

## Halting problem undecidability and infinitely nested simulation (V4)

When a halt decider bases its halt status decision on the behavior of its simulated input then all of the conventional halting problem counter example inputs are determined to be non-halting. A halt decider (because it is a decider) must report on the behavior specified by its finite string input. The behavior specified by this input is the actual behavior of this input when it is correctly simulated by its simulating halt decider (SHD) that contains a UTM.

A SHD computes the mapping from its input to its own accept or reject state based on whether or not the pure simulation of its simulated input could reach its own final state in a finite number of simulated steps.

It is self-evidently correct that when-so-ever a simulating halt decider must abort the simulation of its input to prevent the infinite simulation of this input that this input specifies an infinite sequence of configurations.

$H.q_0 \langle M \rangle w \vdash^* H.q_y$  ----- iff  $UTM(\langle M \rangle, w)$  reaches the final state of  $M$

$H.q_0 \langle M \rangle w \vdash^* H.q_n$  ----- iff  $UTM(\langle M \rangle, w)$  would never reach the final state of  $M$

Simulating halt decider  $H$  performs a pure simulation of its input as if it was a UTM unless and until it detects an infinitely repeating pattern. Then it aborts the simulation of its input and transitions to its final reject state. Otherwise  $H$  transitions to its accept state when its simulation ends.

The following simplifies the syntax for the definition of the Linz Turing machine  $\hat{H}$ , it is now a single machine with a single start state. **A copy of Linz  $H$  is embedded at  $\hat{H}.q_x$**

$\hat{H}.q_0 \langle \hat{H} \rangle \vdash^* \hat{H}.q_x \langle \hat{H} \rangle \langle \hat{H} \rangle \vdash^* \hat{H}.q_y \infty$

If the pure simulation of  $\langle \hat{H} \rangle \langle \hat{H} \rangle$  by embedded\_ $H$  would reach its final state.

$\hat{H}.q_0 \langle \hat{H} \rangle \vdash^* \hat{H}.q_x \langle \hat{H} \rangle \langle \hat{H} \rangle \vdash^* \hat{H}.q_n$

If the pure simulation of  $\langle \hat{H} \rangle \langle \hat{H} \rangle$  by embedded\_ $H$  would never reach its final state.

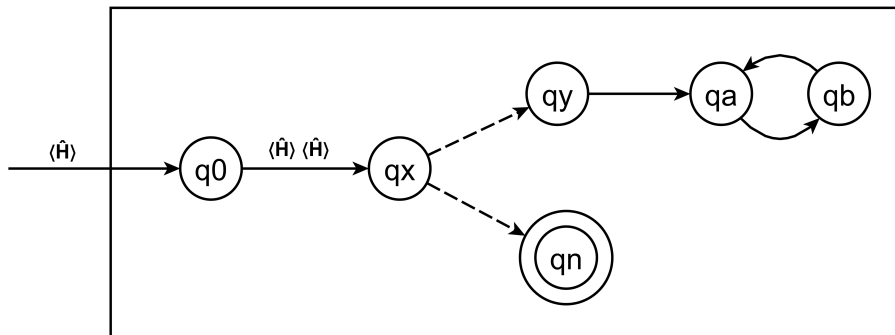

Figure 12.3 Turing Machine  $\hat{H}$  applied to  $\langle \hat{H} \rangle$

## When $\hat{H}$ is applied to $\langle \hat{H} \rangle$

$\hat{H}$  copies its input  $\langle \hat{H}_0 \rangle$  to  $\langle \hat{H}_1 \rangle$  then embedded\_H simulates  $\langle \hat{H}_0 \rangle \langle \hat{H}_1 \rangle$

### Then these steps would keep repeating:

$\hat{H}_0$  copies its input  $\langle \hat{H}_1 \rangle$  to  $\langle \hat{H}_2 \rangle$  then embedded\_H<sub>0</sub> simulates  $\langle \hat{H}_1 \rangle \langle \hat{H}_2 \rangle$

$\hat{H}_1$  copies its input  $\langle \hat{H}_2 \rangle$  to  $\langle \hat{H}_3 \rangle$  then embedded\_H<sub>1</sub> simulates  $\langle \hat{H}_2 \rangle \langle \hat{H}_3 \rangle$

$\hat{H}_2$  copies its input  $\langle \hat{H}_3 \rangle$  to  $\langle \hat{H}_4 \rangle$  then embedded\_H<sub>2</sub> simulates  $\langle \hat{H}_3 \rangle \langle \hat{H}_4 \rangle \dots$

The above shows that the simulated input to embedded\_H never reaches its own final state whether or not its simulation is aborted.

(a) If the simulation is not aborted the above sequence never ends.

(b) If the simulation is aborted the entire chain of recursive simulations immediately stops.

In no case does the simulated input  $\langle \hat{H} \rangle \langle \hat{H} \rangle$  ever reach its final state  $\langle \hat{H} \rangle$ .qn thus never meets the Linz definition of halting:

**computation that halts** ... the Turing machine will halt whenever it enters a final state. (Linz:1990:234) Thus if embedded\_H rejects its input it is necessarily correct.

Because all halt deciders are deciders they compute the mapping from their input finite strings inputs to their own accept or reject state. Halt deciders (because they are deciders) do not compute any mappings from non-finite string non-inputs.

No halt decider ever determines the halt status of the computation that contains its actual self thus embedded\_H does not compute the mapping from  $\hat{H} \langle \hat{H} \rangle$  because it is neither an input nor a finite string.

Even Linz was confused by this. embedded\_H is not supposed to report on itself or the computation that it is contained within.

In the conclusion of his proof Linz said that when the copy of Linz H embedded at  $\hat{H}.q_x$  transitions to  $\hat{H}.q_n$  on the basis that its input:  $\langle \hat{H} \rangle \langle \hat{H} \rangle$  never halts that this forms a contradiction with the fact that  $\hat{H} \langle \hat{H} \rangle$  halts. This assumes that a halt decider must compute the halt status of the computation that contains itself.

$\hat{H}$  applied to  $\langle \hat{H} \rangle$  does not have the same behavior as the simulated input to embedded\_H  $\langle \hat{H} \rangle \langle \hat{H} \rangle$ . This is because embedded\_H recognizes the infinitely repeating pattern in its simulated input and aborts its simulation, thus forcing the simulated input to stop running without reaching its final state.

Because embedded\_H breaks the otherwise infinitely recursive chain at its second invocation the first element in this chain  $\hat{H}$  applied to  $\langle \hat{H} \rangle$  stops running. Whenever a single element of an otherwise infinitely recursive sets of invocations is aborted this breaks otherwise infinitely recursive chain.

# Appendix: Peter Linz Halting Problem Proof

## Definition 12.1

---

Let  $w_M$  describe a Turing machine  $M = (Q, \Sigma, \Gamma, \delta, q_0, \square, F)$ , and let  $w$  be any element of  $\Sigma^+$ . A solution of the halting problem is a Turing machine  $H$ , which for any  $w_M$  and  $w$ , performs the computation

$$q_0 w_M w \vdash^* x_1 q_y x_2,$$

if  $M$  applied to  $w$  halts, and

$$q_0 w_M w \vdash^* y_1 q_n y_2,$$

if  $M$  applied to  $w$  does not halt. Here  $q_y$  and  $q_n$  are both final states of  $H$ .

## Theorem 12.1

---

There does not exist any Turing machine  $H$  that behaves as required by Definition 12.1. The halting problem is therefore undecidable.

---

**Proof:** We assume the contrary, namely that there exists an algorithm, and consequently some Turing machine  $H$ , that solves the halting problem. The input to  $H$  will be the description (encoded in some form) of  $M$ , say  $w_M$ , as well as the input  $w$ . The requirement is then that, given any  $(w_M, w)$ , the Turing machine  $H$  will halt with either a yes or no answer. We achieve this by asking that  $H$  halt in one of two corresponding final states, say,  $q_y$  or  $q_n$ . The situation can be visualized by a block diagram like Figure 12.1. The intent of this diagram is to indicate that, if  $M$  is started in state  $q_0$  with input  $(w_M, w)$ , it will eventually halt in state  $q_y$  or  $q_n$ . As required by Definition 12.1, we want  $H$  to operate according to the following rules:

$$q_0 w_M w \vdash^*_{H} x_1 q_y x_2,$$

if  $M$  applied to  $w$  halts, and

$$q_0 w_M w \vdash^*_{H} y_1 q_n y_2,$$

if  $M$  applied to  $w$  does not halt.

Figure 12.1

Figure 12.2

Next, we modify  $H$  to produce a Turing machine  $H'$  with the structure shown in Figure 12.2. With the added states in Figure 12.2 we want to convey that the transitions between state  $q_y$  and the new states  $q_a$  and  $q_b$  are to be made, regardless of the tape symbol, in such a way that the tape remains unchanged. The way this is done is straightforward. Comparing  $H$  and  $H'$  we see that, in situations where  $H$  reaches  $q_y$  and halts, the modified machine  $H'$  will enter an infinite loop. Formally, the action of  $H'$  is described by

$$q_0 w_M w \vdash^*_{H'} \infty,$$

if  $M$  applied to  $w$  halts, and

$$q_0 w_M w \vdash^*_{H'} y_1 q_n y_2,$$

if  $M$  applied to  $w$  does not halt.

From  $H'$  we construct another Turing machine  $\hat{H}$ . This new machine takes as input  $w_M$ , copies it, and then behaves exactly like  $H'$ . Then the action of  $\hat{H}$  is such that

$$q_0 w_M \vdash^* \hat{H} q_0 w_M w_M \vdash^* \hat{H} \infty,$$

if  $M$  applied to  $w_M$  halts, and

$$q_0 w_M \vdash^* \hat{H} q_0 w_M w_M \vdash^* \hat{H} y_1 q_n y_2,$$

if  $M$  applied to  $w_M$  does not halt.

Now  $\hat{H}$  is a Turing machine, so that it will have some description in  $\Sigma^*$ , say  $\hat{w}$ . This string, in addition to being the description of  $\hat{H}$  can also be used as input string. We can therefore legitimately ask what would happen if  $\hat{H}$  is applied to  $\hat{w}$ . From the above, identifying  $M$  with  $\hat{H}$ , we get

$$q_0 \hat{w} \vdash^* \hat{H} \infty,$$

if  $\hat{H}$  applied to  $\hat{w}$  halts, and

$$q_0 \hat{w} \vdash^* \hat{H} y_1 q_n y_2,$$

if  $\hat{H}$  applied to  $\hat{w}$  does not halt. This is clearly nonsense. The contradiction tells us that our assumption of the existence of  $H$ , and hence the assumption of the decidability of the halting problem, must be false. ■
