with size of  $M \times N$ , NCC measure between them is

$$NCC(A, B) = \sum_{x=1}^M \sum_{y=1}^N \frac{(A(x, y) - \mu_A)(B(x, y) - \mu_B)}{\sigma_A \sigma_B}, \quad (6)$$

where  $A(x, y)$  and  $B(x, y)$  are the pixels' intensities in images  $A$  and  $B$  at  $(x, y)$ , respectively;  $\mu_A$  and  $\mu_B$  are the mean intensities of  $A$  and  $B$ , respectively;  $\sigma_A$  and  $\sigma_B$  are the standard deviation intensities of  $A$  and  $B$ , respectively.  $NCC(A, B)$  is larger when  $A$  and  $B$  are more similar.

#### 3) PSNR (Peak Signal-to-Noise Ratio) measure:

PSNR measure between images  $A$  and  $B$  is defined by

$$PSNR(A, B) = 10 \times \log_{10} \left( \frac{255^2}{MSE(A, B)} \right), \quad (7)$$

where  $MSE(A, B) = \frac{1}{M \times N} \sum_{x=1}^M \sum_{y=1}^N [A(x, y) - B(x, y)]^2$ . PSNR( $A, B$ ) is larger when  $A$  and  $B$  are more similar. Since PSNR measure is very sensitive to illumination changes, it cannot be used for image registration when there are illumination variations between image pairs.

2) *Transformation Estimation*: The estimation for transformation  $T$ , i.e., Eq. (4), is always a non-convex problem and is not so easy to obtain the global maximum [24]. Therefore, advanced optimization methods [25], or intelligent optimization approaches (like genetic, or particle swarm algorithms, etc.) are often used to estimate the optimal transformation  $T$ .

3) *Uncertainty Encountered in Dense Approach*: Since different similarity (dissimilarity) measures compare two images from different aspects, their calculated similarities (dissimilarities) between the reference image and registered sensed image are different. Image registration based on different measures would obtain different spatial transformations to align two images and they have their own pros and cons. Therefore, the selection of similarity (dissimilarity) measure would bring uncertainty problem to the registration results.

To deal with the uncertainty caused by the selection of feature detection algorithms or similarity measures, one feasible way is to combine the registration transformations ( $T_1, T_2, \dots, T_Q$ ) obtained from different feature detection algorithms (or different similarity measures) to expect a better registration result. We propose an evidential reasoning [19] based image registration algorithm to generate a combined transformation from  $T_1, T_2, \dots, T_Q$  thanks to the ability of belief functions for uncertainty modeling and reasoning. Basics of the theory of belief functions are recalled first below.

### III. BASICS OF DEMPSTER-SHAFFER EVIDENCE THEORY

Dempster-Shafer evidence theory (DST) [19] is a theoretical framework for uncertainty modeling and reasoning. In DST, elements in the frame of discernment (FOD)  $\Theta = \{\theta_1, \theta_2, \dots, \theta_Q\}$  are mutually exclusive and exhaustive. The power set of  $\Theta$ , i.e.,  $2^\Theta$ , is the set of all subsets of  $\Theta$ . For example, if  $\Theta = \{\theta_1, \theta_2, \theta_3\}$ , then

$$2^\Theta = \{\{\emptyset\}, \{\theta_1\}, \{\theta_2\}, \{\theta_3\}, \{\theta_1, \theta_2\}, \{\theta_1, \theta_3\}, \{\theta_2, \theta_3\}, \{\theta_1, \theta_2, \theta_3\}\}.$$

The basic belief assignment (BBA, also called mass function) is defined by a function  $m: 2^\Theta \mapsto [0, 1]$ , satisfying

$$m(\emptyset) = 0, \text{ and } \sum_{A \subseteq \Theta} m(A) = 1, \quad (8)$$

where  $m(A)$  depicts the evidence support to the proposition  $A$ .  $A$  is called a focal element when  $m(A) > 0$ . If there is only one element in  $A$ , like  $\{\theta_1\}$  and  $\{\theta_2\}$ ,  $A$  is called the singleton element; if there are more than one element in  $A$ , e.g.,  $\{\theta_1, \theta_2\}$  and  $\{\theta_1, \theta_2, \theta_3\}$ ,  $A$  is called the compound

element. The belief assigned to a compound element represents the degree of ambiguity for the multiple elements.

The plausibility function ( $Pl$ ) and belief function ( $Bel$ ) are defined as follows:

$$Pl(A) = \sum_{A \cap B \neq \emptyset} m(B), \quad (9)$$

$$Bel(A) = \sum_{B \subseteq A} m(B). \quad (10)$$

Dempster's combination rule [19] for combining two distinct pieces of evidence is defined as

$$(m_1 \oplus m_2)(A) = \begin{cases} 0, & \text{if } A = \emptyset, \\ \frac{1}{1-K} \sum_{B \cap C = A} m_1(B)m_2(C) & \text{if } A \neq \emptyset. \end{cases} \quad (11)$$

Here,  $K = \sum_{B \cap C = \emptyset} m_1(B)m_2(C)$  denotes the total conflict or contradictory mass assignments.

An alternative fusion rule PCR6 [26] for the combination of two sources is defined as

$$m_{12}^{PCR6}(A) = m_{12}^{Conj}(A) + \sum_{A \cap Y = \emptyset} \left[ \frac{m_1(A)^2 m_2(Y)}{m_1(A) + m_2(Y)} + \frac{m_2(A)^2 m_1(Y)}{m_2(A) + m_1(Y)} \right], \quad (12)$$

where  $m_{12}^{Conj}(A)$  is the conjunctive rule defined as

$$m_{12}^{Conj}(A) = \sum_{B \cap C = A} m_1(B)m_2(C). \quad (13)$$

General PCR6 formula for the combination of more than two sources is given in [26].

For a probabilistic decision-making, Smets defined the pignistic probability transformation [27] to obtain the probability measure  $BetP$  from a BBA

$$BetP(\theta_i) = \sum_{A \subseteq \Theta | \theta_i \in A} \frac{m(A)}{|A|}. \quad (14)$$

where  $|A|$  is the cardinality of  $A$ . The decision can be made by choosing the element in FOD whose  $BetP$  value is the highest one and higher than a preset threshold. Other types of probability transformation methods can be found in [26,28].

#### IV. IMAGE REGISTRATION BASED ON EVIDENTIAL REASONING

To deal with the uncertainty caused by the choice of keypoint detectors in the sparse approach or the choice of similarity measure in the dense approach, we propose an image registration method based on evidential reasoning. Suppose that the spatial transformation between the reference image and sensed image is projective. Our purpose is to estimate the transformation matrix to align two images. Unlike the prevailing methods estimating the transformation matrix from single method of keypoint detection or similarity (dissimilarity) measure, we estimate the transformation matrix by jointly

utilizing different keypoint detection methods or similarity measures.

To use belief functions for image registration, one should define the frame of discernment (FOD) first. The FOD  $\Theta = \{\theta_1, \theta_2, \dots, \theta_Q\}$ , where  $Q$  is the amount of transformations obtained from different single feature detection algorithms or different single similarity measures. We first model the beliefs for every proposition  $A \subseteq \Theta$  using BBAs.  $A$  can be single transformation in FOD or a set of transformations in FOD. One BBA depicts the support to each proposition  $A$  from one evidence source. The BBA allocations from different evidence sources describes the uncertainty of the transformations in FOD. Next, the BBAs are combined to generate the combined BBA  $m_c$  depicting the fused support to each proposition  $A$ . Then, the combined transformation  $T_c$  is generated from the combined BBA  $m_c$ . Finally, the registered sensed image  $S'_c$  is transformed from the sensed image using Eq. (2). During this process, the resampling [29] is needed to determine the intensity of each pixel in  $S'_c$ . Figure 4 illustrates the flow chart of this new proposed method. It should be noted that the classical interpretation of BFT assumes that the final estimation should be in the FOD. In this work, we relax this assumption and the final transformation is a combination result of those in the FOD.

#### A. Uncertainty Modeling

If the similarity between the reference image  $R$  and registered sensed image  $S'_i$  is large, the corresponding transformation  $T_i$  is quite accurate and should be allocated large support ( $S'_i$  is transformed from sensed image  $S$  by  $T^{-1}$ ). Here we use NCC (other similarity or dissimilarity measures, e.g., MI, are also appropriate to quantify the similarity here) to measure the similarity between  $R$  and  $S'_i$ :

$$NCC_i = \sum_{x=1}^M \sum_{y=1}^N \frac{(R(x,y) - \mu_R)(S'_i(x,y) - \mu_{S'_i})}{\sigma_R \sigma_{S'_i}}, \quad (15)$$

where  $\mu_R$  and  $\mu_{S'_i}$  are the mean intensities of  $R$  and  $S'_i$ , respectively;  $\sigma_R$  and  $\sigma_{S'_i}$  are the standard deviation intensities of  $R$  and  $S'_i$ , respectively.

Since multi-source information can help to reduce the uncertainty through evidence combination, we use different levels of image information to quantify the similarity between  $R$  and  $S'_i$ . The similarity can be calculated from the gray images, edge feature images or reconstructed images using phase angle as shown in Figure 5. Their corresponding  $NCC_i$  are denoted as  $NCC_i(G)$ ,  $NCC_i(E)$  and  $NCC_i(P)$ , respectively. The edge detection method used in Figure 5-b is the Canny detector [30]. More details of the image reconstruction from phase angle information can be found in [29].

The value range of  $NCC_i(\cdot)$  is  $[-1, 1]$ . According to our experiments, most values of  $NCC_i(\cdot)$  are larger than 0. Before allocating BBAs, we first enlarge the differences of  $NCC_i(\cdot)$  within  $[0, 1]$  using function  $y = e^{x-1}$ , as illustrated in Figure 6. Each level of image information (gray images ( $G$ ), edge

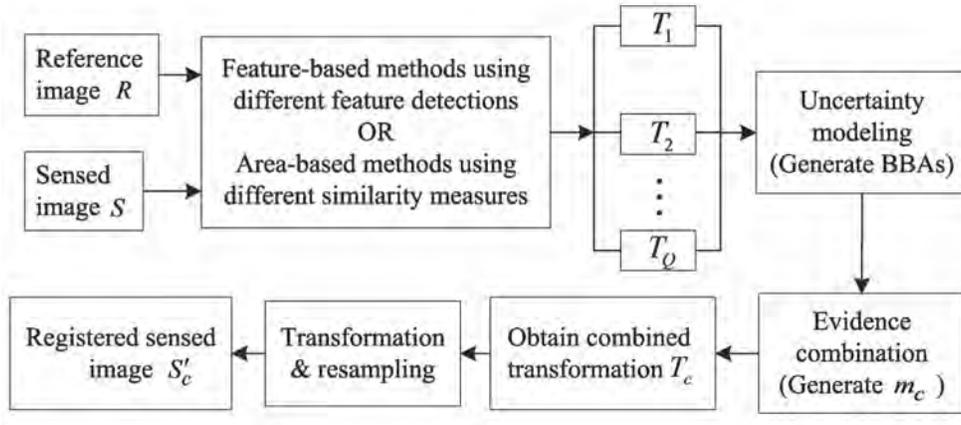

Figure 4. Flow chart of the proposed image registration.

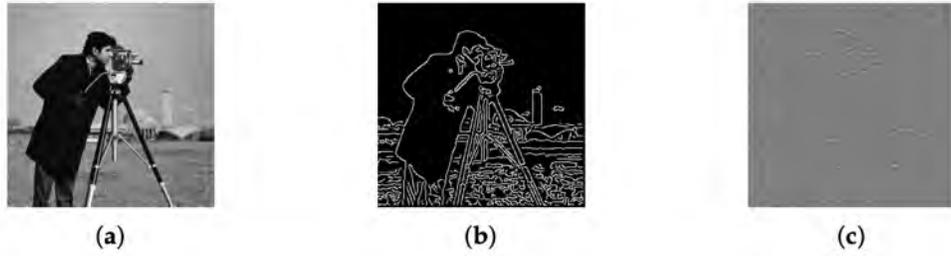

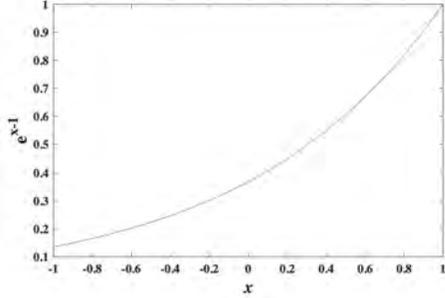

Figure 5. Image information at different levels. (a) Gray image. (b) Edge feature image. (c) Reconstructed image using phase angle.

 Figure 6. The curve of function  $e^{x-1}$ .

feature images ( $E$ ) and reconstructed images using phase angle ( $P$ ) can be viewed as one evidence source and their corresponding  $y = e^{\text{NCC}_i(\cdot)-1}$  can be used to assign beliefs for transformation  $T_i$ :

$$\begin{cases} m_G(T_i) = \frac{e^{\text{NCC}_i(G)-1}}{\sum_{j=1}^Q e^{\text{NCC}_j(G)-1}} \\ m_E(T_i) = \frac{e^{\text{NCC}_i(E)-1}}{\sum_{j=1}^Q e^{\text{NCC}_j(E)-1}} \\ m_P(T_i) = \frac{e^{\text{NCC}_i(P)-1}}{\sum_{j=1}^Q e^{\text{NCC}_j(P)-1}} \end{cases} \quad (16)$$

### B. Fusion-Based Registration

After obtaining BBAs  $m_G$ ,  $m_E$  and  $m_P$ , we generate the combined BBA  $m_c$  using a combination rule denoted

symbolically with  $\oplus$ :

$$m_c(\cdot) = [m_G \oplus m_E \oplus m_P](\cdot). \quad (17)$$

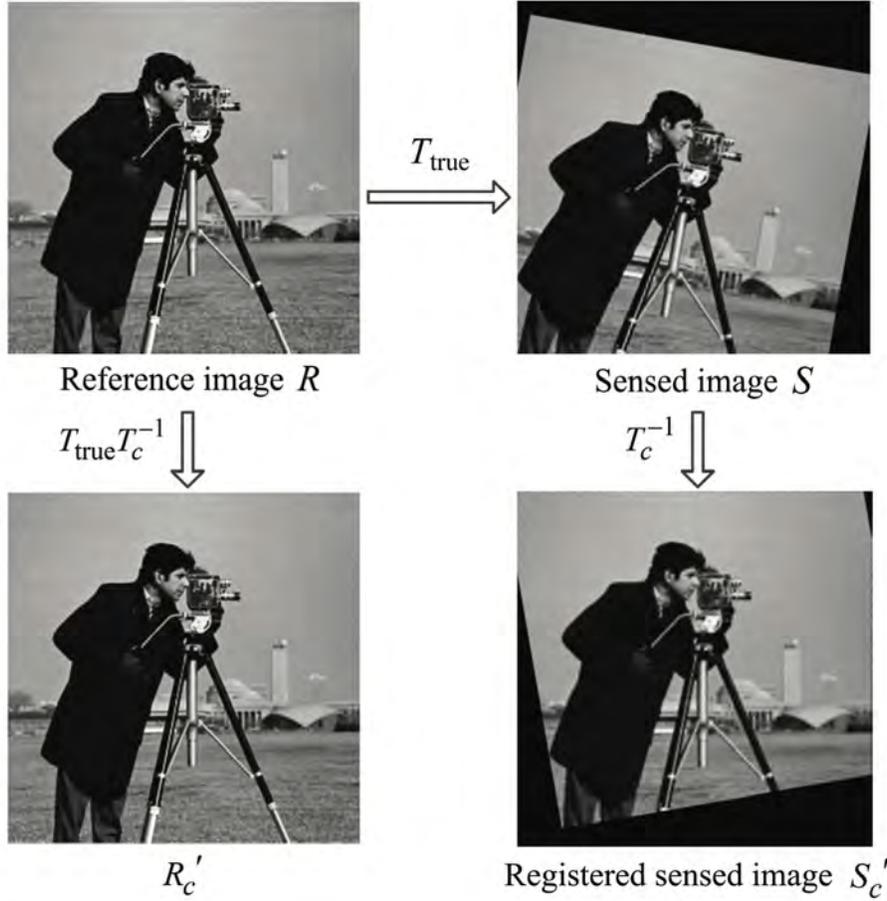

$m_c(T_i)$  describes the combined evidence support to  $T_i$  (a  $3 \times 3$  matrix with 6 unknown parameters). The combined transformation  $T_c$  is computed by

$$T_c^{-1} = \sum_{i=1}^Q m_c(T_i) T_i^{-1}. \quad (18)$$

Finally, the registered sensed image  $S'_c$  can be obtained using Eq. (2) following the resampling.

### V. EVALUATION OF IMAGE REGISTRATION

Since the purpose of image registration is to align the reference image  $R$  and sensed image  $S$  to a single coordinate frame, one popular evaluation method for the registration result is to quantify the difference (usually quantified by Root-Mean-Squared Error (RMSE)) between  $R$  and the registered sensed image  $S'_c$  [31,32]. However, since  $S'_c$  is transformed from the sensed image  $S$ , which may have less information than  $R$  ( $S$  may be part of  $R$  or have lower resolution than  $R$  since  $R$  and  $S$  can be taken from different views or taken by different cameras), the difference between  $R$  and  $S'_c$  could be large even when the estimated transformation  $T_c$  equals to the true transformation  $T_{\text{true}}$  from the reference image  $R$  to the sensed image  $S$ , as shown in Figure 7. Therefore, this kind of evaluation method is not accurate enough.

 Figure 7. Relationship among  $R$ ,  $S$ ,  $R'_c$ , and  $S'_c$ .

Another popular evaluation method is to quantify the difference between the reference image  $R$  and image  $R'_c$ , which is transformed from  $R$  by the transformation matrix  $T_{\text{true}} T_c^{-1}$  [16,33], as shown in Figure 7. The mapping relationship between pixel at  $(v, w)$  in image  $R$  and pixel at  $(v', w')$  in image  $R'_c$  satisfies

$$[v' \ w' \ 1] = [v \ w \ 1] T_{\text{true}} T_c^{-1}, \quad (19)$$

when the registration is absolutely accurate,  $T_c = T_{\text{true}}$  and  $R'_c = R$ .

In this paper, we evaluate the registration performance by quantifying the difference between the reference image  $R$  and image  $R'_c$  using AAID (average absolute intensity difference) [16]:

$$\text{AAID}(R, R'_c) = \frac{1}{M \times N} \sum_{x=1}^M \sum_{y=1}^N |R(x, y) - R'_c(x, y)|. \quad (20)$$

AAID( $R, R'_c$ ) is smaller when the registration result is better.

## VI. EXPERIMENTS

To verify the performance of our new proposed image registration method, we provide experiments on noise-free images and noisy images, respectively. Image registration

under the noisy condition is difficult since the noise pixels bring difficulties for keypoints' detection and matching and reduce the accuracy for similarity measure. For the sparse method, experiment results based on BRISK [34], KAZE [15] and SURF [12] feature detection algorithms are provided for comparison. For the dense method, experiment results based on MI, PSNR and NCC similarity measures are provided for comparison. For the noisy image registration, the experiment result of RANRESAC (a recently proposed method for noisy image registration) [23] is also provided for comparison.

### A. Sparse Image Registration Results

We first do experiments on actual data to illustrate the effectiveness of the proposed method. The reference image and sensed image are taken from different cameras with different views, as shown in Figure 8. BRISK, KAZE and SURF feature detections are used for generating transformations  $T_1$ ,  $T_2$  and  $T_3$ , respectively. When deriving combined BBAs in Eq. (17), an alternative fusion rule PCR6, which is more robust than Dempster's rule [26], is also used for comparison.

The registered results of the proposed method are illustrated in Figure 9. From Figure 9, the proposed method can successfully align the sensed image to the reference image illustrating that the proposed method is effective for actual data.

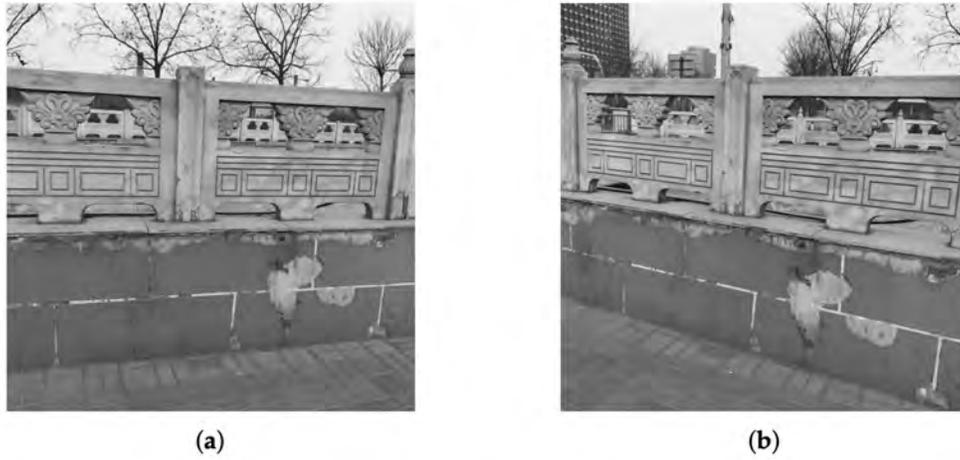

Figure 8. Fence image pair. (a) Reference image. (b) Sensed image.

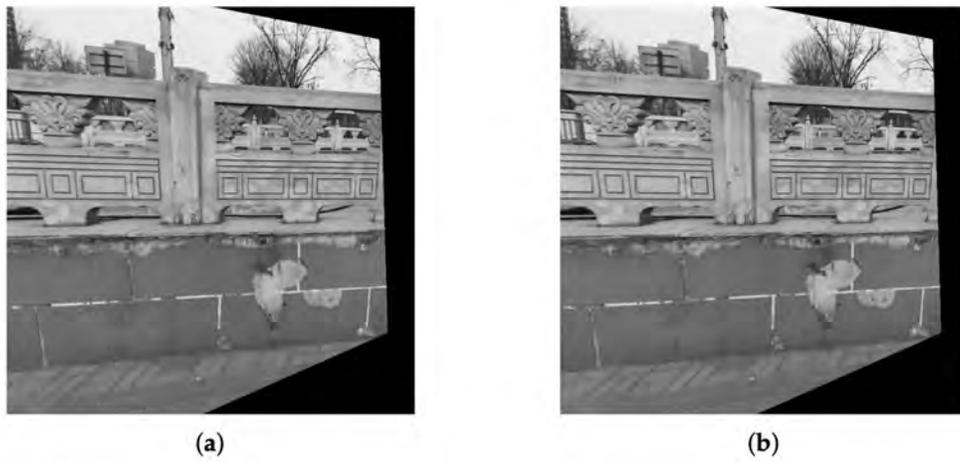

Figure 9. Registered results of the proposed methods for Fence image. (a) Dempster's rule. (b) PCR6.

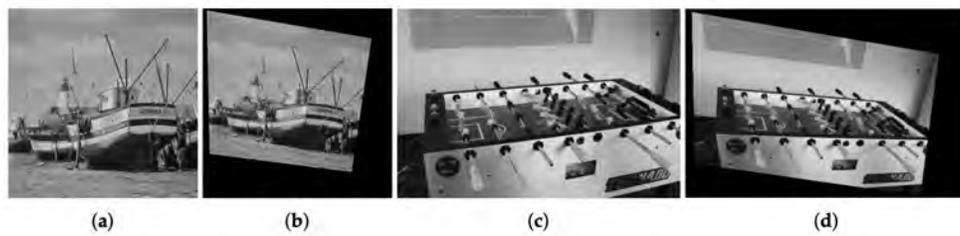

Figure 10. Boats image pair and Foosball image pair. (a) Boats reference image. (b) Boats sensed image. (c) Foosball reference image. (d) Foosball sensed image.

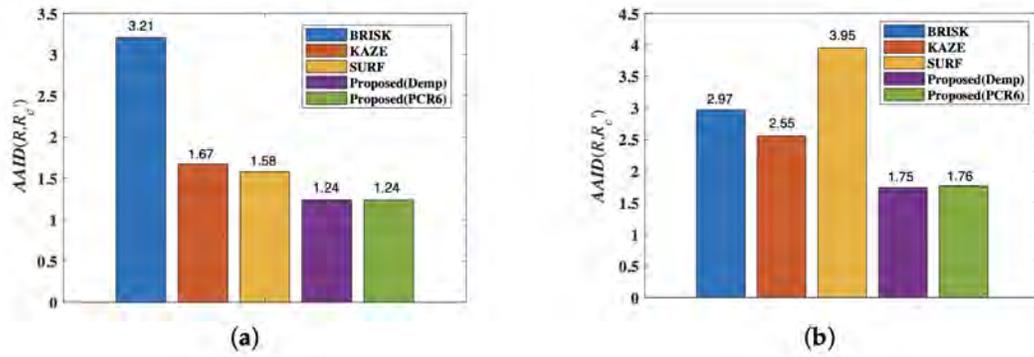

Figure 11. AAID evaluations of registration results for Boats image pair and Foosball image pair. (a) Boats. (b) Foosball.

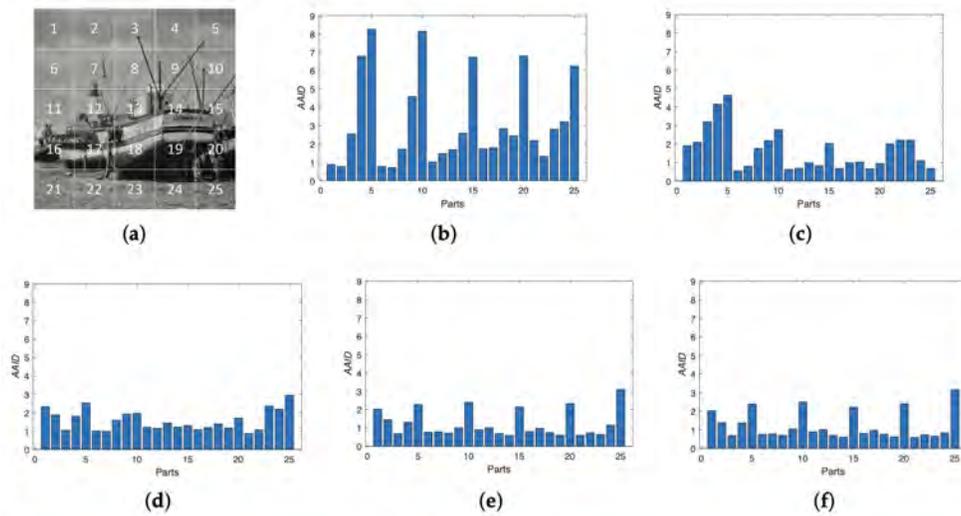

Figure 12. Spatial partition of the AAID evaluation for Boats image. (a) Partition method. (b) BRISK. (c) KAZE. (d) SURF. (e) Proposed (Demp). (f) Proposed (PCR6).

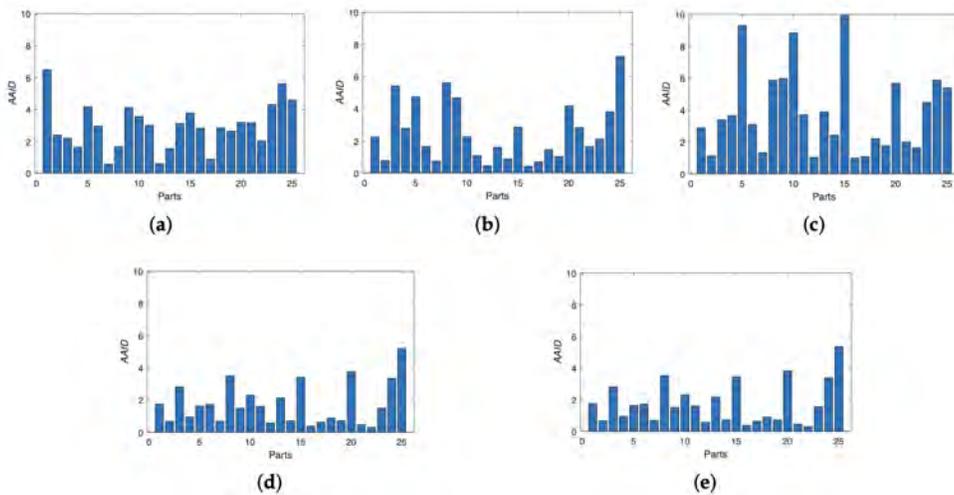

Figure 13. Spatial partition of the AAID evaluation for Foosball image. (a) BRISK. (b) KAZE. (c) SURF. (d) Proposed (Demp). (e) Proposed (PCR6).

To quantify the accuracy of the registration results, the actual transformation between the reference image and sensed image is needed and we do experiments on simulated images. We first do experiments on Boats image (The reference image can be found at <https://imagej.nih.gov/ij/images/boats.gif>) and Foosball image (sample image from the MATLAB), as shown in Figure 10.

The AAID evaluations of these registration results for Boats image and Foosball image are compared in Figure 11, where Demp represents the Dempster's combination rule. According to Figure 11, the proposed fusion-based method achieves much better registration result (smaller AAID) than algorithms based on BRISK, KAZE or SURF feature detections, respectively.

Furthermore, we also analyzed the spatial partition of the AAID evaluation for each result by evenly dividing the reference image into  $5 \times 5$  parts (as shown in Figure 12a) and calculating the AAID between the reference image and the registration result in each part. The AAID spatial partition results for Boats image and Foosball image are illustrated in Figures 12 and 13, respectively. For Boats image, the AAID of BRISK and KAZE results varies significantly for different parts while the SURF result is relatively uniform; the proposed methods have low and similar AAID in most parts while the rightmost parts (parts 5, 10, 15, 20 and 25) have significant larger AAID. For Foosball image, the AAID spatial partition of all these results are uneven.

Then, we consider the noisy image registration and do experiments on West Concord image pair (sample image from the MATLAB) with zero-mean Gaussian noise (variance is 0.01), as shown in Figure 14. The AAID evaluations for these registration results are compared in Figure 15, where the proposed fusion-based methods achieve better performance (smaller AAID) than RANRESAC and methods based on BRISK, KAZE and SURF feature detections, respectively. The spatial partition of the AAID evaluation for each result is illustrated in Figure 16, where the KAZE result is the most uneven one.

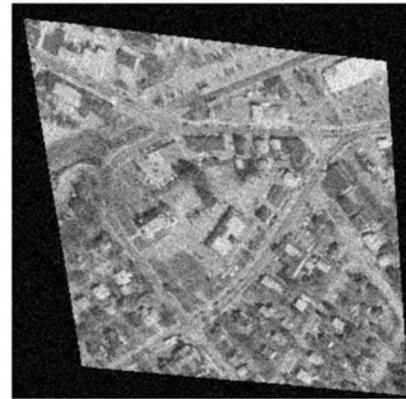

### B. Dense Image Registration Results

Since the optimization of dense registration is intractable when the solution space has high dimensions, we simplify the transformation model to rigid transformation here. The solution space for rigid model only has three dimensions: one for rotation and two for translations in horizontal and vertical directions, respectively. We first provide experiments on Concord image and Hestain image (sample images from the MATLAB) as shown in Figure 17, where the sensed image is transformed from the reference image through the rotation ( $\theta = 10^\circ$  in anti-clockwise) and translation ( $(t_v, t_h) = (-10, 5)$ ) successfully.

In the proposed dense approach, MI, PSNR and NCC similarity measures are used for generating transformations  $T_1$ ,  $T_2$  and  $T_3$ , respectively. The AAID evaluations of these registration results for the Concord image and Hestain image are compared in Figure 18, where the proposed fusion-based

(a)

(b)

Figure 14. West Concord image pair. (a) Reference image. (b) Sensed image.

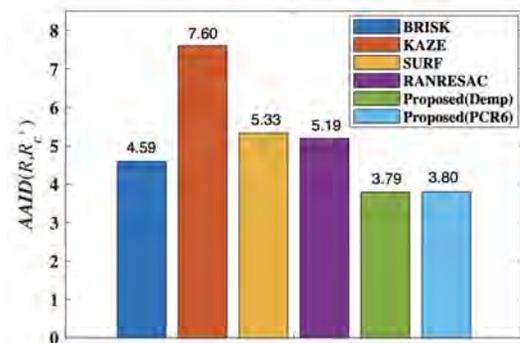

Figure 15. AAID evaluations of registration results for West Concord image pair.

methods achieve much better registration results (smaller AAID) than algorithms based on MI, PSNR or NCC similarities, respectively. The AAID spatial partition results for Concord image and Hestain image are illustrated in Figures 19 and 20, respectively. For these two images, the AAID results of the proposed methods are smaller in the downside parts compared with those in upside parts.

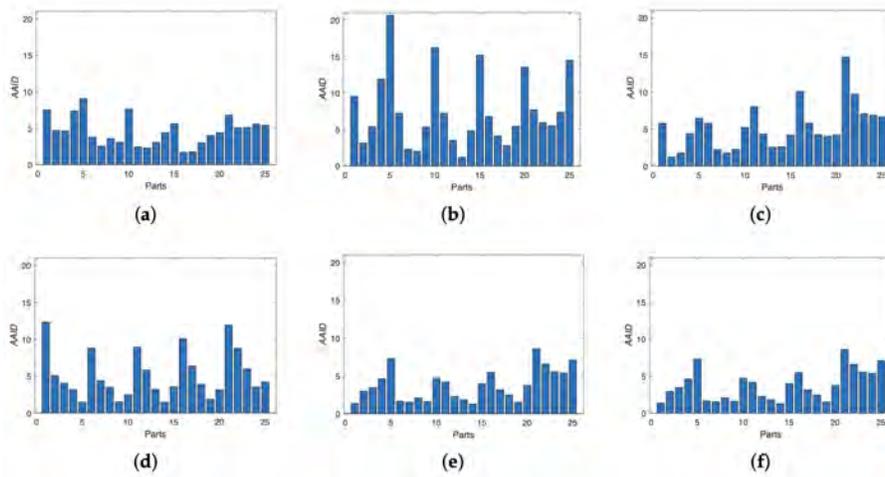

Figure 16. Spatial partition of the AAID evaluation for West Concord image. (a) BRISK. (b) KAZE. (c) SURF. (d) RANRESAC. (e) Proposed (Demp). (f) Proposed (PCR6).

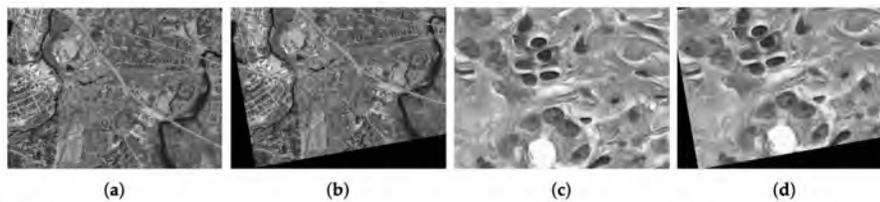

Figure 17. Concord image pair and Hestain image pair. (a) Concord reference image. (b) Concord sensed image. (c) Hestain reference image. (d) Hestain sensed image.

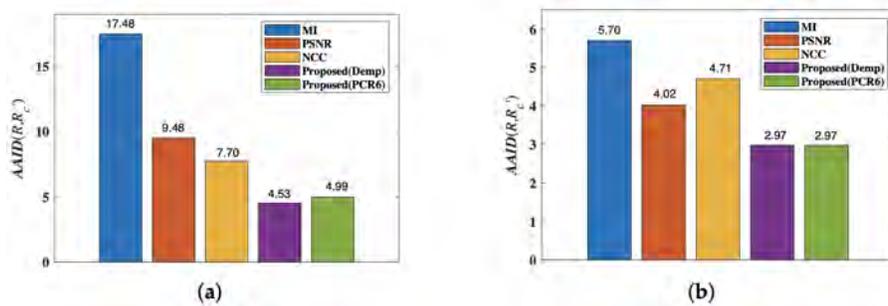

Figure 18. AAID evaluations of registration results for Concord image pair and Hestain image pair. (a) Concord. (b) Hestain.

Then, we consider the noisy image condition and implement experiments on Lifting Body image pair (sample image from the MATLAB) with zero-mean Gaussian noise (variance is 0.01), as shown in Figure 21. The sensed image is transformed from the reference image through the rotation ( $\theta = -10^\circ$ ) and translation ( $(t_v, t_h) = (-10, 5)$ ), successively.

The spatial partition of the AAID evaluation for each result is illustrated in Figure 22, and the AAID evaluations for these registration results are compared in Figure 23. From these two figures, the proposed fusion-based methods achieve better performance and the rightmost parts (parts 5, 10, 15, 20 and 25) have larger AAID than other parts.

According to all the experiments, the proposed fusion-based methods achieve better registration results than those prevailing ones (BRISK, KAZE, SURF, MI, PSNR and NCC). For noisy image registration, the proposed methods also obtain better performance than RANRESAC. This indicates that the theory of belief function can well deal with the uncertainty brought by the selection of keypoint detection algorithms or similarity measures, and the jointly use of the different keypoint detections or similarity measures is effective. Furthermore, from the above provided experiments one sees that the choice of combination rule does not affect the registration performance that much.

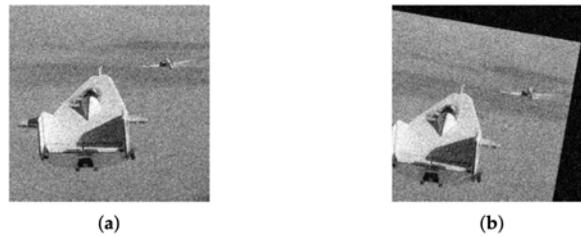

Figure 21. Lifting Body image pair. (a) Reference image. (b) Sensed image.

C. Computational Cost

The computational cost is an important criterion to evaluate an algorithm. We counted the computational costs of the above sparse algorithms and dense algorithms for Cameraman image (Figure 5-a) on a Windows 10 Enterprise system equipped with Intel Core i7-7700HQ CPU at 2.80 GHz and 16.00 GB RAM. The platform is MATLAB R2018a. The average execution time comparisons for the sparse algorithms and dense algorithms are provided in Tables II and III, respectively. Each average execution time is calculated from 100 runs of experiments.

Table II  
AVERAGE EXECUTION TIME (IN s) COMPARISON FOR SPARSE ALGORITHMS.

Method	Noise-Free Images	Noisy Images
BRISK	0.2847	0.2832
KAZE	0.1348	0.1304
SURF	0.0431	0.0437
RANRESAC	—	6.2648
Proposed (Demp)	0.3934	0.3933
Proposed (PCR6)	0.3938	0.3989

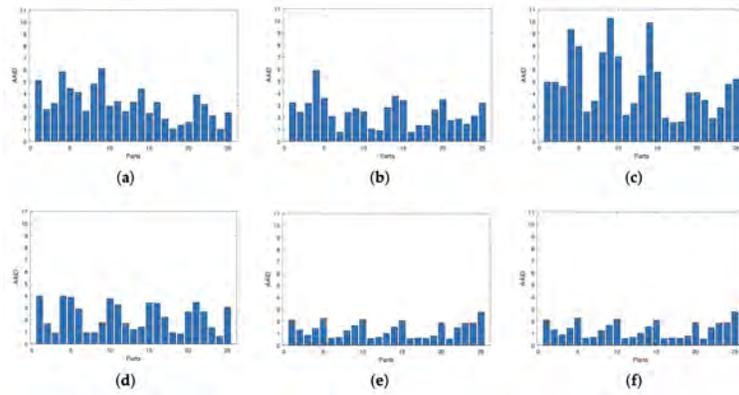

Figure 22. Spatial partition of the AAID evaluation for Lifting Body image. (a) MI. (b) PSNR. (c) NCC. (d) RANRESAC. (e) Proposed (Demp). (f) Proposed (PCR6).

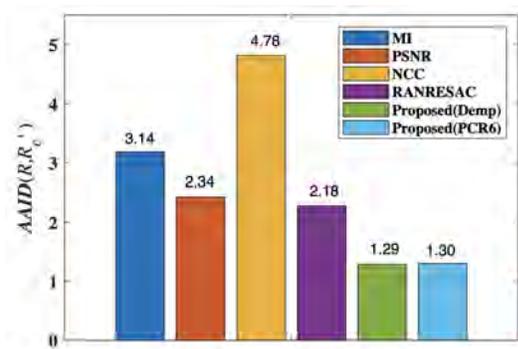

Figure 23. AAID evaluations of registration results for Lifting Body image pair.

Table III  
AVERAGE EXECUTION TIME (IN  $s$ ) COMPARISON FOR DENSE ALGORITHMS.

Method	Noise-Free Images	Noisy Images
MI	16.7622	16.4789
PSNR	12.8583	13.4214
NCC	14.7187	15.1050
Proposed (Demp)	17.0734	16.7945
Proposed (PCR6)	17.0812	16.8729

From Tables II and III, the dense algorithms need more execution time than the sparse algorithms. Furthermore, since the proposed fusion-based method combines the registration transformations generated from the three sparse methods (BRISK, KAZE and SURF) or the three dense methods (PSNR, MI and NCC) and these three methods can be executed in parallel, and the execution time of the proposed fusion-based method is longer than the most time-consuming one among the three methods.

#### D. Discussion of BBA Generation

The BBA generated in Eq. (16) is Bayesian BBA, where all its focal elements are singletons. People in the community of belief function theory may prefer to use the compound focal elements, which usually seems better than only using single-

tons in Bayesian BBAs. We have also designed experiments of generating non-Bayesian BBAs for image registration using FCOWA-ER (Fuzzy-Cautious Ordered Weighted Averaging with Evidential Reasoning) [35] method. In detail, when multiple image information (image's intensities, edges and phase angle) are simultaneously considered, image registration can be viewed as a multi-criteria decision making problem. FCOWA-ER (Fuzzy-Cautious Ordered Weighted Averaging with Evidential Reasoning) [35] is a decision making approach under multi-criteria with uncertainty and it generates non-Bayesian BBAs using  $\alpha$ -cut method (The  $\alpha$ -cut method used in FCOWA-ER boils down to the Dubois and Prade allocation [36] in this case) when modeling uncertainties. According to the experimental results, non-Bayesian BBAs obtain similar registration results with Bayesian BBAs. Since Bayesian BBAs are easier to generate than non-Bayesian BBAs, we recommend Bayesian BBAs for image registration and do not provide the non-Bayesian BBA based method in this work.

## VII. CONCLUSION

In this paper, we proposed a new image registration algorithm based on evidential reasoning. The uncertainty encountered in image registration is taken into account and modeled by belief functions. Image information at different levels are jointly used to achieve a more effective registration. Experimental results show that the proposed algorithm can improve the precision of image registration.

The generation of BBA is crucial in evidential reasoning and most methods are proposed based on applications. In this paper, we generate BBAs from three different image information, i.e., intensity, edge and phase angle. In future work, other image information, such as texture feature and gradient feature, will also be considered and jointly used in image registration. Furthermore, we will attempt to apply the proposed method to color image registration. Different color channels of the color image provide different image information and can be jointly used in image registration. We will also focus on the comparison with the state-of-the-art approaches based on convolutional neural networks (CNN).

**Abstract**—In this paper we present two applications of a new Belief Function-based Inter-Criteria Analysis (BF-ICrA) approach for the assessment of the degree of redundancy of criteria involved in multi-criteria decision-making (MCDM) problems. This BF-ICrA method allows to simplify the original MCDM problem by suppressing redundant criteria (if any) and thus diminish the complexity of MCDM problem. This approach is appealing for solving large MCDM problems whose solution requires the fusion of many belief functions. We show how this approach can be used in two distinct fields of applications: The GPS Surveying Problem, and the car selection problem.

**Keywords:** Inter-Criteria Analysis, ICrA-BF, MultiCriteria Decision Making, MCDM, belief functions.

## I. INTRODUCTION

In a Multi-Criteria Decision-Making (MCDM) problem we consider a set of alternatives (or objects)  $\mathbf{A} \triangleq \{A_1, A_2, \dots, A_M\}$  ( $M > 2$ ), and a set of criteria  $\mathbf{C} \triangleq \{C_1, C_2, \dots, C_N\}$  ( $N \geq 1$ ). We search for the best alternative  $A^*$  given the available information expressed by a  $M \times N$  score matrix (also called benefit or payoff matrix)  $\mathbf{S} \triangleq [S_{ij} = C_j(A_i)]$ , and (eventually) the importance factor  $w_j \in [0, 1]$  of each criterion  $C_j$  with  $\sum_{j=1}^N w_j = 1$ . The set of normalized weighting factors is denoted by  $\mathbf{w} \triangleq \{w_1, w_2, \dots, w_N\}$ . Depending on the context of the MCDM problem, the score  $S_{ij}$  of each alternative  $A_i$  with respect to each criteria  $C_j$  can be interpreted either as a cost (i.e. an expense), or as a reward (i.e. a benefit). By convention and without loss of generality<sup>1</sup> we will always interpret the score as a reward having monotonically increasing preference. Thus, the best alternative  $A_j^*$  for a given criteria  $C_j$  will be the one providing the highest reward/benefit.

The MCDM problem is not easy to solve because the scores are usually expressed in different (physical) units and different scales. This necessitates a choice of score/data normalization yielding rank reversal problems [1], [2]. Usually there is no same best alternative choice  $A^*$  for all criteria, so a compromise must be established to provide a reasonable

and acceptable solution of the MCDM problem for decision-making support.

Many MCDM methods exist, see references in [3]. Most popular methods are AHP<sup>2</sup> [4], ELECTRE<sup>3</sup> [5], TOPSIS<sup>4</sup> [6], [7]. In 2016 and 2017, we did develop BF-TOPSIS methods [3], [8] based on Belief Functions (BF) to improve the original TOPSIS approach to avoid data normalization and to deal also with imprecise score values as well. It appears however that the complexity of these new BF-TOPSIS methods can become a bottleneck for their use in large MCDM problems because of the fusion step of basic belief assignments required for the implementation of the BF-TOPSIS. That is why a simplification of the MCDM problem (if possible) is very welcome in order to save computational time and resources. This is the motivation of the present work.

For this aim we propose a new Inter-Criteria Analysis (ICrA) based on belief functions for identifying and estimating the possible degree of agreement (i.e. redundancy) between some criteria driven from the data (score values). This permits to remove all redundant criteria of the original MCDM problem and thus solving a simplified (almost) equivalent MCDM problem faster and at lower computational cost. ICrA has been developed originally by Atanassov et al. [9]–[11] based on Intuitionistic Fuzzy Sets [12], and it has been applied in different fields like medicine [13]–[15], optimization [16]–[20], workforce planning [21], competitiveness analysis [22], radar detection [23], ranking [24]–[27], etc. In this paper we improve ICrA approach thanks to belief functions introduced by Shafer in [28] from original Dempster's works [29]. We will refer it as BF-ICrA method in the sequel.

After a short presentation of basics of belief functions in section II, we present Atanassov's ICrA method in section III and discuss its limitations. In Section IV we present the new BF-ICrA approach based on a new construction of Basic Belief Assignment (BBA) matrix from the score matrix and a new establishment of Inter-Criteria belief matrix. In section

<sup>2</sup>Analytic Hierarchy Process

<sup>3</sup>ELimination Et Choix Taduisant la REalité

<sup>4</sup>Technique for Order Preference by Similarity to Ideal Solution

<sup>1</sup>because it suffices to multiply the scores values by  $-1$  to reverse the preference ordering.

V a method of simplification of MCDM using BF-ICrA is proposed. Two distinct applications of BF-ICrA are presented in VI with concluding remarks in Section VII.

## II. BASICS OF THE THEORY OF BELIEF FUNCTIONS

To follow classical notations of the theory of belief functions, also called Dempster-Shafer Theory (DST) [28], we assume that the answer (i.e. the solution, or the decision to take) of the problem under concern belongs to a known finite discrete frame of discernment (FoD)  $\Theta = \{\theta_1, \theta_2, \dots, \theta_n\}$ , with  $n > 1$ , and where all elements of  $\Theta$  are exclusive. The set of all subsets of  $\Theta$  (including empty set  $\emptyset$  and  $\Theta$ ) is the power-set of  $\Theta$  denoted by  $2^\Theta$ . A BBA (or mass function) associated with a given source of evidence is defined [28] as the mapping  $m(\cdot) : 2^\Theta \rightarrow [0, 1]$  satisfying  $m(\emptyset) = 0$  and  $\sum_{A \in 2^\Theta} m(A) = 1$ . The quantity  $m(A)$  is called the mass of  $A$  committed by the source of evidence. Belief and plausibility functions are usually interpreted respectively as lower and upper bounds of unknown (possibly subjective) probability measure [29]. They are defined by<sup>5</sup>

$$\text{Bel}(A) \triangleq \sum_{B \subseteq A, B \in 2^\Theta} m(B), \quad \text{and} \quad \text{Pl}(A) \triangleq 1 - \text{Bel}(\bar{A}). \quad (1)$$

If  $m(A) > 0$ ,  $A$  is called a focal element of  $m(\cdot)$ . When all focal elements are singletons then  $m(\cdot)$  is called a *Bayesian BBA* [28] and its corresponding  $\text{Bel}(\cdot)$  function is homogeneous to a probability measure. The vacuous BBA, or VBBA for short, representing a totally ignorant source is defined as  $m_v(\Theta) = 1$ . The main challenge of the decision-maker consists to combine efficiently the possible multiple BBAs  $m_s(\cdot)$  given by  $s > 1$  distinct sources of evidence to obtain a global (combined) BBA, and to make a final decision from it. Historically the combination of BBAs is accomplished by Dempster's rule proposed by Shafer in DST. Because Dempster's rule presents several serious problems (insensitivity to the level of conflict between sources in some cases, inconsistency with bounds of conditional probabilities when used for belief conditioning, dictatorial behavior, counter-intuitive results), many fusion rules have been proposed in the literature as alternative to Dempster's rule, see [30], Vol. 2 for a detailed list of fusion rules. We will not detail here all the possible combination rules but just mention that the Proportional Conflict Redistribution rule no. 6 (PCR6) proposed by Martin and Osswald in [30] (Vol. 3) is one of the most serious alternative rule for BBA combination available so far.

## III. ATANASSOV'S INTER-CRITERIA ANALYSIS (ICrA)

Atanassov's Inter-Criteria Analysis (ICrA) approach is based on a  $M \times N$  score matrix<sup>6</sup>  $\mathbf{S} \triangleq [S_{ij} = C_j(A_i), i = 1, \dots, M, j = 1, \dots, N]$ , and intuitionistic fuzzy pairs [12] including two membership functions  $\mu(\cdot)$  and  $\nu(\cdot)$ . Mathematically, an intuitionistic fuzzy set (IFS)  $A$  is denoted by  $A \triangleq \{(x, \mu_A(x), \nu_A(x)) | x \in E\}$ , where  $E$  is the set of possible values of  $x$ ,  $\mu_A(x) \in [0, 1]$  defines the membership of

$x$  to the set  $A$ , and  $\nu_A(x) \in [0, 1]$  defines the non-membership of  $x$  to the set  $A$ , with the restriction  $0 \leq \mu_A(x) + \nu_A(x) \leq 1$ . The ICrA method consists to build an  $N \times N$  Inter-Criteria (IC) matrix from the score matrix  $\mathbf{S}$ . The elements of the IC matrix consist of all intuitionistic fuzzy pairs  $(\mu_{jj'}, \nu_{jj'})$  whose components express respectively the degree of agreement and the degree of disagreement between criteria  $C_j$  and  $C_{j'}$  for  $j, j' \in \{1, 2, \dots, N\}$ . For a given column  $j$  (i.e. criterion  $C_j$ ), it is always possible to compare with  $>$ ,  $<$  and  $=$  operators all the scores  $S_{ij}$  for  $i = 1, 2, \dots, M$  because the scores of each column are expressed in same unit. The construction of IC matrix can be used to search relations between the criteria because the method compares homogeneous data relatively to a same column. In [32] Atanassov prescribes to normalize the score matrix before applying ICrA as follows

$$S_{ij}^{\text{norm}} = (S_{ij} - S_j^{\text{min}}) / (S_j^{\text{max}} - S_j^{\text{min}}), \quad (2)$$

if one wants to apply it in the dual manner for the search of InterObjects analysis (IOBa).

Because we focus on ICrA only, we don't need to apply a score matrix normalization because each column of the score matrix represents the values of a same criterion for different alternatives, and the criterion values are expressed with the same unit (e.g.  $m$ ,  $m^2$ ,  $\text{sec}$ ,  $Kg$ , or  $\text{€}$ , etc).

### A. Construction of Inter-Criteria matrix

The construction of the  $N \times N$  IC matrix, denoted<sup>7</sup>  $\mathbf{K}$ , is based on the pairwise comparisons between every two criteria along all evaluated alternatives. Let  $K_{jj'}^\mu$  be the number of cases in which the inequalities  $S_{ij} > S_{i'j}$  and  $S_{ij'} > S_{i'j'}$  hold simultaneously, and let  $K_{jj'}^\nu$  be the number of cases in which the inequalities  $S_{ij} > S_{i'j}$  and  $S_{ij'} < S_{i'j'}$  hold simultaneously. Because the total number of comparisons between the alternatives is  $M(M-1)/2$  then one always has necessarily

$$0 \leq K_{jj'}^\mu + K_{jj'}^\nu \leq \frac{M(M-1)}{2}, \quad (3)$$

or equivalently after the division by  $\frac{M(M-1)}{2} > 0$

$$0 \leq \frac{2K_{jj'}^\mu}{M(M-1)} + \frac{2K_{jj'}^\nu}{M(M-1)} \leq 1. \quad (4)$$

This inequality permits to define the elements of  $N \times N$  IC matrix  $\mathbf{K} = [K_{jj'}]$  as intuitionistic fuzzy (IF) pairs  $K_{jj'} = (\mu_{jj'}, \nu_{jj'})$  where

$$\mu_{jj'} \triangleq \frac{2K_{jj'}^\mu}{M(M-1)}, \quad \text{and} \quad \nu_{jj'} \triangleq \frac{2K_{jj'}^\nu}{M(M-1)}. \quad (5)$$

$\mu_{jj'}$  measures the degree of agreement between criteria  $C_j$  and  $C_{j'}$ , and  $\nu_{jj'}$  measures their degree of disagreement. By construction the IC matrix  $\mathbf{K}$  is always a symmetric matrix.

<sup>5</sup>where the symbol  $\triangleq$  means *equal by definition*.

<sup>6</sup>called index matrix by Atanassov in [31].

<sup>7</sup>We use  $\mathbf{K}$  because it corresponds to the first letter of word Kriterium, meaning criteria in German. The letter  $C$  is being already in use.

The computation of  $K_{jj'}^\mu$  and  $K_{jj'}^\nu$  can be done explicitly thanks to Atanassov's formulas [32]

$$K_{jj'}^\mu = \sum_{i=1}^{M-1} \sum_{i'=i+1}^M [\text{sgn}(S_{ij} - S_{i'j})\text{sgn}(S_{ij'} - S_{i'j'}) + \text{sgn}(S_{i'j} - S_{ij})\text{sgn}(S_{i'j'} - S_{ij'})], \quad (6)$$

and

$$K_{jj'}^\nu = \sum_{i=1}^{M-1} \sum_{i'=i+1}^M [\text{sgn}(S_{ij} - S_{i'j})\text{sgn}(S_{i'j'} - S_{ij'}) + \text{sgn}(S_{i'j} - S_{ij})\text{sgn}(S_{ij'} - S_{i'j'})], \quad (7)$$

where the signum function  $\text{sgn}(\cdot)$  used by Atanassov is defined as follows

$$\text{sgn}(x) = \begin{cases} 1, & \text{if } x > 0, \\ 0, & \text{if } x \leq 0. \end{cases} \quad (8)$$

Actually the values of  $K_{jj'}^\mu$  and  $K_{jj'}^\nu$  depend on the choice of  $\text{sgn}(x)$  function<sup>8</sup>. That is why in [21], [33], the authors propose different algorithms implemented under Java in an ICRA software yielding different  $K_{jj'}^\mu$  and  $K_{jj'}^\nu$  values for making the analysis and to reduce the dimension (complexity) of the original MCDM problem.

### B. Inter-criteria analysis

Once the Inter-Criteria matrix  $\mathbf{K} = [K_{jj'}]$  of intuitionistic fuzzy pairs is calculated one needs to analyze it to decide which criteria  $C_j$  and  $C_{j'}$  are in strong agreement (or positive consonance) reflecting the correlation between  $C_j$  and  $C_{j'}$ , in strong disagreement (or negative consonance) reflecting non correlation between  $C_j$  and  $C_{j'}$ , or in dissonance reflecting the uncertainty situation where nothing can be said about the non correlation or the correlation between  $C_j$  and  $C_{j'}$ . If one wants to identify the set of criteria  $C_{j'}$  for  $j' \neq j$  that are strongly correlated with  $C_j$  then we can sort  $\mu_{jj'}$  values in descending order to identify those in strong positive consonance with  $C_j$ . In [25], [26], the authors propose a qualitative scale to refine the levels of consonance and dissonance and for helping the decision making procedure. A dual approach based on  $\nu_{jj'}$  values can be made to determine the set of criteria that are not correlated with  $C_j$ . An other approach [10], [27] proposes to define two thresholds  $\alpha, \beta \in [0; 1]$  for the positive and negative consonance respectively against which the components  $\mu_{jj'}$  and  $\nu_{jj'}$  of  $K_{jj'} = (\mu_{jj'}, \nu_{jj'})$  will be compared. The correlations between the criteria  $C_j$  and  $C_{j'}$  are called "positive consonance", "negative consonance" or "dissonance" depending on their  $\mu_{jj'}$  and  $\nu_{jj'}$  values with respect to chosen thresholds  $\alpha$  and  $\beta$ , see [22] for details. More precisely,  $C_j$  and  $C_{j'}$  are in

- $(\alpha, \beta)$  positive consonance (i.e. correlated):  
If  $\mu_{jj'} > \alpha$  and  $\nu_{jj'} < \beta$ .
- $(\alpha, \beta)$  negative consonance (i.e. no correlated):

<sup>8</sup>for instance if we use  $\text{sgn}(x) = 1$  if  $x \geq 0$  and  $\text{sgn}(x) = 0$  if  $x < 0$ , we will obtain, in general, other  $K_{jj'}^\mu$  and  $K_{jj'}^\nu$  values.

If  $\mu_{jj'} < \beta$  and  $\nu_{jj'} > \alpha$ .

- $(\alpha, \beta)$  dissonance (i.e. full uncertainty): Otherwise.

At the beginning of ICRA development it was not very clear how these intuitionistic fuzzy (IF) pairs  $(\mu_{jj'}, \nu_{jj'})$  had to be used and that is why Atanassova [34], [35] proposed to handle both components of the IF pair. For this, she interpreted pairs  $(\mu_{jj'}, \nu_{jj'})$  as points located in the elementary  $TFU$  triangle, where the point  $T$  of coordinate  $(1, 0)$  represents the maximal positive consonance (i.e. the true consonance), the point  $F$  with coordinate  $(0, 1)$  represents the maximal negative consonance (i.e. the falsity), and the point  $U$  with coordinates  $(0, 0)$  represents the maximal dissonance (i.e. the uncertainty). From this interpretation it becomes easy to identify the top of consonant IF pairs  $(\mu_{jj'}, \nu_{jj'})$  that fall in bottom right corner of  $(TFU)$  triangle limited by vertical line from  $x$ -axis  $x = \alpha$ , and horizontal line from  $y$ -axis  $y = \beta$ . The set of consonant IF pairs are then ranked according to their Euclidean distance  $d_{C_j C_{j'}}^T$  with respect to  $T$  point of coordinate  $(1, 0)$  defined by

$$d_{C_j C_{j'}}^T = d((1, 0), (\mu_{jj'}, \nu_{jj'})) = \sqrt{(1 - \mu_{jj'})^2 + \nu_{jj'}^2}. \quad (9)$$

In the MCDM context only the criteria that are negatively consonant (or uncorrelated) must be kept for solving MCDM and saving computational resources because they have no (or only very low) dependency with each other, so that each uncorrelated criterion provides useful information. The set of criteria that are positively consonant (if any), called the consonant set, indicates somehow a redundancy of information between the criteria belonging to it in term of decisional behavior. Therefore all these positively consonant criteria must be represented by only one representative criterion that will be kept in the MCDM analysis to simplify MCDM problem. Also all the criteria that are deemed strongly dissonant (if any) could be taken out of the original MCDM problem because they only introduce uncertainty in the decision-making.

### C. General comments on ICRA

Although appealing at the first glance, the classical ICRA approach induces the following comments:

- 1) The IF values  $\mu_{jj'}$  and  $\nu_{jj'}$  can be easily interpreted in the belief function framework. Indeed, the belief and plausibility of (positive) consonance between criteria  $C_j$  and  $C_{j'}$  can be directly linked to the values  $\mu_{jj'}$  and  $\nu_{jj'}$  by taking  $Bel_{jj'}(\theta) = \mu_{jj'}$  and  $Pl_{jj'}(\theta) = 1 - \nu_{jj'}$ . Moreover  $U_{jj'}(\theta) = Pl_{jj'}(\theta) - Bel_{jj'}(\theta) = 1 - \nu_{jj'} - \mu_{jj'}$  represents the dissonance (the uncertainty about the correlation) of the criteria  $C_j$  and  $C_{j'}$ . Here the proposition  $\theta$  means: the criteria  $C_j$  and  $C_{j'}$  are totally positively consonant (i.e. totally correlated) and the frame of discernment is defined as  $\Theta \triangleq \{\theta, \bar{\theta}\}$ , where  $\bar{\theta}$  means: the criteria  $C_j$  and  $C_{j'}$  are totally negatively

consonant (uncorrelated). From this, one can define any BBA  $m_{jj'}(\theta)$ ,  $m_{jj'}(\bar{\theta})$  and  $m_{jj'}(\theta \cup \bar{\theta})$  of  $2^\Theta$  by

$$m_{jj'}(\theta) = \mu_{jj'}, \quad (10)$$

$$m_{jj'}(\bar{\theta}) = \nu_{jj'}, \quad (11)$$

$$m_{jj'}(\theta \cup \bar{\theta}) = 1 - \mu_{jj'} - \nu_{jj'}. \quad (12)$$

- 2) The construction of  $\mu_{jj'}$  and  $\nu_{jj'}$  proposed in the classical ICRA is disputable because it is only based on counting the valid “>” or “<” inequalities but it does not exploit how bigger and how smaller the scores values are in each comparison done in the construction of the Inter-Criteria Matrix  $\mathbf{K}$ . Therefore the construction of  $\mu_{jj'}$  and  $\nu_{jj'}$  is actually only a very crude method to estimate IF pairs.
- 3) The construction of the Inter-Criteria Matrix  $\mathbf{K}$  is in fact not unique as reported in [33]. This will yield different results in general.
- 4) The exploitation of the ICRA method depends on the choice of  $\alpha$  and  $\beta$  thresholds that will impact the final result.
- 5) The classical ICRA method cannot deal directly with imprecise or missing score values.

#### IV. A NEW ICRA METHOD BASED ON BELIEF FUNCTIONS

We present in this section a new ICRA method, called BF-ICRA for short, based on belief functions that circumvents most of the aforementioned drawbacks of classical ICRA. Here we show how to get more precisely the Inter-Criteria Belief Matrix and how to exploit it for MCDM simplification.

##### A. Construction of BBA matrix from the score matrix

From any non-zero score matrix  $\mathbf{S} = [S_{ij}]$ , we can construct the  $M \times N$  BBA matrix  $\mathbf{M} = [m_{ij}(\cdot)]$  as follows

$$m_{ij}(A_i) = Bel_{ij}(A_i), \quad (13)$$

$$m_{ij}(\bar{A}_i) = Bel_{ij}(\bar{A}_i) = 1 - Pl_{ij}(A_i), \quad (14)$$

$$m_{ij}(A_i \cup \bar{A}_i) = Pl_{ij}(A_i) - Bel_{ij}(A_i). \quad (15)$$

Assuming  $A_{\max}^j \neq 0$  and  $A_{\min}^j \neq 0$ , we take<sup>9</sup>

$$Bel_{ij}(A_i) \triangleq Sup_j(A_i)/A_{\max}^j, \quad (16)$$

$$Bel_{ij}(\bar{A}_i) \triangleq Inf_j(A_i)/A_{\min}^j, \quad (17)$$

where  $A_{\max}^j \triangleq \max_i Sup_j(A_i)$  and  $A_{\min}^j \triangleq \min_i Inf_j(A_i)$  and with

$$Sup_j(A_i) \triangleq \sum_{k \in \{1, \dots, M\} | S_{kj} \leq S_{ij}} |S_{ij} - S_{kj}|, \quad (18)$$

$$Inf_j(A_i) \triangleq - \sum_{k \in \{1, \dots, M\} | S_{kj} \geq S_{ij}} |S_{ij} - S_{kj}|. \quad (19)$$

The entire justification of these formulas can be found in our previous works [3]. For another criterion  $C_{j'}$  and the  $j'$ -th column of the score matrix we will obtain another set of BBA values  $m_{ij'}(\cdot)$ . Applying this method for each column

of the score matrix we are able to compute the BBA matrix  $\mathbf{M} = [m_{ij}(\cdot)]$  whose each component is in fact a triplet  $(m_{ij}(A_i), m_{ij}(\bar{A}_i), m_{ij}(A_i \cup \bar{A}_i))$  of BBA values in  $[0, 1]$  such that  $m_{ij}(A_i) + m_{ij}(\bar{A}_i) + m_{ij}(A_i \cup \bar{A}_i) = 1$  for all  $i = 1, \dots, M$  and  $j = 1, \dots, N$ .

##### B. Construction of Inter-Criteria Matrix from BBA matrix

The next step of BF-ICRA approach is the construction of the  $N \times N$  Inter-Criteria Matrix  $\mathbf{K} = [K_{jj'}]$  from  $M \times N$  BBA matrix  $\mathbf{M} = [m_{ij}(\cdot)]$  where elements  $K_{jj'}$  corresponds to the BBA  $(m_{jj'}(\theta), m_{jj'}(\bar{\theta}), m_{jj'}(\theta \cup \bar{\theta}))$  about positive consonance  $\theta$ , negative consonance  $\bar{\theta}$  and uncertainty between criteria  $C_j$  and  $C_{j'}$  respectively. The principle of construction of the triplet  $K_{jj'} = (m_{jj'}(\theta), m_{jj'}(\bar{\theta}), m_{jj'}(\theta \cup \bar{\theta}))$  is based on two steps that will be detailed in the sequel:

- Step 1: For each alternative  $A_i$ , we first compute the BBA  $(m_{jj'}^i(\theta), m_{jj'}^i(\bar{\theta}), m_{jj'}^i(\theta \cup \bar{\theta}))$  for any two criteria  $j, j' \in \{1, 2, \dots, N\}$ .
- Step 2: The BBA  $(m_{jj'}(\theta), m_{jj'}(\bar{\theta}), m_{jj'}(\theta \cup \bar{\theta}))$  is then obtained by the combinations of the  $M$  BBA  $m_{jj'}^i(\cdot)$ .

We present the details of each step of BF-ICRA method.

##### Step 1: Construction of BBA $m_{jj'}^i(\cdot)$

The mass of belief  $m_{jj'}^i(\theta)$  represents the degree of agreement between the BBA  $m_{ij}(\cdot)$  and  $m_{ij'}(\cdot)$  for the alternative  $A_i$ , and  $m_{jj'}^i(\bar{\theta})$  represents the degree of disagreement between  $m_{ij}(\cdot)$  and  $m_{ij'}(\cdot)$ . The mass  $m_{jj'}^i(\theta \cup \bar{\theta})$  is the degree of uncertainty about the agreement (or disagreement) between  $m_{ij}(\cdot)$  and  $m_{ij'}(\cdot)$  for the alternative  $A_i$ . The calculation of  $m_{jj'}^i(\theta)$  could be envisaged in several manners.

The first manner would consist to consider the degree of conflict [28]  $k_{jj'}^i \triangleq \sum_{X, Y \in \Theta | X \cap Y = \emptyset} m_{ij}(X) m_{ij'}(Y)$  and consider the Bayesian BBA  $m_{jj'}^i(\theta) = 1 - k_{jj'}^i$ ,  $m_{jj'}^i(\bar{\theta}) = k_{jj'}^i$  and  $m_{jj'}^i(\theta \cup \bar{\theta}) = 0$ . Instead of using Shafer's conflict, the second manner would consist to use a normalized distance  $d_{jj'}^i = d(m_{ij}, m_{ij'})$  to measure the closeness between  $m_{ij}(\cdot)$  and  $m_{ij'}(\cdot)$ , and then consider the Bayesian BBA modeling defined by  $m_{jj'}^i(\theta) = 1 - d_{jj'}^i$ ,  $m_{jj'}^i(\bar{\theta}) = d_{jj'}^i$  and  $m_{jj'}^i(\theta \cup \bar{\theta}) = 0$ . These two manners however are not very satisfying because they always set to zero the degree of uncertainty between the agreement and disagreement of the BBA, and the second manner depends also on the choice of the distance metric. So, we propose a more appealing third manner of the BBA modeling of  $m_{jj'}^i(\theta)$ ,  $m_{jj'}^i(\bar{\theta})$ , and  $m_{jj'}^i(\theta \cup \bar{\theta})$ . For this, we consider two sources of evidences (SoE) indexed by  $j$  and  $j'$  providing the BBA  $m_{ij}$  and  $m_{ij'}$  defined on the simple FoD  $\{A_i, \bar{A}_i\}$  and denoted  $m_{ij} = [m_{ij}(A_i), m_{ij}(\bar{A}_i), m_{ij}(A_i \cup \bar{A}_i)]$  and  $m_{ij'} = [m_{ij'}(A_i), m_{ij'}(\bar{A}_i), m_{ij'}(A_i \cup \bar{A}_i)]$ . We also denote  $\Theta = \{\theta, \bar{\theta}\}$  the FoD about the relative state of the two SoE, where  $\theta$  means that the two SoE agree,  $\bar{\theta}$  means that they disagree and  $\theta \cup \bar{\theta}$  means that we don't know. Then the BBA modeling is based on the important remarks

- Two SoE are in total agreement if both commit their maximum belief mass to the element  $A_i$  or to element

<sup>9</sup>If  $A_{\max}^j = 0$  then  $Bel_{ij}(A_i) = 0$ , and if  $A_{\min}^j = 0$  then  $Pl_{ij}(A_i) = 1$ .

$\bar{A}_i$ . So they perfectly agree if  $m_{ij}(A_i) = m_{ij'}(A_i) = 1$ , or if  $m_{ij}(\bar{A}_i) = m_{ij'}(\bar{A}_i) = 1$ . Therefore the pure degree of agreement<sup>10</sup> between two sources is modeled by

$$m_{jj'}^i(\theta) = m_{ij}(A_i)m_{ij'}(A_i) + m_{ij}(\bar{A}_i)m_{ij'}(\bar{A}_i). \quad (20)$$

- Two SoE are in total disagreement if each one commits its maximum mass of belief to one element and the other to its opposite, that is if one has  $m_{ij}(A_i) = 1$  and  $m_{ij'}(\bar{A}_i) = 1$ , or if  $m_{ij}(\bar{A}_i) = 1$  and  $m_{ij'}(A_i) = 1$ . Hence the pure degree of disagreement<sup>11</sup> between two sources is modeled by

$$m_{jj'}^i(\bar{\theta}) = m_{ij}(A_i)m_{ij'}(\bar{A}_i) + m_{ij}(\bar{A}_i)m_{ij'}(A_i). \quad (21)$$

- All possible remaining products between components of  $m_{ij}$  and  $m_{ij'}$  reflect the part of uncertainty we have about the SoE (i.e. we don't know if they agree or disagree). Hence the degree of uncertainty between the two sources is modeled by

$$\begin{aligned} m_{jj'}^i(\theta \cup \bar{\theta}) &= m_{ij}(A_i)m_{ij'}(A_i \cup \bar{A}_i) \\ &\quad + m_{ij}(\bar{A}_i)m_{ij'}(A_i \cup \bar{A}_i) \\ &\quad + m_{ij}(A_i \cup \bar{A}_i)m_{ij'}(A_i) \\ &\quad + m_{ij}(A_i \cup \bar{A}_i)m_{ij'}(\bar{A}_i) \\ &\quad + m_{ij}(A_i \cup \bar{A}_i)m_{ij'}(A_i \cup \bar{A}_i). \end{aligned} \quad (22)$$

By construction  $m_{jj'}^i(\cdot) = m_{ij'}^i(\cdot)$ , hence this BBA modeling permits to build a set of  $M$  symmetrical Inter-Criteria Belief Matrices (ICBM)  $\mathbf{K}^i = [K_{jj'}^i]$  of dimension  $N \times N$  relative to each alternative  $A_i$  whose components  $K_{jj'}^i$  correspond to the triplet of BBA values  $m_{jj'}^i = (m_{jj'}^i(\theta), m_{jj'}^i(\bar{\theta}), m_{jj'}^i(\theta \cup \bar{\theta}))$  modeling the belief of agreement and of disagreement between  $C_j$  and  $C_{j'}$  based on  $A_i$ . One has also<sup>12</sup>  $m_{jj'}^i(\theta), m_{jj'}^i(\bar{\theta}), m_{jj'}^i(\theta \cup \bar{\theta}) \in [0, 1]$  and  $m_{jj'}^i(\theta) + m_{jj'}^i(\bar{\theta}) + m_{jj'}^i(\theta \cup \bar{\theta}) = 1$ . This BBA construction can be easily extended for modeling the agreement, disagreement and uncertainty of  $n > 2$  criteria  $C_{j_1}, \dots, C_{j_n}$  altogether if needed by taking

$$\begin{aligned} m_{j_1 \dots j_n}^i(\theta) &= \prod_{k=1}^n m_{ij_k}(A_i) + \prod_{k=1}^n m_{ij_k}(\bar{A}_i), \\ m_{j_1 \dots j_n}^i(\bar{\theta}) &= \sum_{\substack{X_{j_1}, \dots, X_{j_n} \in \{A_i, \bar{A}_i\} \\ X_{j_1} \cap \dots \cap X_{j_n} = \emptyset}} \prod_{k=1}^n m_{ij_k}(X_{j_k}), \\ m_{j_1 \dots j_n}^i(\theta \cup \bar{\theta}) &= 1 - m_{j_1 \dots j_n}^i(\theta) - m_{j_1 \dots j_n}^i(\bar{\theta}). \end{aligned}$$

## Step 2: Construction of BBA $m_{jj'}(\cdot)$ (fusion step)

Once all the BBAs  $m_{jj'}^i(\cdot)$  ( $i = 1, \dots, M$ ) are calculated one combines them to get the component  $K_{jj'} = (m_{jj'}(\theta), m_{jj'}(\bar{\theta}), m_{jj'}(\theta \cup \bar{\theta}))$  of the Inter-Criteria Belief matrix (ICBM)  $\mathbf{K} = [K_{jj'}]$ . This fusion step can be done in many ways depending on the combination rule chosen by the user. If the number of alternatives  $M$  is not too large we recommend

<sup>10</sup>or positive consonance according Atanassov's terminology.

<sup>11</sup>or negative consonance according Atanassov's terminology.

<sup>12</sup>because  $(m_{ij}(A_i) + m_{ij}(\bar{A}_i) + m_{ij}(A_i \cup \bar{A}_i))(m_{ij'}(A_i) + m_{ij'}(\bar{A}_i) + m_{ij'}(A_i \cup \bar{A}_i)) = 1 \cdot 1 = 1$ .

to combine the BBAs  $m_{jj'}^i(\cdot)$  with PCR6 fusion rule [30] (Vol. 3) because of known deficiencies of Dempster's rule. If  $M$  is too large to prevent PCR6 working on computer, we can just use the simple averaging rule of combination in these high dimensional MCDM problems. Simple Matlab™ code for PCR6 rule can be found in [42] for convenience.

The computational complexity of BF-ICrA is of course higher than the complexity of ICrA because it makes a more precise evaluation of local and global inter-criteria belief matrices with respect to Intuitionistic Fuzzy inter-criteria matrices of ICrA. The overall reduction of the computational burden of the original MCDM problem thanks to BF-ICrA depends highly on the problem under concern, the complexity and cost to evaluate each criteria involved in it, as well as the number of redundant criteria identified by BF-ICrA method.

## V. SIMPLIFICATION OF ORIGINAL MCDM THANKS TO BF-ICrA

Once the global Inter-Criteria Belief Matrix  $\mathbf{K} = [K_{jj'} = (m_{jj'}(\theta), m_{jj'}(\bar{\theta}), m_{jj'}(\theta \cup \bar{\theta}))]$  is calculated, we need to identify and cluster the criteria that are in strong agreement, in strong disagreement, and those on which we are uncertain. For identifying the criteria that are in very strong agreement, we evaluate the distance of each component of  $K_{jj'}$  with the BBA representing the best agreement state and characterized by the specific BBA<sup>13</sup>  $m_T(\theta) = 1$ . From a similar approach we can also identify, if we want, the criteria that are in very strong disagreement using the distance of  $m_{jj'}(\cdot)$  with respect to the BBA representing the best disagreement state characterized by the specific BBA  $m_F(\bar{\theta}) = 1$ . As alternative of Jousselme's distance [37], we use the  $d_{BI}(\cdot, \cdot)$  distance based on belief interval [36] because it is a good method for measuring the distance  $d(m_1, m_2)$  between the two BBAs<sup>14</sup>  $m_1(\cdot)$  and  $m_2(\cdot)$  over the same FoD. It is defined by

$$d_{BI}(m_1, m_2) \triangleq \sqrt{N_c \cdot \sum_{X \in 2^\Theta} d_W^2(BI_1(X), BI_2(X))}, \quad (23)$$

where the *Belief-Intervals* are defined by  $BI_1(X) \triangleq [Bel_1(X), Pl_1(X)]$  and  $BI_2(X) \triangleq [Bel_2(X), Pl_2(X)]$  and computed from  $m_1(\cdot)$  and  $m_2(\cdot)$  thanks to formula (1).  $d_W(BI_1(X), BI_2(X))$  is Wassertein's distance between intervals calculated by

$$\begin{aligned} d_W([a_1, b_1], [a_2, b_2]) &= \\ &= \sqrt{\left[ \frac{a_1 + b_1}{2} - \frac{a_2 + b_2}{2} \right]^2 + \frac{1}{3} \left[ \frac{b_1 - a_1}{2} - \frac{b_2 - a_2}{2} \right]^2}, \end{aligned} \quad (24)$$

and  $N_c = 1/2^{|\Theta|-1}$  is a factor to get  $d_{BI}(m_1, m_2) \in [0, 1]$ .

Because all criteria that are in strong agreement somehow contain redundant (correlated) information and behave similarly from decision-making standpoint, we propose to simplify

<sup>13</sup>We use the index  $T$  in the notation  $m_T(\cdot)$  to refer that the agreement is true, and  $F$  in  $m_F(\cdot)$  to specify that the agreement is false.

<sup>14</sup>Here  $m_1(\cdot) = m_{jj'}(\cdot)$ , and  $m_2(\cdot) = m_T(\cdot)$  or  $m_2(\cdot) = m_F(\cdot)$ .

the original MCDM problem by keeping in the MCDM only criteria that are non redundant. The remaining criteria can be eventually weighted by their degree of importance reflecting the number of different criteria that are in agreement through this BF-ICrA approach.

For instance, if one has a seven criteria MCDM problem and if criteria  $C_1$ ,  $C_2$  and  $C_3$  are in strong agreement we will only select one remaining criterion among  $\{C_1, C_2, C_3\}$  and we give it a weight of  $w_1 + w_2 + w_3$ . Moreover if  $C_4$  and  $C_5$  are in strong agreement also we will only select one remaining criterion among  $\{C_4, C_5\}$  and we give it a weight of  $w_4 + w_5$ , and we will use the weight  $w_6$  for  $C_6$ , and  $w_7$  for  $C_7$ . Hence the original MCDM problem will reduce to a four simplified MCDM problem that can be solved using BF-TOPSIS method already presented in details in [3] and in [8], or with AHP [4] if one prefers, or with any other chosen method that the system-designer may prefer.

The strategy for selecting the most representative criterion among a set of redundant criteria is not unique and depends mainly on the cost necessary (i.e. human efforts, data mining, computational resources, etc) for getting the values of the score matrix of the problem under concern. The least costly criteria may be a good option of selection.

In [38], we provided simple detailed examples for BF-ICrA where we selected the representative criterion as being the one with smallest index. So in the aforementioned example the simplified MCDM problem will reduce to a  $M \times 4$  MCDM problem involving only four criteria  $C_1$ ,  $C_4$ ,  $C_6$  and  $C_7$ .

The BF-ICrA method proposed in this work allows also, in principle, to make a refined analysis (if necessary) based on IC matrices  $K_{jj}^i$ , about the origin of disagreement between criteria with respect to each alternative  $A_i$  in order to identify the potential inconsistencies in original MCDM problem. This aspect is not developed in this paper and has been left for future investigations. It is worth mentioning that the analysis of the number of redundant criteria versus time improvements that could be proposed as an effective measure of performance of this approach depends highly of the application under consideration and the difficulty (and cost) to get the value of each criteria.

## VI. TWO APPLICATIONS OF BF-ICrA

In this section we present two applications of the BF-ICrA approach. The first one is for Global Positioning System (GPS) Surveying Problems (GSP) presented in [39], and the second one is for the car selection problem.

### A. Application of BF-ICrA for the GPS surveying problem

GPS surveying is an NP-hard problem. For designing Global Positioning System surveying network, a given set of earth points must be observed consecutively. The survey cost is the sum of the distances to go from one point to another one. This kind of problems is hard to be solved with traditional numerical methods. Here we use BF-ICrA to analyze an Ant Colony Optimization (ACO) algorithm developed to provide

near-optimal solutions for Global Positioning System surveying problem.

GPS satellites continuously transmit radio signals to the Earth while orbiting it. A receiver, with unknown position on Earth, has to detect and convert the signals received from all of the satellites into useful measurements. These measurements would allow a user to compute a three-dimensional coordinate position: location of the receiver. Any GPS observation is proven to have biases, hence, in order to survey an appropriate combination of measurement processing strategies must be used to minimize their effect on the positioning results. Differencing data collected simultaneously from two or more GPS receivers to several GPS satellites allows to eliminate or significantly reduce most of the biases. The GPS network can be defined as set of stations  $(a_1, a_2, \dots, a_n)$ , which are co-ordinated by placing receivers  $(X1, X2, \dots)$  on them to determine sessions  $(a_1a_2, a_1a_3, a_2a_3, \dots)$  among them. The problem is to search for the best order in which these sessions can be organized to give the best schedule. Thus, the schedule can be defined as a sequence of sessions to be observed consecutively. The solution is represented by linear graph with weighted edges. The nodes represent the stations and the edges represent the moving cost. The objective function of the problem is the cost of the solution which is the sum of the costs (time) to move from one point to another one,  $C(V) = \sum C(a_i, a_j)$ , where  $a_i a_j$  is a session in solution  $V$ . For example if the number of points (stations) is 4, a possible solution is  $V = (a_1, a_3, a_2, a_4)$  and it can be represented by linear graph  $a_1 \rightarrow a_3 \rightarrow a_2 \rightarrow a_4$ . The moving costs are as follows:  $C(a_1, a_3), C(a_3, a_2), C(a_2, a_4)$ . Thus the cost of the solution is  $C(V) = C(a_1, a_3) + C(a_3, a_2) + C(a_2, a_4)$ . In practice, determining how each GPS receiver should be moved between stations to be surveyed in an efficient manner taking into account some important factors such as time, cost etc. The problem is to search for the best order, with respect to the time, in which these sessions can be observed to give the cheapest schedule or to minimize  $C(V)$ . The initial data is a cost matrix, which represents the cost (time, or distance) of moving a receiver from one point to another. Solving such problems - GSPs - to optimality requires a very high computational time. Therefore, meta-heuristic methods are used to provide near-optimal solutions for large networks within acceptable amount of computational effort. In this paper, we consider the Max-Min Ant System (MMAS) meta-heuristic [40] and we present it briefly in the next subsection.

Real ants foraging for food lay down quantities of pheromone (chemical cues) marking the path that they follow. An isolated ant moves essentially at random but an ant encountering a previously laid pheromone will detect it and decide to follow it with high probability and thereby reinforce it with a further quantity of pheromone. The repetition of the above mechanism represents the auto-catalytic behavior of real ant colony where the more the ants follow a trail, the more attractive that trail becomes.

The ACO algorithm uses a colony of artificial ants that behave as cooperative agents in a mathematics space were

they are allowed to search and reinforce pathways (solutions) in order to find the optimal ones. The problem is represented by graph and the ants walk on the graph to construct solutions. The solution is represented by path in the graph. After initialization of the pheromone trails, ants construct feasible solutions, starting from random nodes, then the pheromone trails are updated. At each step ants compute a set of feasible moves and select the best one (according to some probabilistic rules) to carry out the rest of the tour. The transition probability  $p_{ij}$ , to chose the node  $j$  when the current node is  $i$ , is based on the heuristic information  $\eta_{ij}$  and pheromone trail level  $\tau_{ij}$  of the move, where  $i, j = 1, \dots, n$ .

$$p_{ij} = \frac{\tau_{ij}^\alpha \eta_{ij}^\beta}{\sum_{k \in U_{\text{unused}}} \tau_{ik}^\alpha \eta_{ik}^\beta}. \quad (25)$$

The higher value of the pheromone and the heuristic information, the more profitable is to select this move and resume the search. In the beginning, the initial pheromone level is set to a small positive constant value  $\tau_0$  and then ants update this value after completing the construction stage. ACO algorithms adopt different criteria to update the pheromone level.

In our implementation we use MAX-MIN Ant System (MMAS) [40], [41], which is ones of the best ant approaches. In MMAS the main is using fixed upper bound  $\tau_{max}$  and lower bound  $\tau_{min}$  of the pheromone trails. Thus accumulation of big amount of pheromone by part of the possible movements and repetition of same solutions is partially prevented. The main features of MMAS are:

The aim of using only one solution is to make solution elements, which frequently occur in the best found solutions, get large reinforcement. Pheromone trail update is given by:

$$\tau_{ij} \leftarrow \rho \tau_{ij} + \Delta \tau_{ij}, \quad (26)$$

where

$$\Delta \tau_{ij} = \begin{cases} 1/C(V_{best}) & \text{if } (i, j) \in \text{best solution,} \\ 0 & \text{otherwise,} \end{cases}$$

and  $V_{best}$  is the iteration best solution and  $i, j = 1, \dots, n$ .

To avoid stagnation of the search, the range of possible pheromone value on each movement is limited to an interval  $[\tau_{min}, \tau_{max}]$ .  $\tau_{max}$  is an asymptotic maximum of  $\tau_{ij}$  and  $\tau_{max} = 1/(1 - \rho)C(V^*)$ , while  $\tau_{min} = 0.087\tau_{max}$ . Where  $V^*$  is the optimal solution, but it is unknown, therefore we use  $V_{best}$  instead of  $V^*$ .

When all ants have completed their solutions, the pheromone level is updated by applying the global update rule. Only the pheromone corresponding to the best found solution is increased by the similar to the MMAS way. The global update rule is intended to provide a greater amount of pheromone on the paths of the best solution. It is a kind of intensification of the search around the best found solution. We use heuristic information equals to one over the cost of the session.

Here, we analyze the experimental results obtained using MMAS algorithm. For this, we use real data from Malta and

Seychelles GPS networks composed of 38 sessions and 71 sessions respectively denoted GSP1 and GSP2. We use also 6 larger test problems range from 100 to 443 sessions denoted GSP3, ..., GSP8. The results are obtained by performing 30 independent runs, for every experiment. The details of our MMAS implementation are given in [43]. So in our GSP example we consider 8 GSP criteria  $C_i = GSP_i, i = 1, \dots, 8$  and six average costs as results  $A_1, \dots, A_6$ , where  $A_1$  is the cost average for the first 5 runs,  $A_2$  the cost average for the first 10 runs,  $A_3$  for the first 15 runs, ... and finally  $C_6$  for all the 30 runs. Table I shows the values of averaged costs obtained for this problem. It corresponds to the transpose of the score matrix  $\mathbf{S}$ .

Hence in this problem  $M = 6$  and  $N = 8$ , and  $\mathbf{S} = [S_{ij}]$  is a  $6 \times 8$  score matrix. Based on classical ICRA approach, one gets the following IC matrices<sup>15</sup>  $\mathbf{K}^\mu$  and  $\mathbf{K}^\nu$  matrices given in (27) and (28).

The element  $K_{jj'}^\mu$  of matrix  $\mathbf{K}^\mu$  expresses the *degree of agreement* between criteria  $C_j = GSP_j$  and  $C_{j'} = GSP_{j'}$ , whereas the element  $K_{jj'}^\nu$  of matrix  $\mathbf{K}^\nu$  expresses the *degree of disagreement* between  $C_j = GSP_j$  and  $C_{j'} = GSP_{j'}$ .

Based on these results, one sees that ACO algorithm performs similarly for  $GSP_2, GSP_4, GSP_5$  and  $GSP_8$  because they are all in high agreement. Indeed  $\mu_{jj'}$  values for  $j, j' \in \{2, 4, 5, 8\}$  are quite high (greater than 70%). They are GPS networks with different numbers of sessions, but may have a similar structure, therefore, the value of agreement is high. For other networks, we can conclude that they have very different structure.

What is worth noting is that there appears also a strong agreement of GSP1 with GSP8 because  $\mu_{18} = 0.87$ . But because GSP8 is also in strong agreement with GSP2, GSP4, GSP5 and with GSP1 it is logically expected that GSP1 should be also in agreement with GSP2, GSP4, GSP5, which is unfortunately not the case based on this classical ICRA. This example points out some inconsistency of ICRA result because of the too crude method of estimation of the degree of agreement and disagreement between criteria based on IFS.

Now if we consider the same example with the same score matrix  $\mathbf{S}$  (built from Table I), we obtain the following IC Belief matrices<sup>16</sup>  $\mathbf{K}(\theta)$  and  $\mathbf{K}(\bar{\theta})$  given by (29) and (30). From ICBM  $\mathbf{K}(\theta)$  and  $\mathbf{K}(\bar{\theta})$  we compute the matrix  $\mathbf{D}(\theta)$  of distance of  $m_{jj'}(\cdot)$  to the full agreement state with BBA  $m_F(\theta) = 1$  based on  $d_{BI}(\cdot)$  distance. We get the following distances to full agreement  $\mathbf{D}(\theta)$  given in (31).

The element  $D_{jj'}$  represents the agreement distance between  $C_j$  and  $C_{j'}$ , the lower the better. From the values of elements of  $\mathbf{D}(\theta)$  matrix one sees clearly that ACO performs similarly for GSP2, GSP4 and GSP5 because distances  $D_{24}$ ,

<sup>15</sup>For presentation convenience and due to typesetting column width, we decompose et present the IC matrix  $\mathbf{K} = [K_{jj'} = (K_{jj'}^\mu, K_{jj'}^\nu)]$  into two distinct matrices  $\mathbf{K}^\mu = [K_{jj'}^\mu]$  and  $\mathbf{K}^\nu = [K_{jj'}^\nu]$ .

<sup>16</sup>For presentation convenience, the ICBM  $\mathbf{K} = [K_{jj'} = (m_{jj'}(\theta), m_{jj'}(\bar{\theta}), m_{jj'}(\theta \cup \bar{\theta}))]$  is decomposed into three matrices  $\mathbf{K}(\theta) = [K_{jj'}^\theta = m_{jj'}(\theta)]$ ,  $\mathbf{K}(\bar{\theta}) = [K_{jj'}^{\bar{\theta}} = m_{jj'}(\bar{\theta})]$  and  $\mathbf{K}(\theta \cup \bar{\theta}) = [K_{jj'}^{\theta \cup \bar{\theta}} = 1 - m_{jj'}(\theta) - m_{jj'}(\bar{\theta})]$ .

	$A_1$	$A_2$	$A_3$	$A_4$	$A_5$	$A_6$
$C_1 = GSP1$	899.00	898.00	898.33	898.50	899.40	899.50
$C_2 = GSP2$	916.40	915.60	922.47	924.80	924.72	922.07
